**Key Concept:** UDP packages application layer data into a very simple message format that includes only four header fields. One of these is an optional checksum field; when used, the checksum is computed over both the real header and a “pseudo header” of fields from the UDP and IP headers, in a manner very similar to how the TCP checksum is calculated.

---

Note that the use of the *Checksum* field is optional in UDP. If it is not used, it is set to a value of all zeroes. This could potentially create confusion, however, since when the checksum *is* used, the calculation can sometimes result in a value of zero. To avoid having the destination think the checksum was not used in this case, this zero value is instead represented as a value of all ones (65,535 decimal).

## UDP Common Applications and Server Port Assignments

As we have seen in our exploration of the User Datagram Protocol, UDP contains very little functionality. With the exception of the important addressing capability that UDP ports represent, using UDP is very much like using IP directly. This means [UDP has most of the same disadvantages that IP has](#). It doesn't establish a lasting connection between devices; it doesn't acknowledge received data or retransmit lost messages, and it certainly doesn't concern itself with esoterics such as [flow control and congestion management](#).

The lack of these features makes UDP simply unsuitable for the majority of “classical” networking applications. These usually need to be able to establish a connection, so the two devices can exchange data back and forth. Many also need the ability to occasionally or even regularly send very large amounts of data that must be received intact for it to be of value. For example, consider a message transfer protocol like HTTP. If only part of a Web page gets from a server back to a Web browser, it's useless. HTTP and other [file and message transfer protocols](#) like it need the capabilities we mentioned just above.

I have read about problems that have occurred in the past in applications using UDP. Sometimes programmers don't realize how little UDP does, and that it leaves the application responsible for handling all the potential vagaries of an internetworking environment. Someone writing a UDP-based application must ***always*** keep in mind that no assumptions can be made about how or even whether any message will be received by its destination, and must plan accordingly. Insufficient testing can lead to disaster in worst-case scenarios on a larger internet and especially, the Internet.

---

## ***Why Some TCP/IP Applications Use UDP***

What applications use UDP then? Well, the classic “disclaimer” with UDP is that since it doesn't provide the features we saw earlier, an application that uses UDP is responsible for those functions. In reality, if an application needs the features that TCP provides but UDP does not, having the application implement them is inefficient, except in special cases. If the application needs what TCP provides, it should just use TCP! However, applications that only need **some** of what TCP implements are sometimes better off to use UDP and implement that limited set of functionality at the application level.

So, the applications that run over UDP are normally those that do **not** require all or even most of the features that TCP has, and that can benefit from the increased efficiency of avoiding the setup and overhead associated with TCP. Applications usually (but not always) meet this description because the data they send falls into one of two categories.

### **Data Where Performance Is More Important Than Completeness**

The classic example of this category is a multimedia application. If you are streaming a video clip over the Internet, the most important thing is that the stream starts flowing quickly and keeps flowing. Humans only really notice significant disruptions in the flow of this type of information, so a few bytes of data missing due to a lost datagram is not only not a big problem, it's unlikely to even be noticed.

Furthermore, even if TCP were used for something like this and a lost datagram was noticed and retransmitted, it would be useless because it would belong to a part of the clip that is long past—and the time spent in that retransmission might make the actual *current* part of the clip arrive late. Clearly, UDP is best for this situation.

### **Data Exchanges That Are “Short And Sweet”**

There are many TCP/IP applications where the underlying protocol consists of only a very simple request/reply exchange. A short request message is sent from a client to a server, and a short reply message goes back from the server to the client. In this situation, there is no real need to set up a connection like TCP does. Also, if only one short message is sent, it can be carried in a single IP datagram. This means there is no need to worry about data arriving out of order, flow control between the devices and so forth.

How about loss of the request or the reply? These can be handled simply at the application level using timers. If a client sends a request and the server doesn't get it, it won't reply, and the client will eventually send a replacement request. The same logic applies if the server sends a response that never arrives.

### ***Other Cases Where UDP Is Required***

As I said before, these are the most common cases where UDP is used, but there are other reasons. For example, if an application needs to multicast or broadcast data, it must use UDP, because TCP is only supported for unicast communication between two devices.

**Key Concept:** UDP is most often used by a protocol instead of TCP in two situations. The first is when an application values timely delivery over reliable delivery, and where TCP's retransmission of lost data would be of limited or even no value. The second is when a simple protocol is able to handle the potential loss of an IP datagram itself at the application layer using a timer/retransmit strategy, and where the other features of TCP are not required. UDP is also used for applications that require multicast or broadcast transmissions, since these are not supported by TCP.

### ***Common UDP Applications and Server Port Use***

Table 149 shows some of the more interesting protocols that use UDP and the well-known and registered port numbers used for each one's server processes. It also provides a very brief description of why these protocols use UDP instead of TCP. See the sections or topics devoted to each application for more details:

**Table 149: Common UDP Applications and Server Port Assignments (Page 1 of 2)**

Port #	Keyword	Protocol	Comments
53	domain	Domain Name Server (DNS)	Uses a simple request/reply messaging system for most exchanges (but also uses TCP for longer ones).
67 and 68	bootps / bootpc	Bootstrap Protocol (BOOTP) and Dynamic Host Configuration Protocol (DHCP)	Host configuration protocols that consist of short request and reply exchanges.
69	tftp	Trivial File Transfer Protocol (TFTP)	TFTP is a great example of a protocol that was specifically designed for UDP, especially when it is compared to regular FTP. The latter protocol uses TCP to establish a session between two devices, and then makes use of its own large command set and TCP's features to ensure reliable transfer of possibly very large files. In contrast, TFTP is designed for the quick and easy transfer of small files. It includes simple versions of some of TCP's features, such as acknowledgments, to avoid file corruption.
161 and 162	snmp	Simple Network Management Protocol	An administrative protocol that uses relatively short messages.

---

**Table 149: Common UDP Applications and Server Port Assignments (Page 2 of 2)**

Port #	Keyword	Protocol	Comments
520 and 521	router / ripng	Routing Information Protocol (RIP-1, RIP-2, RIPng)	Unlike more complex routing protocols like BGP, RIP uses a simple request/reply messaging system, doesn't require connections, and does require multi-casts/broadcasts. This makes it a natural choice for UDP. If a routing update is sent due to a request and is lost, it can be replaced by sending a new request. Routine (unsolicited) updates that are lost are replaced in the next cycle.
2049	nfs	Network File System	NFS is an interesting case. Since it is a file sharing protocol, one would think that it would use TCP instead of UDP, but it was originally designed to use UDP for performance reasons. There were many people who felt this was not the best design decision, and later versions moved to the use of TCP. The latest version of NFS uses only TCP.

### ***Applications That Use Both UDP and TCP***

There are some protocols that actually use both UDP **and** TCP. This is often the case either for utility protocols that are designed to accept connection using both transport layer protocols, or for applications that need the benefits of TCP in some cases, but not others.

The classic example of the latter is [DNS](#), which normally uses UDP port 53 for simple requests and replies, which are usually short. Larger messages requiring reliable delivery, such as [zone transfers](#), use TCP port 53 instead. Note that in the table above I have omitted some of the less-significant protocols, such as the ones used for diagnostic purposes (Echo, Discard, CharGen, etc.) For a full list of all common applications, [see the topic on common TCP/IP applications and port numbers](#).

---

## **TCP/IP Transmission Control Protocol (TCP)**

In my [description of the Internet Protocol](#), I call it the “workhorse” of the TCP/IP protocol suite. IP is, in fact, the foundation upon which the other protocols of the suite are built. Well, if IP is the “workhorse”, then the “worker” that rides on that horse would have to be the TCP/ *IP Transmission Control Protocol (TCP)*. Like horse and rider, TCP and IP form a team that work together to make it possible for applications to easily run over an internetwork.

TCP and IP share the marquee in the name of the suite, and are very important complements to each other. IP concerns itself with classic network-layer tasks such as addressing, datagram packaging and routing, which provide basic internetworking capabilities. TCP provides to applications a method of easily making use of IP, while filling in the capabilities that IP lacks. It allows TCP/IP devices to establish and manage connections and send data reliably, and takes care of handling all the potential “gotchas” that can occur during transmission so each application doesn't need to worry about such matters. To applications, TCP could thus be considered almost like a nice *user interface* to the fairly rudimentary capabilities of IP.

This section provides a comprehensive description of the concepts, characteristics and functions of the Transmission Control Protocol (TCP). TCP is a rather complex protocol that includes a number of sophisticated functions to ensure that applications function in the potentially difficult environment of a large internetwork. It's also, as I said above, a very important part of the TCP/IP protocol suite. For this reason, the section is rather large, and has been divided into five subsections.

The first subsection provides an overview of TCP, describing its history, what it does and how it works. The second paints some important background information that is necessary to understanding how TCP operates. This is done by explaining key concepts such as streams and segments, sliding windows and TCP ports and connections. The third subsection describes the process used by TCP to establish, maintain and terminate sessions. The fourth describes TCP messages, and how they are formatted and transferred. Finally, the last subsection shows how TCP provides reliability and other important transport layer functions to applications, such as flow control, retransmission of lost data and congestion avoidance.

**Background Information:** Since TCP is built on top of IP, in describing TCP, I make the assumption that the reader has at least a basic familiarity with IP. If you have come to this section without first gaining an understanding of IP, I'd suggest [reading that section first](#). Since it's large, reviewing [the portion describing IP concepts](#) will likely suffice for background.

---

---

## **TCP Overview, Functions and Characteristics**

As I mentioned in the previous [section overview](#), the Transmission Control Protocol (TCP) is a critically important part of the TCP/IP suite. It's also a fairly complicated protocol, with a lot of important concepts and mechanisms to understand. The old joke says the best way to eat an elephant is "one bite at a time". Similarly here, we can best comprehend the operation of this complicated protocol by going slowly, starting with a high-level look at it, where it came from, and what it does in general terms.

In this section I begin our look at TCP with an introduction to the protocol. I first provide an overview and history of TCP, and describe the standards that define it. I then give a "bird's eye" view of TCP by describing it in two important ways. I illustrate what TCP actually does by listing its functions, and then explain how TCP works by describing its most important characteristics. This will give you a feel for what TCP is all about, and hopefully set the stage for the more complex technical discussions in subsequent sections.

### **TCP Overview, History and Standards**

Between them, layers three and four of the [OSI Reference Model](#) represent the interface between networking software (the applications that need to move data across networks) and networking hardware (the devices that carry the data over networks). Any protocol suite must have a protocol or set of protocols that handles these layer three and layer four functions.

The TCP/IP protocol suite is named for the two main protocols that provides these capabilities, allowing software to run on an internetwork: the Transmission Control Protocol (TCP) and the Internet Protocol (IP). IP deals with internetwork datagram delivery and routing, while TCP handles connections and provides reliability. What's interesting, however, is that in the early days of the protocol suite, there was, in fact, no "TCP/IP" at all.

#### ***TCP History***

Due to its prominent role, the history of TCP is impossible to describe without going back to the early days of the protocol suite as a whole. In the early 1970s, what we know of today as the global Internet was a small research internetwork called the *ARPAnet*, named for the United States *Defense Advanced Research Projects Agency* (DARPA or ARPA). This network used a technology called the *Network Control Protocol* (NCP) to allow hosts to connect to each other. NCP did approximately the jobs that TCP and IP do together today.

Due to limitations in the NCP, development began on a new protocol that would be better suited to a growing internetwork. This new protocol, first formalized in RFC 675, was called the *Internet Transmission Control Program* (TCP). Like its predecessor NCP, TCP was responsible for basically everything that was needed to allow applications to run on an internetwork. Thus, TCP was at first both TCP and IP.

As I explain in detail in [the topic describing the history of TCP/IP as a whole](#), several years were spent adjusting and revising TCP, with version 2 of the protocol documented in 1977. While the functionality of TCP was steadily improved, there was a problem with the basic

---

concept behind the protocol. Having TCP by itself handle both datagram transmissions and routing (layer three functions) as well as connections, reliability and data flow management (layer four functions) meant that TCP violated key concepts of protocol layering and modularity. TCP forced all applications to use the layer four functions in order to use the layer three functions. This made TCP inflexible, and poorly-suited to the needs of applications that only need the lower-level functions and not the higher-level ones.

As a result, the decision was made to split TCP into two: the layer four functions were retained, with TCP renamed the Transmission Control **Protocol** (as opposed to *Program*). The layer three functions became the Internet Protocol. This split was finalized in version 4 of TCP, and so the first IP was given “version 4” as well, for consistency. Version 4 of TCP was defined in RFC 793, *Transmission Control Protocol*, published September 1981, and is still the current version of the standard.

Even though it is more than 20 years old and is the first version most people have ever used, version 4 was the result of several years work and many earlier TCP versions tested on the early Internet. It is therefore a very mature protocol for its age. A *precocious* protocol, you could say. (To be fair, many additional features and modifications to how TCP works have been described in other standards, rather than upgrading the main document.)

### ***Overview of TCP Characteristics and Operation***

TCP is a full-featured transport layer protocol that provides all the functions needed by a typical application for the reliable transportation of data across an arbitrary internetwork. It provides transport-layer addressing for application processes in the form of [TCP ports](#), and allows these ports to be used in establishing connections between machines. Once connections have been created, data can be passed bidirectionally between two devices. Applications can send data to TCP as a simple [stream of bytes](#), and TCP takes care of packaging and sending the data as *segments* that are packaged into IP datagrams. The receiving device's TCP implementation reverses the process, passing up to the application the stream of data originally sent.

TCP includes an extensive set of mechanisms to ensure that data gets from source to destination reliably, consistently and in a timely fashion. The key to its operation in this regard is the [sliding window acknowledgement system](#), which allows each device to keep track of which bytes of data have been sent and to confirm receipt of data received from the other device in the connection. Unacknowledged data is eventually [retransmitted automatically](#), and the parameters of the system can be adjusted to the needs of the devices and the connection. This same system also provides buffering and [flow control capabilities](#) between devices, to handle uneven data delivery rates and other problems.

The inclusion of so many capabilities in TCP maximizes the likelihood that just about any application requiring connection-oriented reliable data delivery will be satisfied by the protocol. This is a primary goal of TCP, as it means that higher-layer applications don't individually have to provide these common functions. TCP is the most widely used TCP/IP transport protocol, employed by the majority of conventional message-passing applications.

**Key Concept:** The primary transport layer protocol in the TCP/IP suite is the *Transmission Control Protocol (TCP)*. TCP is a connection-oriented, acknowledged, reliable, fully-featured protocol designed to provide applications with a reliable way to send data using the unreliable Internet Protocol. It allows applications to send bytes of data as a *stream* of bytes, and automatically packages them into appropriately-sized *segments* for transmission. It uses a special *sliding window acknowledgment system* to ensure that all data is received by its recipient, to handle necessary retransmissions, and to provide flow control so each device in a connection can manage the rate at which it is sent data.

## TCP Standards

RFC 793 is the defining standard for TCP, but it doesn't include all the details of how modern TCP operates. Several other standards include additional information about how the protocol works, and describe enhancements to the basic TCP mechanisms that were developed over the years. Some of these are fairly “esoteric” and not widely known, but they are useful in gaining a more complete understanding of TCP. I have listed some of them in [Table 150](#)

**Table 150: Supplementary TCP Standards (Page 1 of 2)**

RFC Number	Name	Description
813	<u><i>Window and Acknowledgment Strategy in TCP</i></u>	Discusses the TCP <a href="#">sliding window acknowledgment system</a> , describing certain problems that can occur with it and methods to correct them.
879	<u><i>The TCP Maximum Segment Size and Related Topics</i></u>	Discusses the important <a href="#">Maximum Segment Size (MSS)</a> parameter that controls the size of TCP messages, and relates this parameter to IP datagram size.
896	<u><i>Congestion Control in IP/TCP Internetworks</i></u>	Talks about congestion problems and how TCP can be used to handle them.  Note the interesting inversion of the normal protocol suite name: “IP/TCP”.
1122	<u><i>Requirements for Internet Hosts — Communication Layers</i></u>	Describes important details of how TCP should be implemented on hosts.
1146	<u><i>TCP Alternate Checksum Options</i></u>	Specifies a mechanism for having TCP devices use an alternative method of checksum generation.
1323	<u><i>TCP Extensions for High Performance</i></u>	Defines extensions to TCP for high-speed links, and new TCP options.
2018	<u><i>TCP Selective Acknowledgment Options</i></u>	An enhancement to basic TCP functionality that allows TCP devices to <a href="#">selectively specify specific segments for retransmission</a> .

Table 150: Supplementary TCP Standards (Page 2 of 2)

RFC Number	Name	Description
2581	<i><a href="#">TCP Congestion Control</a></i>	Describes <a href="#">four algorithms used for congestion control in TCP networks</a> : slow start, congestion avoidance, fast retransmit and fast recovery.
2988	<i><a href="#">Computing TCP's Retransmission Timer</a></i>	Discusses issues related to setting the TCP <a href="#">retransmission timer</a> , which controls how long a device waits for acknowledgment of sent data before retransmitting it.

Of course, there are hundreds of higher-layer application protocols that use TCP, and whose defining standards therefore make at least glancing reference to it.

TCP is of course designed to use the Internet Protocol, since they were developed together and as we have seen, were even once part of the same specification. At the same time, they were split up for the specific reason of respect the principles of architectural layering. For this reason, TCP tries to make as few assumptions as possible regarding the underlying protocol over which it runs. It is not as strictly tied to the use of IP as one might imagine, and can even be adapted for use over other network-layer protocols. For our purposes, however, this should be considered mainly an "interesting aside". We will be assuming TCP works over IP in our discussions, since that is almost always how it is used.

## **TCP Functions: What TCP Does**

We have now seen [where TCP comes from and the standards that describe it](#). As I said in the introduction to this section, TCP is a complicated protocol, so it will take some time to explain how it works. The most logical first "bite" in consuming this particular "elephant" is to look at exactly what TCP does. From there, we can describe its characteristics and then get into the details of its operation.

### ***Functions Performed By TCP***

Despite the complexity of TCP, its basic operation can be reasonably simplified by describing its primary functions. The following are what I believe to be the five main tasks that TCP performs:

- ☉ **Addressing/Multiplexing:** TCP is used by many different applications for their transport protocol. Therefore, like its simpler sibling UDP, an important job for TCP is *multiplexing* the data received from these different processes so they can be sent out using the underlying network-layer protocol. At the same time, these higher-layer application processes are identified using TCP ports. [The section on TCP/IP transport layer addressing](#) contains a great deal of detail on how this addressing works.
- ☉ **Connection Establishment, Management and Termination:** TCP provides a set of procedures that devices follow to [negotiate and establish a TCP connection](#) over which data can travel. Once opened, TCP includes logic for managing connections and handling problems that may result with them. When a device is done with a TCP connection, a special process is followed to terminate it.

- 
- ☛ **Data Handling and Packaging:** TCP defines a mechanism by which applications are able to send data to it from higher layers. This data is then [packaged into messages](#) to be sent to the destination TCP software. The destination software unpackages the data and gives it to the application on the destination machine.
  - ☛ **Data Transfer:** Conceptually, the TCP implementation on a transmitting device is responsible for the transfer of packaged data to the TCP process on the other device. Following the principle of layering, this is done by having the TCP software on the sending machine pass the data packets to the underlying network-layer protocol, which again normally means IP.
  - ☛ **Providing Reliability and Transmission Quality Services:** TCP includes [a set of services and features](#) that allow an application to consider the sending of data using the protocol to be “reliable”. This means that normally, a TCP application doesn't have to worry about data being sent and never showing up, or arriving in the wrong order. It also means other common problems that might arise if IP were used directly are avoided.
  - ☛ **Providing Flow Control and Congestion Avoidance Features:** TCP allows the flow of data between two devices to be controlled and managed. It also includes features to deal with congestion that may be experienced during communication between devices.

Clearly, TCP is responsible for a fairly significant number of key functions. This list may not seem that impressive. The reason is that this is just a high-level look at the protocol, and these functions are summarized in the list above; when we look at them in detail we will see that each one actually involves a rather significant amount of work for TCP to do.

### ***Functions Not Performed By TCP***

TCP does so much that sometimes it is described as doing “everything” an application needs to use an internetwork. I may even have been guilty of this myself. However, the protocol **doesn't** do everything. It has limitations and certain areas that its designers specifically did not address. Among the notable functions TCP does not perform include:

- ☛ **Specifying Application Use:** TCP defines the transport protocol. It does not describe specifically how applications are to use TCP.
- ☛ **Providing Security:** TCP does not provide any mechanism for ensuring the authenticity or privacy of data it transmits. If these are needed they must be accomplished using some other means, such as [IPSec](#), for example.
- ☛ **Maintaining Message Boundaries:** TCP sends data as a continuous stream, not as discrete messages. It is up to the application to specify where one message ends and the next begins.
- ☛ **Guaranteeing Communication:** Wait a minute... isn't the whole point of TCP supposed to be that it guarantees data will get to its destination? Well, yes and no. ☺ TCP will detect unacknowledged transmissions and re-send them if needed. However, in the event of some sort of problem that prevents reliable communication, all TCP can do is “keep trying”. It can't make any guarantees because there are too many things out of its control. Similarly, it can attempt to manage the flow of data, but cannot resolve every problem.

---

This last point might seem a bit pedantic, but is important to keep in mind, especially since the tendency is to think of TCP as somewhat “bulletproof”. The overall success of communication depends entirely on the underlying internetwork and the networks that constitute it. A chain is as strong as its weakest link, and if there is a problem at the lower layers, nothing TCP can do will guarantee successful data transfer.

**Key Concept:** TCP provides reliable communication only by detecting failed transmissions and re-sending them. It cannot guarantee any particular transmission, because it relies on IP, which is unreliable. All it can do is keep trying if an initial delivery attempt fails.

---

## **TCP Characteristics: How TCP Does What It Does**

In [the preceding topic](#) we began our high-level look at TCP by examining the most important functions the protocol performs—as well as a few that it does not. In many ways, it is more interesting to look at **how** TCP does its job than the functions of the job itself. By examining the most important attributes of TCP and its operation, we can get a better handle on the way TCP works. We can also see the many ways that it contrasts to its simpler transport layer sibling, UDP.

### ***TCP Characteristics***

The following are the ways that I would best describe the Transmission Control Protocol and how it performs the functions described in the preceding topic:

- ☉ **Connection-Oriented:** TCP requires that devices first establish a connection with each other before they send data. The connection creates the equivalent of a circuit between the units, and is analogous to a telephone call. A process of negotiation occurs to establish the connection, ensuring that both devices agree on how data is to be exchanged.
- ☉ **Bidirectional:** Once a connection is established, TCP devices send data bidirectionally. Both devices on the connection can send and receive, regardless of which of them initiated the connection.
- ☉ **Multiply-Connected and Endpoint-Identified:** TCP connections are identified by the pair of sockets used by the two devices in the connection. This allows each device to have multiple connections opened, either to the same IP device or different IP devices, and to handle each connection independently without conflicts.
- ☉ **Reliable:** Communication using TCP is said to be *reliable* because TCP keeps track of data that has been sent and received to ensure it all gets to its destination. As we saw in the previous topic, TCP can't really “guarantee” that data will always be received. However, it **can** guarantee that all data sent will be checked for reception, and checked for data integrity, and then retransmitted when needed. So, while IP uses “best effort” transmissions, you could say TCP *tries harder*, as the old rent-a-car commercial goes.

- 
- ☉ **Acknowledged:** A key to providing reliability is that all transmissions in TCP are acknowledged (at the TCP layer—TCP cannot guarantee that all such transmissions are received by the remote application). The recipient must tell the sender “yes, I got that” for each piece of data transferred. This is in stark contrast to typical messaging protocols where the sender never knows what happened to its transmission. As we will see, this is fundamental to the operation of TCP as a whole.
  - ☉ **Stream-Oriented:** Most lower-layer protocols are designed so that to use them, higher-layer protocols must send them data in blocks. IP is the best example of this; you send it a message to be formatted and it puts that message into a datagram. **UDP is the same.** In contrast, TCP allows applications to send it a continuous stream of data for transmission. Applications don't need to worry about making this into chunks for transmission; TCP does it.
  - ☉ **Data-Unstructured:** An important consequence of TCP's stream orientation is that there are no natural divisions between data elements in the application's data stream. When multiple messages are sent over TCP, applications must provide a way of differentiating one message (data element, record, etc.) from the next.
  - ☉ **Data-Flow-Managed:** TCP does more than just package data and send it as fast as possible. A TCP connection is *managed* to ensure that data flows evenly and smoothly, with means included to deal with problems that arise along the way.

**Key Concept:** To summarize TCP's key characteristics, we can say that it is connection-oriented, bidirectional, multiply-connected, reliable, acknowledged, stream-oriented and flow-managed.

---

### ***The Robustness Principle***

There's one more thing about TCP that is more an indication of the general maxim behind its creation than a particular characteristic of its operation. The TCP standard says that TCP follows the *robustness principle*, which is described thusly: “be conservative in what you do; be liberal in what you accept from others”. It means that every TCP implementation tries to avoid doing anything that would cause a problem for another device's TCP layer, while at the same time **also** trying to anticipate problems another TCP may cause and deal with them gracefully.

This principle represents a “belt and suspenders” approach that helps provide extra protection against unusual conditions in TCP operation. In fact, this general principle is applied to many other protocols in the TCP/IP suite, which is part of the reason why it has proven so capable over the years. It allows TCP and other protocols to often deal with even unanticipated problems that might show up in the difficult environment of a large inter-network such as the Internet.

---

### ***Putting TCP's Performance In Perspective***

Also, while we are on the subject of TCP's characteristics, I want to reinforce one other thing I said in [the overview of TCP and UDP](#): TCP has many attributes but one of them is ***not*** "slow". It is true that UDP is usually used by applications for performance reasons when they don't want to deal with the overhead TCP incorporates for connections and reliability. That, however, should not lead one to conclude that TCP is glacial, by any means. It is in fact quite efficient—were it not, it's unlikely it would have ever achieved such widespread use.

---

## **TCP Fundamentals and General Operation**

Many people have a difficult time really understanding how the Transmission Control Protocol works. (After spending dozens of hours writing almost 100 pages on the protocol, I am quite sympathetic.) I think a main reason for the difficulty in absorbing TCP is that too many descriptions of the protocol quickly jump from a brief introduction straight into the mind-boggling details of TCP's operation. The problem is that TCP has a very particular **way** of doing certain things. Its operation is built around a few very important fundamentals that it is essential to understand before the details of TCP operation will make much sense.

In this section I describe some of the key operating fundamentals of TCP. I begin with a discussion of how TCP handles data, and introduce the concepts of streams, segments and sequences. I then describe the very important TCP *sliding window* system, used for acknowledgment, reliability and data flow control. I discuss how TCP uses ports, and how connections are identified. I also describe the most important applications that use TCP and what ports they use for server applications.

### **TCP Data Handling and Processing: Streams, Segments and Sequence Numbers**

One of the “givens” in the operation of most of the protocols we find at upper layers in the OSI Reference Model is that they are oriented around the use of [messages](#). These messages are analogous to a written letter in an envelope, containing a specific piece of information. They are passed from higher layers down to lower ones, where they are [encapsulated in the lower layer's headers](#) (like putting them in another envelope) and then passed down further until they are actually sent out at the physical layer.

A good example of this can be seen in looking at the [User Datagram Protocol](#), TCP's transport layer peer. To use UDP, an application passes it a distinct block of data that is usually fairly short. The block is packaged into a UDP message, then sent to IP. IP packs the message into an IP datagram and eventually passes it to a layer two protocol such as Ethernet. There it is placed into a *frame* and sent to layer one for transmission.

### ***Increasing the Flexibility of Application Data Handling: TCP's Stream Orientation***

The use of discrete messaging is pretty simple, and it obviously works well enough since most protocols make use of it. However, it is inherently limiting, because it forces applications to create discrete blocks of data in order to communicate. There are many applications that need to send information continuously in a manner that doesn't lend itself well to creating “chunks” of data. Others need to send data in chunks that are so large that they could never be sent as a single message at the lower layers anyway.

To use a protocol like UDP, many applications would be forced to artificially divide their data into messages of a size that has no inherent meaning to them. This would immediately introduce new problems requiring more work for the application. It would have to keep track

---

of what data is in what message, and replace any that were lost. It would need to ensure that the messages could be reassembled in the correct order, since IP might deliver them out of order.

Of course, one **could** program applications to do this, but these functions are already ones that TCP is charged with taking care of, so it would make little sense. Instead, the designers of TCP took the very smart approach of generalizing TCP so it could accept application data of any size and structure, without requiring that it be in discrete pieces. More specifically, TCP is said to treat data coming from an application as a *stream*; thus, the description of TCP as *stream-oriented*. Each application sends the data it wishes to transmit as a steady stream of octets (bytes). It doesn't need to carve them into blocks, or worry about how lengthy streams will get across the internetwork. It just "pumps bytes" to TCP.

### **TCP Data Packaging: Segments**

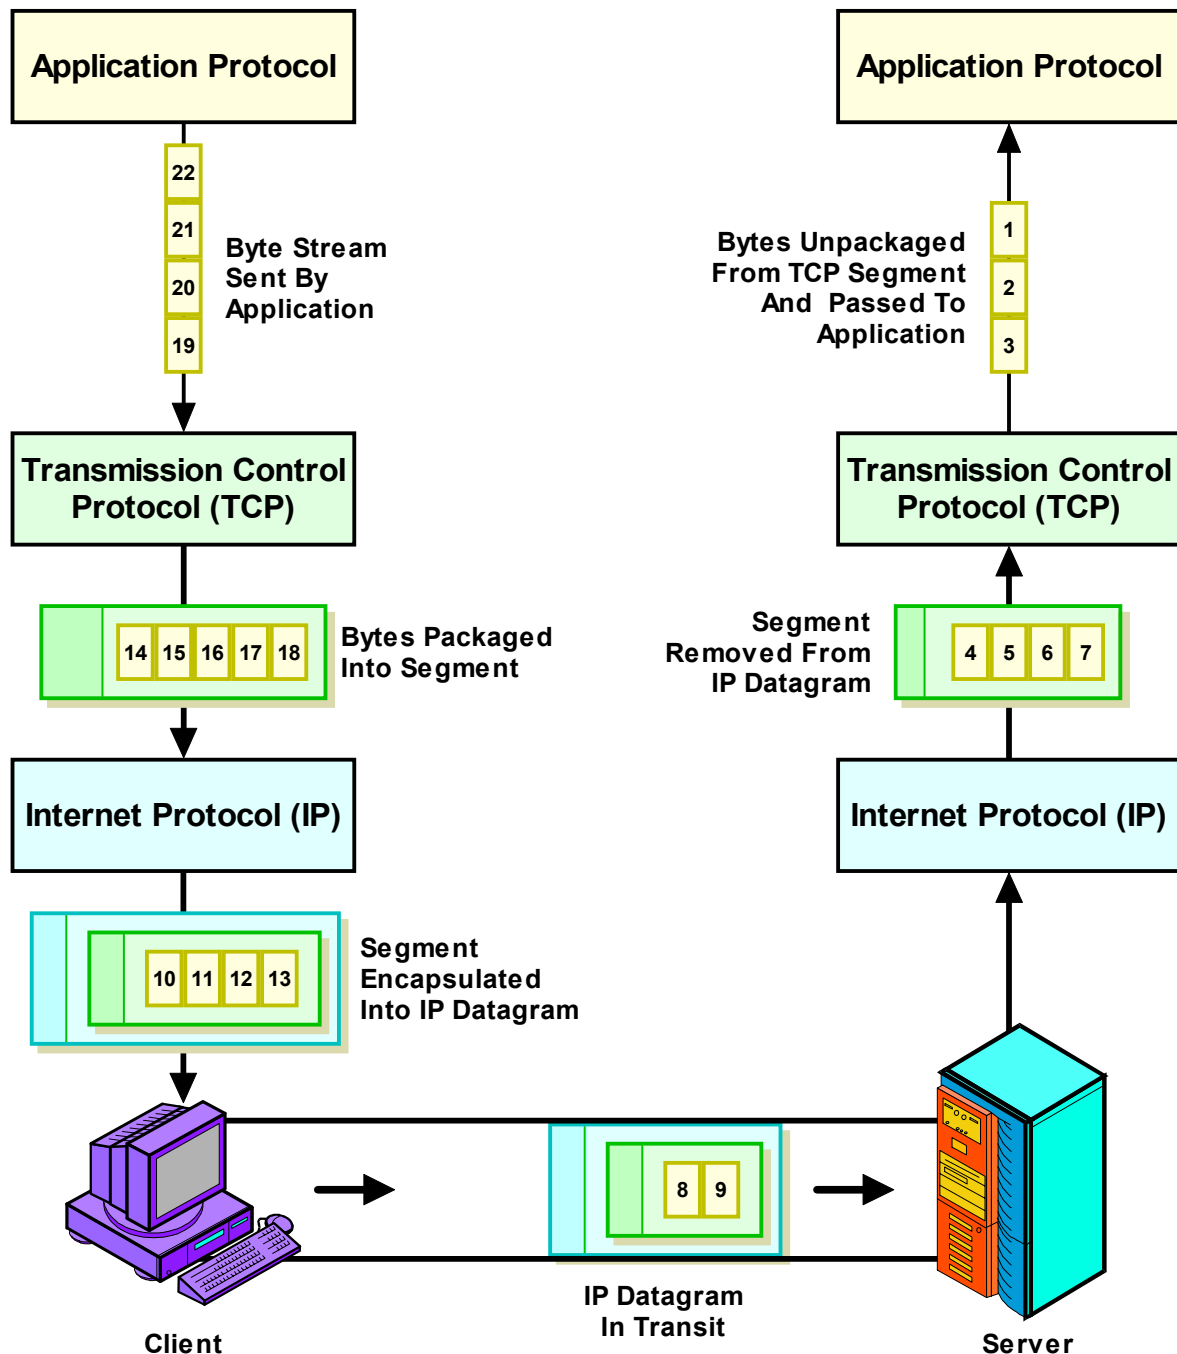

Of course, TCP must take these bytes and send them using a network-layer protocol, meaning the Internet Protocol. IP is a message-oriented protocol, not stream-oriented. Thus, we have simply "passed the buck" to TCP, which must take the stream from the application and divide it into discrete messages for IP. These messages are called TCP *segments*.

**Note:** As an aside, this is one of the most confusing data structure names in the world of networking. From a dictionary definition standpoint, referring to a piece of a stream as a *segment* is sensible, but most people working with networks don't think of a message as being a "segment". In the industry, the term also refers to a length of cable or a part of a local area network, among other things, so watch out for that.

TCP segments are treated by IP like all other discrete messages for transmission. They are placed into IP datagrams and transmitted to the destination device. The recipient unpackages the segments and passes them to TCP, which converts them back to a byte stream to send to the application. This process is illustrated in [Figure 202](#).

The TCP layer on a device accumulates data it receives from the application process stream. On regular intervals, it forms segments to be transmitted using IP. The size of the segment is controlled by two primary factors. The first issue is that there is an overall limit to the size of a segment, chosen to prevent unnecessary fragmentation at the IP layer. This is governed by a parameter called the [maximum segment size \(MSS\)](#), which is determined during connection establishment. The second is that TCP is designed so that once a connection is set up, each of the devices tells the other how much data it is ready to accept at any given time. If this is lower than the MSS value, a smaller segment must be sent. This is part of the [sliding window system described in the next topic](#).

**Figure 202: TCP Data Stream Processing and Segment Packaging**

TCP is different from most protocols because it does not require applications that use it to send data to it in messages. Once a TCP connection is set up, an application protocol can send TCP a steady stream of bytes that does not need to conform to any particular structure. TCP packages these bytes into *segments* that are sized based on a number of different parameters. These segments are passed to IP, where they are encapsulated into IP datagrams and transmitted. The process is reversed by the receiving device: segments are removed from IP datagrams, then the bytes are taken from the segments and passed up to the appropriate recipient application protocol as a byte stream.

**Key Concept:** TCP is designed to have applications send data to it as a *stream* of bytes, rather than requiring fixed-size messages to be used. This provides maximum flexibility for a wide variety of uses, because applications don't need to worry about data packaging, and can send files or messages of any size. TCP takes care of packaging these bytes into messages called *segments*.

---

### ***TCP Data Identification: Sequence Numbers***

The fact that TCP treats data coming from an application as a stream of octets has a couple of very significant implications on the operation of the protocol. The first is related to *data identification*. Since TCP is reliable, it needs to keep track of all the data it receives from an application so it can make sure it is all received by the destination. Furthermore, it must make sure the data is received in the order it was sent, and must retransmit any lost data.

If data were conveyed to TCP in block-like messages, it would be fairly simple to keep track of the data by adding an identifier to each message. Since TCP is stream-oriented, however, that identification must be done for each byte of data! This may seem surprising, but it is actually what TCP does, through the use of *sequence numbers*. Each byte of data is assigned a sequence number which is used to keep track of it through the process of transmission, reception and acknowledgment (though in practice, blocks of many bytes are managed using the sequence numbers of bytes at the start and end of the block). These sequence numbers are used to ensure that data sent in segments is reassembled into the original stream of data transmitted by the sending application. They are required to implement the sliding window system that enables TCP to provide reliability and data flow control.

**Key Concept:** Since TCP works with individual bytes of data rather than discrete messages, it must use an identification scheme that works at the byte level to implement its data transmission and tracking system. This is accomplished by assigning each byte TCP processes a *sequence number*.

---

### ***The Need For Application Data Delimiting***

The other impact of TCP treating incoming data as a stream is that data received by an application using TCP is *unstructured*. For transmission, a stream of data goes into TCP on one device, and on reception, a stream of data goes back to the application on the receiving device. Even though the stream is broken into segments for transmission by TCP, these segments are TCP-level details that are hidden from the application. So, when a device wants to send multiple pieces of data, TCP provides no mechanism for indicating where the "dividing line" is between the pieces, since TCP doesn't examine the meaning of the data at all. The application must provide a means for doing this.

---

Consider for example an application that is sending database records. It needs to transmit record #579 from the *Employees* database table, followed by record #581 and record #611. It sends these records to TCP, which treats them all collectively as a stream of bytes. TCP will package these bytes into segments, but in a manner the application cannot predict. It is possible that each will end up in a different segment, but more likely they will all be in one segment, or part of each will end up in different segments, depending on their length. The records themselves must have some sort of explicit markers so the receiving device can tell where one record ends and the next starts.

**Key Concept:** Since applications send data to TCP as a stream of bytes and not prepackaged messages, each application must use its own scheme to determine where one application data element ends and the next begins.

---

## **TCP Sliding Window Acknowledgment System For Data Transport, Reliability and Flow Control**

What differentiates the Transmission Control Protocol from simpler transport protocols like UDP is the **quality** of the manner in which it sends data between devices. Rather than just sticking data in a message and saying “off you go”, TCP carefully keeps track of the data it sends and what happens to it. This management of data is required to facilitate two key requirements of the protocol:

- 🕒 **Reliability:** Ensuring that data that is sent actually arrives at its destination, and if not, detecting this and re-sending the data.
- 🕒 **Data Flow Control:** Managing the rate at which data is sent so that it does not overwhelm the device that is receiving it.

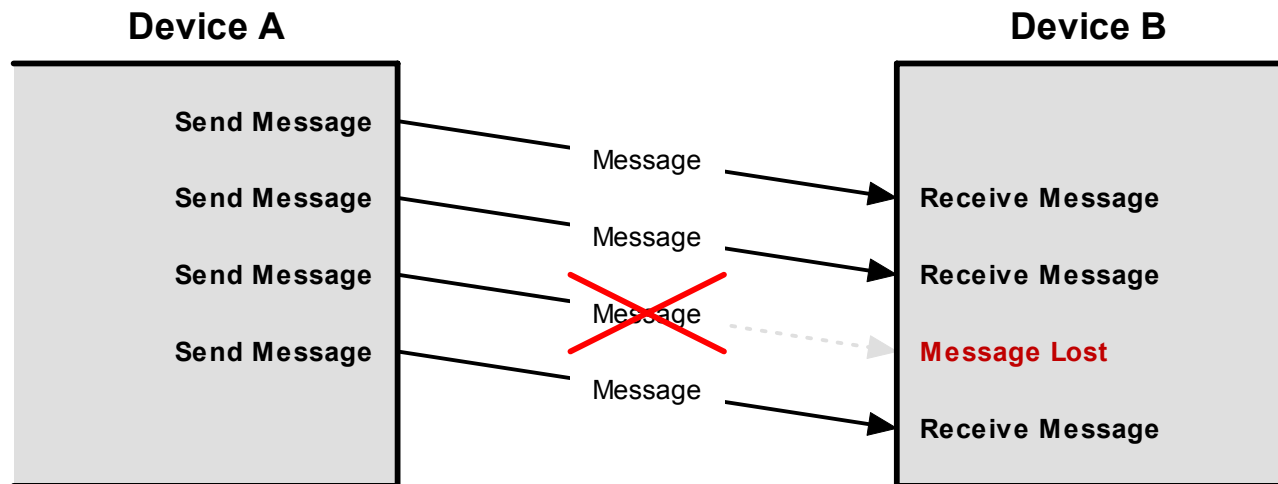

To accomplish these tasks, the entire operation of the protocol is oriented around something called the *sliding window acknowledgment system*. It is no exaggeration to say that comprehending how sliding windows works is critical to understanding just about everything else in TCP. It is also, unfortunately, a bit hard to follow if you try to grasp it all at once, which means many people's eyes glaze over trying to make sense of it.

Since you can't really **get** TCP without understanding sliding windows, I wanted to make sure that I explained the mechanism thoroughly—and without assuming you already understand a great deal, as most references do. For this reason I am going to start with the concepts behind sliding windows and eventually explain how the technique works in general terms and why it is so powerful. Doing this properly required a considerable amount of explanation (which took a long time to get right, I might add!) so buckle your seat belt. 😊

### ***The Problem With Unreliable Protocols: Lack of Feedback***

A simple “send and forget” protocol like IP is unreliable and includes no flow control for one main reason: it is an *open loop* system where the transmitter receives no feedback from the recipient. (I'm ignoring error reports using ICMP and the like for the purpose of this

discussion.) A datagram is sent and it may or may not get there, but the transmitter will never have any way of knowing because no mechanism for feedback exists. This is shown conceptually in [Figure 203](#).

**Figure 203: Operation Of An Unreliable Protocol**

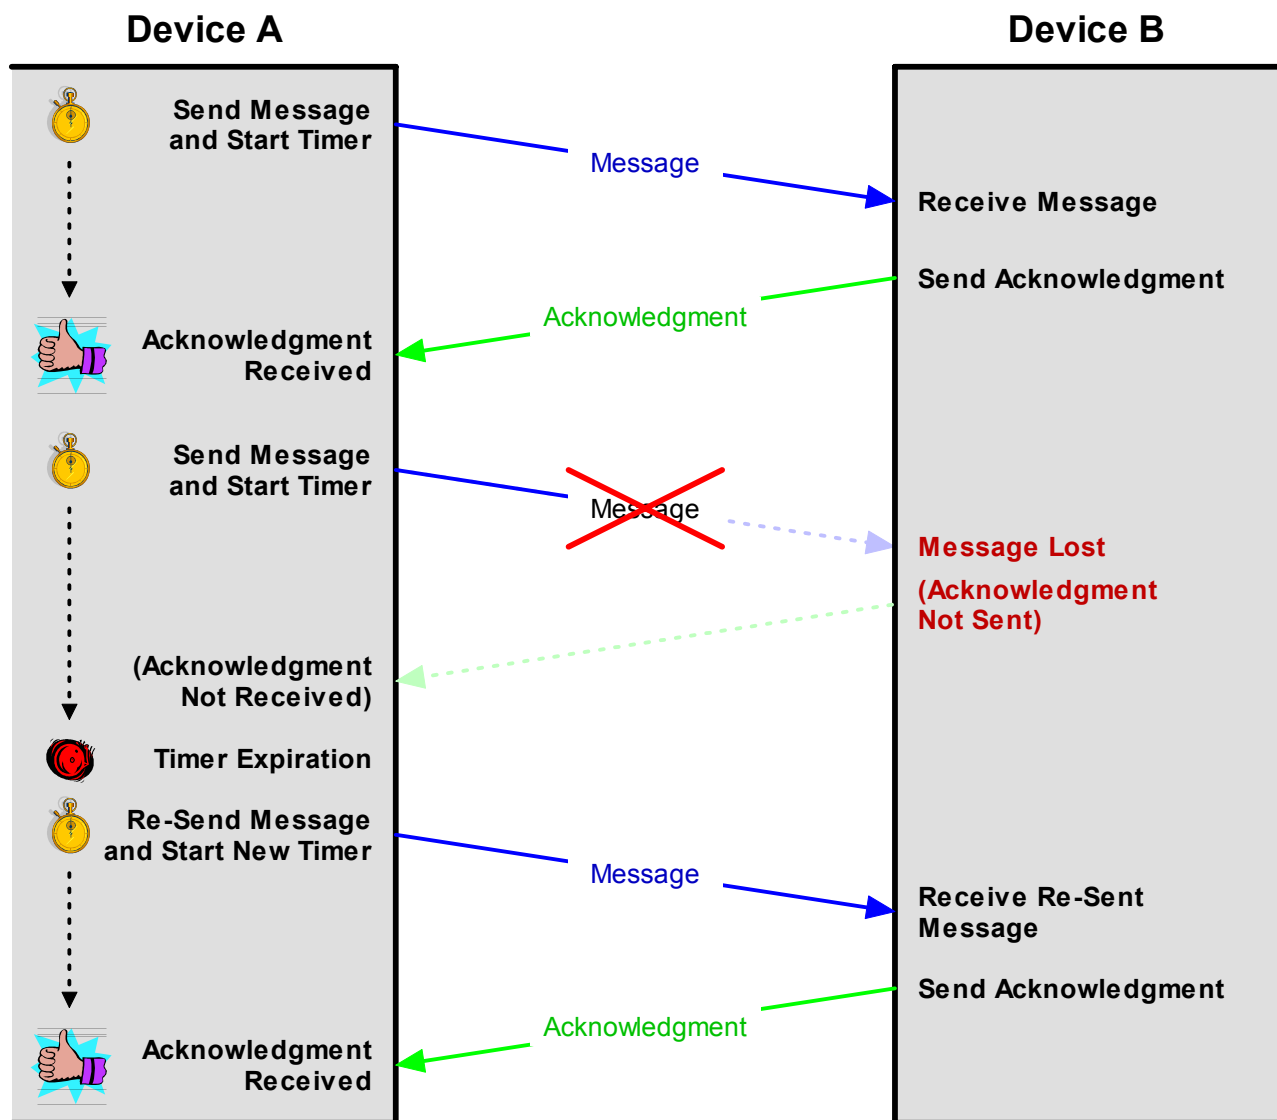

In a system such as that used by IP, if it gets there, great; otherwise, nobody will have a clue. ☺ Some external mechanism is needed to take care of the lost message, unless the protocol doesn't really care whether a few bits and pieces are missing from its message stream.

### ***Providing Basic Reliability Using Positive Acknowledgment with Retransmission (PAR)***

Basic reliability in a protocol running over an unreliable protocol like IP can be implemented by *closing the loop* so the recipient provides feedback to the sender. This is most easily done with a simple acknowledgment system. Device *A* sends a piece of data to Device *B*. Device *B*, receiving the data, sends back an *acknowledgment* saying, "Device *A*, I received your message". Device *A* then knows its transmission was successful.

Of course, since IP is unreliable, that message may in fact never get to where it is going. Device *A* will sit waiting for the acknowledgment and never receive it. Conversely, it is also possible that Device *B* gets the message from Device *A*, but the ***acknowledgment itself*** vanishes somehow. In either case, we don't want Device *A* to sit forever waiting for an acknowledgment that is never going to ever arrive.

To prevent this from happening, Device *A* starts a *timer* when it first sends the message to Device *B*, which allows sufficient time for the message to get to *B* and the acknowledgment to travel back, plus some reasonable time to allow for possible delays. If the timer expires before the acknowledgment is received, *A* assumes there was a problem and *retransmits* its original message. Since this method involves positive acknowledgments ("yes, I got your message") and a facility for retransmission when needed, it is commonly called (ta-da!) *positive acknowledgment with retransmission (PAR)*, as shown in [Figure 204](#).

**Figure 204: Basic Reliability: Positive Acknowledgment With Retransmission (PAR)**

This diagram shows one of the most common simple techniques for ensuring reliability. Each time a message is sent by Device A, it starts a timer. Device B sends an acknowledgment back to A when it receives a message so A know it was successfully transmitted. If a message is lost, the timer goes off and A retransmits the data. Note that only one message can be outstanding at any time, making this system rather slow.

**Key Concept:** A basic technique for ensuring reliability in communications uses a rule that requires a device to send back an acknowledgment each time it successfully receives a transmission. If a transmission is not acknowledged after a period of time, it is retransmitted by its sender. This system is called *positive acknowledgment with retransmission (PAR)*. One drawback with this basic scheme is that the transmitter cannot send a second message until the first has been acknowledged.

---

## Improving the Utility of PAR Through Message Identification and Send Limits

PAR is a technique that is used widely in networking and communications for protocols that exchange relatively small amounts of data, or exchange data infrequently. The basic method is functional, but it is not well-suited to a protocol like TCP for two reasons. The first is that it is **inefficient**. Device *A* sends a message and then waits for the acknowledgment. Device *A* cannot send another message to Device *B* until it hears that its original message was received, which is very wasteful and would make the protocol extremely slow.

The first improvement we can make to this system is to provide some means of identification to the messages sent and to the acknowledgments. For example, we could put a *message ID* field in the message header. The device sending the message would uniquely identify it, and the recipient would use this identifier in the acknowledgment. For example, Device *A* might send a piece of data in a message with the message ID #1. Device *B* would receive the message and then send its own message back to Device *A* saying “Device *A*, I received your message #1”. The advantage of this system is that Device *A* can send multiple messages at once. It must keep track of each one sent, and whether or not it was acknowledged. Each also requires a separate timer, but that's not a big problem.

Of course, we also need to consider this exchange from the standpoint of Device *B*. Before, it only had to deal with one message at a time from Device *A*. Now it may have several show up all at once. What if it is already busy with transmissions from another device (or ten)? We need some mechanism that lets Device *B* say “I am only willing to handle the following number of messages from you at a time”. We could do that by having the acknowledgment message contain a field, such as *send limit*, which specifies the maximum number of unacknowledged messages *A* was allowed to have in transit to *B* at one time.

Device *A* would use this *send limit* field to restrict the rate at which it sent messages to Device *B*. Device *B* could adjust this field depending on its current load and other factors to maximize performance in its discussions with Device *A*. This enhanced system would thus provide reliability, efficiency and basic data flow control, as illustrated in [Figure 205](#).

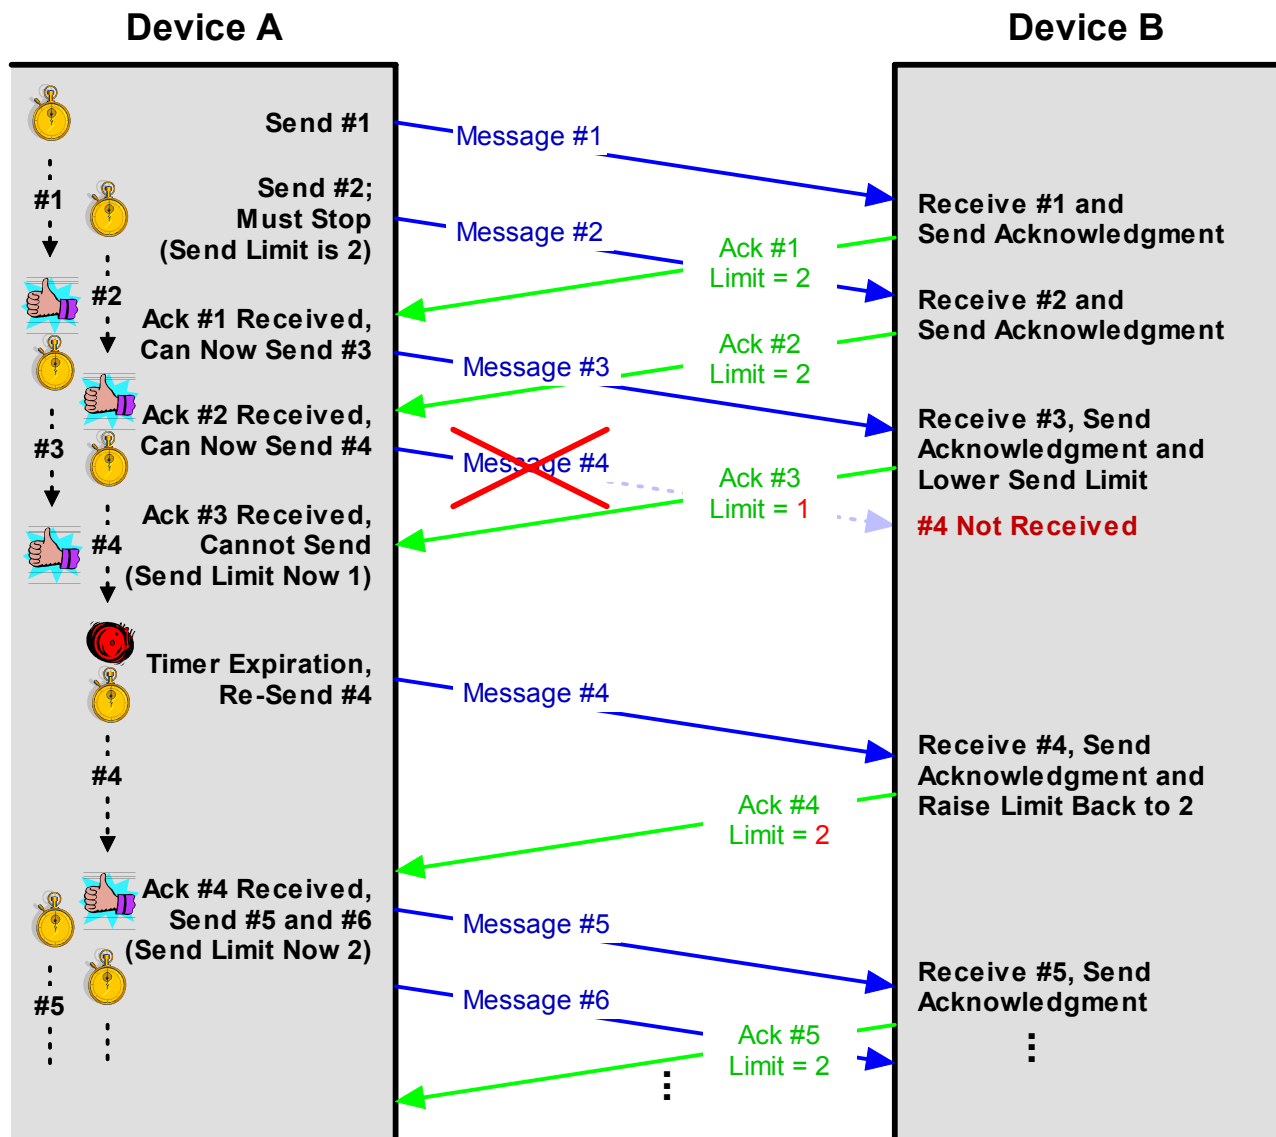

**Key Concept:** The basic PAR reliability scheme can be enhanced by identifying each message to be sent, so multiple messages can be in transit at once. The use of a *send limit* allows the mechanism to also provide flow control capabilities, by allowing each device to control the rate at which it is sent data.

---

## TCP's Stream-Oriented Sliding Window Acknowledgment System

So, does TCP use this variation on PAR? Of course not! That would be too simple. Well, actually, the TCP sliding window system **is** very similar to this method, conceptually, which is why it is important for us to understand. However, it requires some adjustment. The main reason has to do with the way TCP handles data: the matter of *stream orientation* compared to *message orientation* [discussed in the previous topic](#). The technique we have

**Figure 205: Enhanced Positive Acknowledgment With Retransmission (PAR)**

This diagram shows two enhancements to the basic PAR scheme of Figure 204. First, each message now has an identification number; each can be acknowledged individually, so more than one can be in transit at a given time. Second, device *B* regularly communicates to *A* a *send limit* parameter, which restricts the number of messages *A* can have outstanding at once. *B* can adjust this parameter to control the flow of data from *A*.

outlined involves **explicit** acknowledgments and (if necessary) retransmissions for messages. Thus, it would work well for a protocol that exchanged reasonably large messages on a fairly infrequent basis.

TCP, on the other hand, deals with individual bytes of data as a stream. Transmitting each byte one at a time and acknowledging each one at a time would quite obviously be absurd. It would require too much work, and even with overlapped transmissions (not waiting for an acknowledgment before sending the next piece of data) the result would be horribly slow.

---

Of course, this is why TCP doesn't send bytes individually, it divides them into *segments*. All of the bytes in a segment are sent together and received together, and thus acknowledged together. TCP uses a variation on the method we described above, where the identification of data sent and acknowledged is done using [the sequence numbers we discussed in the previous topic](#). Instead of acknowledging using something like a *message ID* field, we acknowledge data using the sequence number of the last byte of data in the segment. Thus, we are dealing with a **range** of bytes in each case, the range representing the sequence numbers of all the bytes in the segment.

### Conceptual Division of the TCP Transmission Stream Into Categories

Imagine a newly-established TCP connection between Device A and Device B. Device A has a long stream of bytes to be transmitted, but Device B can't accept them all at once. So it limits Device A to sending a particular number of bytes at once in segments, until the bytes in the segments already sent have been acknowledged. Then Device A is allowed to send more bytes. Each device keeps track of which bytes have been sent and which not, and which have been acknowledged.

At any point in time we can take a “snapshot” of the process. If we do, we can conceptually divide the bytes that the sending TCP has in its buffer into four categories, viewed as a timeline ([Figure 206](#)):

1. **Bytes Sent And Acknowledged:** The earliest bytes in the stream will have been sent and acknowledged. These are basically “accomplished” from the standpoint of the device sending data. For example, let's suppose that 31 bytes of data have already been sent and acknowledged. These would fall into Category #1.
2. **Bytes Sent But Not Yet Acknowledged:** These are the bytes that the device has sent but for which it has not yet received an acknowledgment. The sender cannot consider these “accomplished” until they are acknowledged. Let's say there are 14 bytes here, in Category #2.
3. **Bytes Not Yet Sent For Which Recipient Is Ready:** These are bytes that have not yet been sent, but which the recipient has room for based on its most recent communication to the sender of how many bytes it is willing to handle at once. The sender will try to send these immediately (subject to certain algorithmic restrictions we'll explore later). Suppose there are 6 bytes in Category #3.
4. **Bytes Not Yet Sent For Which Recipient Is Not Ready:** These are the bytes further “down the stream” which the sender is not yet allowed to send because the receiver is not ready. There are 44 bytes in Category #4.

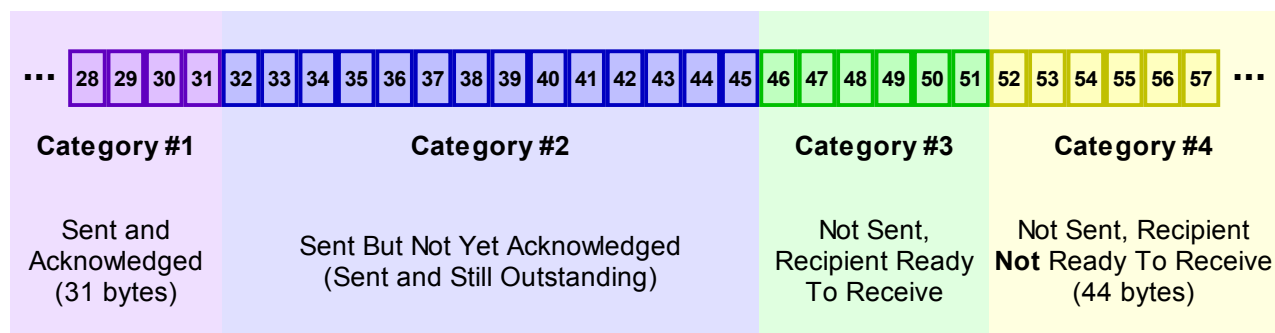

**Note:** I am using very small numbers here to keep the example simple (and to make the diagrams a bit easier to construct!) TCP doesn't normally send tiny numbers of bytes around for efficiency reasons.

---

The receiving device uses a similar system to differentiate between data received and acknowledged, not yet received but ready to receive, and not yet received and not yet ready to receive. In fact, both devices maintain a separate set of variables to keep track of the

**Figure 206: Conceptual Division of TCP Transmission Stream Into Categories**

categories into which bytes fall in the stream they are sending as well as the one they are receiving. This is explored in [the topic describing the detailed sliding window data transfer procedure](#) (yes, there's even more on this subject!)

**Key Concept:** The TCP sliding window system is a variation on the enhanced PAR system, with changes made to support TCP's *stream orientation*. Each device keeps track of the status of the byte stream it needs to transmit by dividing them into four conceptual categories: bytes sent and acknowledged, bytes sent but not yet acknowledged, bytes not yet sent but that can be sent immediately, and bytes not yet sent that cannot be sent until the recipient signals that it is ready for them.

### Sequence Number Assignment and Synchronization

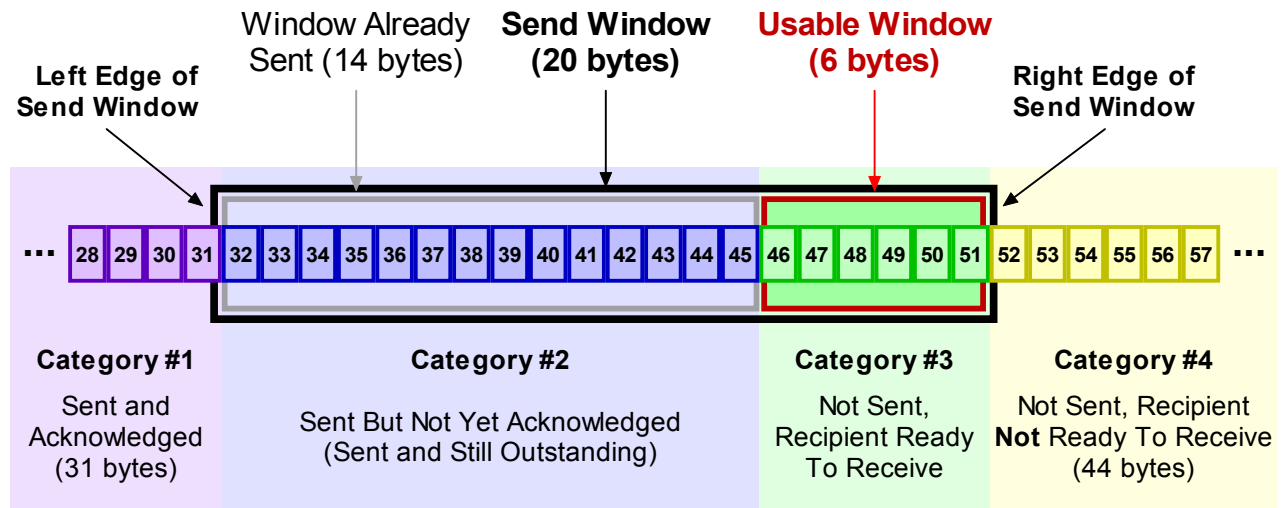

The sender and receiver must agree on the sequence numbers to assign to the bytes in the stream. This is called *synchronization* and [is done when the TCP connection is established](#). For simplicity, let's assume the first byte was sent with sequence number 1 (this is not normally the case). Thus, in our example the byte ranges for the four categories are:

1. **Bytes Sent And Acknowledged:** Bytes 1 to 31.
2. **Bytes Sent But Not Yet Acknowledged:** Bytes 32 to 45.
3. **Bytes Not Yet Sent For Which Recipient Is Ready:** Bytes 46 to 51.
4. **Bytes Not Yet Sent For Which Recipient Is Not Ready:** Bytes 52 to 95.

### The Send Window and Usable Window

The key to the operation of the entire process is the number of bytes that the recipient is allowing the transmitter to have unacknowledged at one time. This is called the *send window*, or often, just the *window*. The window is what determines how many bytes the sender is allowed to transmit, and is equal to the sum of the number of bytes in Category #2 and Category #3. Thus, the dividing line between the last two categories (bytes not sent

that recipient is ready for and ones it is **not** ready for) is determined by adding the window to the byte number of the first unacknowledged byte in the stream. In our example above, the first unacknowledged byte is #32. The total window size is 20.

**Figure 207: TCP Transmission Stream Categories and Send Window Terminology**

This diagram shows the same categories as [Figure 206](#), with the *send window* indicated as well. The black box is the overall send window (categories #2 and #3 combined); the gray represents the bytes already sent (category #2) and the red box is the *usable window* (category #3).

The term *usable window* is defined as the amount of data the transmitter is still allowed to send given the amount of data that is outstanding. It is thus exactly equal to the size of Category #3. You may also commonly hear mention of the *edges* of the window. The *left edge* marks the first byte in the window (byte 32 above). The *right edge* marks the last byte in the window (byte 51). Please see [Figure 207](#) for a graphical view of these concepts.

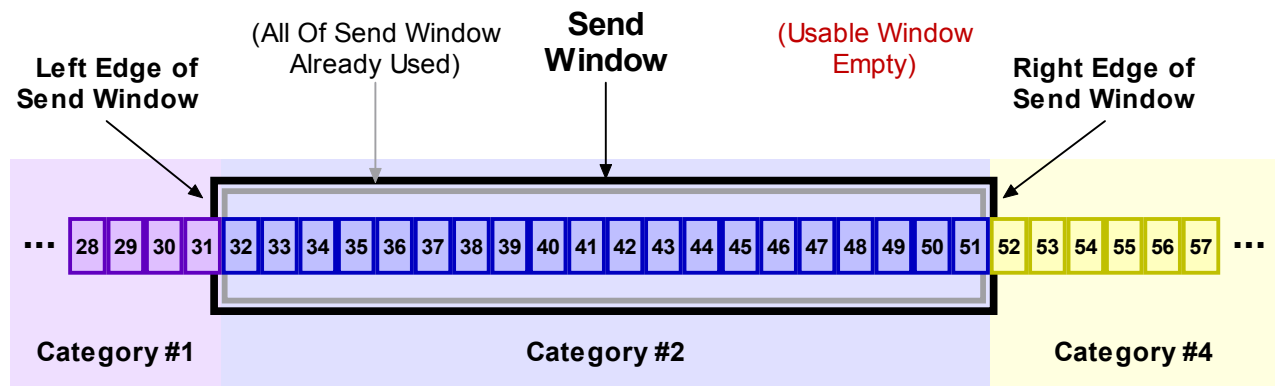

**Key Concept:** The *send window* is the key to the entire TCP sliding window system: it represents the maximum number of unacknowledged bytes a device is allowed to have outstanding at once. The *usable window* is the amount of the send window that the sender is still allowed to send at any point in time; it is equal to the size of the send window less the number of unacknowledged bytes already transmitted.

### Changes to TCP Categories and Window Sizes After Sending Bytes In the Usable Window

Now, let's suppose that in our example above, there is nothing stopping the sender from immediately transmitting the 6 bytes in the Category #3 (the usable window). When it does so, the 6 bytes will shift from Category #3 to Category #2. The byte ranges will now be as follows ([Figure 208](#)):

1. **Bytes Sent And Acknowledged:** Bytes 1 to 31.
2. **Bytes Sent But Not Yet Acknowledged:** Bytes 32 to 51.

3. **Bytes Not Yet Sent For Which Recipient Is Ready:** None.
4. **Bytes Not Yet Sent For Which Recipient Is Not Ready:** Bytes 52 to 95.

**Figure 208: TCP Stream Categories and Window After Sending Usable Window Bytes**

This diagram shows the result of the device sending all the bytes it is allowed to transmit in its usable window. It is the same as [Figure 207](#), except that all the bytes in category #3 have moved to category #2. The usable window is now zero, and will remain so until an acknowledgment is received for bytes in category #2.

### Processing Acknowledgments and Sliding the Send Window

Some time later, the destination device sends back a message to the sender providing an acknowledgment. It will not specifically list out the bytes that have been acknowledged, because as we said before, doing this would be inefficient. Instead, it will acknowledge a **range** of bytes that represents the longest contiguous sequence of bytes received since the ones it had previously acknowledged.

For example, let's suppose that the bytes already sent but not yet acknowledged at the start of the example (32 to 45) were transmitted in four different segments. These segments carried bytes 32 to 34, 35 to 36, 37 to 41 and 42 to 45 respectively. The first, second and fourth segments arrived, but the third did not. The receiver will send back an acknowledgment **only** for bytes 32 to 36 (32-34 and 35-36). It will hold bytes 42 to 45 but not acknowledge them, because this would imply receipt of bytes 37 to 41, which have not shown up yet. This is necessary because TCP is a *cumulative acknowledgment* system, which can only use a single number to acknowledge data, the number of the last contiguous byte in the stream successfully received. Let's also say the destination keeps the window size the same, at 20 bytes.

**Note:** An optional feature called *selective acknowledgments* does allow non-contiguous blocks of data to be acknowledged. This is explained in [a separate topic in a later section](#); we'll ignore this complication for now.

---

When the sending device receives this acknowledgment, it will be able to transfer some of the bytes from Category #2 to Category #1, since they have now been acknowledged. When it does so, something interesting will happen. Since five bytes have been acknowledged, and the window size didn't change, the sender is allowed to send five more bytes. In effect, the window shifts, or **slides**, over to the right in the timeline. At the same time five bytes move from Category #2 to Category #1, five bytes move from Category #4 to Category #3, creating a new usable window for subsequent transmission. So, after receipt of the acknowledgment, the groups will look like this (Figure 209):

1. **Bytes Sent And Acknowledged:** Bytes 1 to 36.
2. **Bytes Sent But Not Yet Acknowledged:** Bytes 37 to 51.
3. **Bytes Not Yet Sent For Which Recipient Is Ready:** Bytes 52 to 56.
4. **Bytes Not Yet Sent For Which Recipient Is Not Ready:** Bytes 57 to 95.

This process will occur each time an acknowledgment is received, causing the window to slide across the entire stream to be transmitted. And thus, ladies and gentlemen, we have the TCP *sliding window* acknowledgment system. It is a very powerful technique, which allows TCP to easily acknowledge an arbitrary number of bytes using a single acknowledgment number, thus providing reliability to the byte-oriented protocol without spending time on an excessive number of acknowledgments. For simplicity, the example above leaves the window size constant, but in reality it can be adjusted to allow a recipient to control the rate at which data is sent, enabling [flow control and congestion handling](#).

**Figure 209: Sliding The TCP Send Window**

After receiving acknowledgment for bytes 32 to 36, they move from category #2 to #1. The send window of Figure 208 slides right by five bytes; shifting five bytes from category #4 to #3, opening a new usable window.

**Key Concept:** When a device gets an acknowledgment for a range of bytes, it knows they have been successfully received by their destination. It moves them from the “sent but unacknowledged” to the “sent and acknowledged” category. This causes the send window to *slide* to the right, allowing the device to send more data.

---

---

## Dealing With Missing Acknowledgments

But wait... what about bytes 42 through 45 in our example? Well, until segment #3 (containing bytes 37 to 41) shows up, the receiving device will not send an acknowledgment for those bytes, nor any others that show up after it. The sender will be able to send the new bytes added to Category #3: bytes 52 to 56. It will then stop, with the window “stuck” on bytes 37 to 41.

Of course, like any PAR system, TCP includes a system for timing transmissions and retransmitting. Eventually, the TCP device will re-send the lost segment, and hopefully this time it will arrive again. Unfortunately, one drawback of TCP is that since it does **not** separately acknowledge segments, this may mean retransmitting other segments that actually were received by the recipient (such as the segment with bytes 42 to 45). This starts to get very complex, [as discussed in the topic on TCP retransmissions](#).

**Key Concept:** TCP acknowledgments are *cumulative*, and tell a transmitter that all the bytes up to the sequence number indicated in the acknowledgment were received successfully. Thus, if bytes are received out of order, they cannot be acknowledged until all the preceding bytes are received. TCP includes a method for timing transmissions and retransmitting lost segments if necessary.

---

## More Information on TCP Sliding Windows

I should explicitly point out that despite the length of this topic, the preceding is just a **summary** description of the overall operation of sliding windows, and one that does not include all of the modifications used in modern TCP! As you can see, the sliding window mechanism is at the heart of the operation of TCP as a whole.

In [the section that describes segments and discusses data transfer](#) we will see in more detail how TCP transmitters decide how and when to create segments for transmission. [The section describing TCP's reliability and data flow control features](#) will provide much more information on how sliding windows enable a device to manage the flow of data to it on a TCP connection. It also discusses [special problems that can arise if windows size is not carefully managed](#), and how [problems such as congestion are avoided](#) in TCP implementations through key changes to the basic sliding window mechanism described in this topic.

## TCP Ports, Connections and Connection Identification

The two TCP/IP transport layer protocols, TCP and UDP, play the same architectural role in the protocol suite, but do it in *very* different ways. In fact, one of the few functions that the two have in common is providing a method of transport-layer addressing and multiplexing. Through the use of *ports*, both protocols allow the data from many different application processes to be aggregated and sent through the IP layer, and then returned up the stack to the proper application process on the destination device. This is all explained in detail in [the section describing ports and sockets](#).

---

Despite this commonality, TCP and UDP diverge somewhat even in how they deal with processes. UDP is a connectionless protocol, which of course means devices do not set up a formal connection before sending data. UDP doesn't have to use sliding windows, or keep track of how long it has been since a transmission was sent and so forth. When the UDP layer on a device receives data it just sends it to the process indicated by the destination port, and that's that. It can seamlessly handle any number of processes sending it messages because they are all handled identically.

### ***Connection-Handling Responsibilities***

Since TCP is connection-oriented, it has many more responsibilities. Each TCP software layer needs to be able to support connections to several other TCPs simultaneously. The operation of each connection is separate from of each other connection, and the TCP software must manage each independently. It must be sure not only that data is routed to the right process, but that data transmitted on each connection is managed without any overlap or confusion.

### ***Connection Identification***

The first consequence of this is that each connection must be uniquely identified. This is done by using the pair of socket identifiers corresponding to the two *endpoints* of the connection, where a socket is simply the combination of the IP address and the port number of each process. This means a socket pair contains four pieces of information: source address, source port, destination address. Thus, TCP connections are sometimes said to be described by this addressing *quadruple*.

I introduced this in [the general topic on TCP/IP sockets](#), where I gave the example of an HTTP request sent from a client at 177.41.72.6 to a Web site at 41.199.222.3. The server for that Web site will use well-known port number 80, so its socket is 41.199.222.3:80. If the client has been assigned ephemeral port number 3,022 for the Web browser, the client socket is 177.41.72.6:3022. The overall connection between these devices can be described using this socket pair:

(41.199.222.3:80, 177.41.72.6:3022)

### ***Multiple Connection Management***

This identification of connections using both client and server sockets is what provides the flexibility in allowing multiple connections between devices that we take for granted on the Internet. For example, busy application server processes (such as Web servers) must be able to handle connections from more than one client, or the World Wide Web would be pretty much unusable. Since the connection is identified using the client's socket as well as the server's, this is no problem. At the same time that the Web server maintains the connection mentioned just above, it can easily have another connection to say, port 2,199 at IP address 219.31.0.44. This is represented by the connection identifier:

(41.199.222.3:80, 219.31.0.44:2199).

---

In fact, we can have multiple connections from the same client to the same server. Each client process will be assigned a different ephemeral port number, so even if they all try to access the same server process (such as the Web server process at 41.199.222.3:80), they will all have a different client socket and represent unique connections. This is what lets you make several simultaneous requests to the same Web site from your computer.

Again, TCP keeps track of each of these connections independently, so each connection is unaware of the others. TCP can handle hundreds or even thousands of simultaneous connections. The only limit is the capacity of the computer running TCP, and the bandwidth of the physical connections to it—the more connections running at once, the more each one has to *share* limited resources.

**Key Concept:** Each device can handle simultaneous TCP connections to many different processes on one or more devices. Each connection is identified by the socket numbers of the devices in the connection, called the connection's *endpoints*. Each endpoint consists of the device's IP address and port number, so each connection is identified by the *quadruple* of client IP address and port number, and server IP address and port number.

---

## **TCP Common Applications and Server Port Assignments**

We saw in [the overview of TCP](#) that the protocol originally included the functions of both modern TCP and the Internet Protocol. TCP was split into TCP and IP to allow applications that didn't need TCP's complexity to bypass it, using the much simpler [UDP](#) instead as a transport layer protocol instead. This was an important step in the development of the TCP/IP protocol suite, since there are several important protocols for which UDP is ideally suited, and even some where TCP is more of a nuisance than a benefit.

Most commonly, however, UDP is only used in special cases. The UDP applications topic describes the two types of protocols that may be better suited to UDP than TCP: ones where speed is more important than reliability, and ones that send only short messages infrequently. The majority of TCP/IP applications do not fall into these categories. Thus, even though the layering of TCP and IP means most protocols aren't **required** to use TCP, most of them do anyway. The majority of the protocols that use it employ all or at least most of the features it provides. The establishment of a persistent connection is necessary for many interactive protocols, such as [Telnet](#), as well as for ones that send commands and status replies, like [HTTP](#). Reliability and flow control are essential for protocols that send large files, like [FTP](#) or [the e-mail protocols](#).

**Table 151** shows some of the more significant application protocols that run on TCP. I have shown for each the well-known or registered port number reserved for that protocol's server process (clients use [ephemeral ports](#), not the port numbers in the table). I have also shown the special “keyword” shortcut for each port assignment, and provided brief comments on why the protocol is well-matched to TCP.

**Table 151: Common TCP Applications and Server Port Assignments (Page 1 of 2)**

Port #	Keyword	Protocol	Comments
<b>20 and 21</b>	ftp-data / ftp	File Transfer Protocol (FTP, data and control)	Used to send large files, so ideally suited for TCP.
<b>23</b>	telnet	Telnet Protocol	Interactive session-based protocol. Requires the connection-based nature of TCP.
<b>25</b>	smtp	Simple Mail Transfer Protocol (SMTP)	Uses an exchange of commands, and sends possibly large files between devices.
<b>53</b>	domain	Domain Name Server (DNS)	An example of a protocol that uses both UDP and TCP. For simple requests and replies, DNS uses UDP. For larger messages, especially zone transfers, TCP is used.
<b>70</b>	gopher	Gopher Protocol	A messaging protocol that has been largely replaced by the WWW.
<b>80</b>	http	Hypertext Transfer Protocol (HTTP / World Wide Web)	The classic example of a TCP-based messaging protocol.
<b>110</b>	pop3	Post Office Protocol (POP version 3)	E-mail message retrieval protocols; use TCP to exchange commands and data.
<b>119</b>	nntp	Network News Transfer Protocol (NNTP)	Used for transferring NetNews (USEnet) messages, which can be lengthy.
<b>139</b>	netbios-ssn	NetBIOS Session Service	A session protocol, clearly better suited to TCP than UDP.
<b>143</b>	imap	Internet Message Access Protocol (IMAP)	Another e-mail message retrieval protocol.
<b>179</b>	bgp	Border Gateway Protocol (BGP)	While interior routing protocols like RIP and OSPF use either UDP or IP directly, BGP runs over TCP. This allows BGP to assume reliable communication even as it sends data over potentially long distances.
<b>194</b>	irc	Internet Relay Chat (IRC)	IRC is like Telnet in that it is an interactive protocol that is strongly based on the notion of a persistent connection between a client and server.

---

**Table 151: Common TCP Applications and Server Port Assignments (Page 2 of 2)**

Port #	Keyword	Protocol	Comments
2049	nfs	Network File System (NFS)	NFS was original implemented using UDP for performance reasons. Given that it is responsible for large transfers of files and UDP is unreliable, this was probably not the best idea, and TCP versions were created. The latest version of NFS uses TCP exclusively.
6000 - 6063	TCP	x11	Used for the X Window graphical system. Multiple ports are dedicated to allow many sessions.

A couple of the protocols in the table above use both TCP and UDP, to get the “best of both worlds”. Short, simple messages can be sent with UDP, while larger files are moved with TCP. Many of the protocols that use both TCP and UDP are actually [utility/diagnostic protocols](#) (such as Echo, Discard and the Time Protocol). These are a special case, because they were designed to use both UDP and TCP specifically to allow their use for diagnostics on both protocols.

I haven't included an exhaustive list of TCP applications above; see [the topic on common TCP/IP applications and port numbers](#), which also contains a pointer to the full (massive) list of TCP well-known and registered server ports.

---

## **TCP Basic Operation: Connection Establishment, Management and Termination**

While I have described the Transmission Control Protocol as *connection-oriented*, this term isn't "just any old characteristic" of TCP. The overall operation of the entire protocol can be described in terms of how TCP software prepares, negotiates, establishes, manages and terminates connections. TCP implementations certainly do more than handle connections, but the other major tasks they perform, such as data handling and providing reliability and flow control, can only occur over a stable connection. This makes connections the logical place to begin in exploring the details of how TCP does its thing.

In this section I describe TCP connections from start to finish. I begin with an overview of TCP's operation by providing a summary of the *finite state machine* that formally defines the stages of a connection. State machines can be a bit mind-boggling when you read about them in standards, but a simplified version provides an excellent high-level view of the "life" of a connection, so it is a good place to start.

From there, I move on to provide details about TCP's handling of connections. I described how connections are prepared and transmission control blocks (TCBs) set up, and the difference between a passive and an active socket open. I explain the three-way handshake used to create a connection, and the method by which parameters are exchanged and sequence numbers synchronized. I talk about how an established connection is managed, including the method by which TCP handles problem conditions and resets the connection when necessary. Finally, I describe how a connection can be terminated when it is no longer needed.

**Background Information:** The detailed topics in this section assume your familiarity with [the concepts in the previous fundamentals section](#), especially the notion of [sequence numbers](#).

---

## **TCP Operational Overview and the TCP Finite State Machine (FSM)**

It is essential that all devices that implement any networking protocol do so in a consistent manner. Otherwise, one device might behave in a manner the other wouldn't expect. Naturally, this is why there are standards that describe the operation of each protocol. The problem with a protocol like TCP is that it performs so many tasks that it is difficult to specify the exact operation of all aspects of the protocol succinctly.

### ***Using A Finite State Machine to Explain Complex Protocols***

One way that computer scientists explain how a complex protocol works is through a theoretical tool called a *finite state machine (FSM)*. An FSM attempts to describe a protocol or algorithm by considering it like a virtual "machine" that progresses through a series of stages of operation in response to various happenings. You need to understand four essential concepts to comprehend the workings of a finite state machine:

- 
- ☉ **State:** The particular “circumstance” or “status” that describes the protocol software on a machine at a given time.
  - ☉ **Transition:** The act of moving from one state to another.
  - ☉ **Event:** Something that causes a transition to occur between states.
  - ☉ **Action:** Something a device does in response to an event before it transitions to another state.

A FSM describes the protocol by explaining all the different states the protocol can be in, the events that can occur in each state, what actions are taken in response to the events and what transitions happen as a result. The protocol usually starts in a particular *beginning state* when it is first run. It then follows a sequence of steps to get it into a regular operating state, and moves to other states in response to particular types of input or other circumstances. The state machine is called *finite* because there are only a limited number of states.

**Key Concept:** A tool used by many computer scientists to describe the operation of a protocol or algorithm is the *finite state machine*. It describes the different actions taken by a piece of software over time by defining a finite number of operating *states*, *events* that can cause *transitions* between states, and *actions* taken in response to events.

---

### ***The Simplified TCP Finite State Machine***

In the case of TCP, the finite state machine can be considered to describe the “life stages” of a connection. Each connection between one TCP device and another begins in a null state where there is no connection, and then proceeds through a series of states until a connection is established. It remains in that state until something occurs to cause the connection to be closed again, at which point it proceeds through another sequence of transitional states and returns to the closed state.

The full description of the states, events and transitions in a TCP connection is lengthy and complicated—not surprising, since that would cover much of the entire TCP standard. For our purposes, that level of detail would be a good cure for insomnia but not much else. However, a **simplified** look at the TCP FSM will help give us a nice overall feel for how TCP establishes connections and then functions when a connection has been created.

Table 152 briefly describes each of the TCP states in a TCP connection, and also describes the main events that occur in each state, and what actions and transitions occur as a result. For brevity, three abbreviations are used for three types of message that control transitions between states, which correspond to the TCP header flags that are set to indicate a message is serving that function. These are:

- ☉ **SYN:** A *synchronize* message, used to initiate and establish a connection. It is so named since one of its functions is to synchronize sequence numbers between devices.

- ☹ **FIN:** A *finish* message, which is a TCP segment with the *FIN* bit set, indicating that a device wants to terminate the connection.
- ☹ **ACK:** An *acknowledgment*, indicating receipt of a message such as a *SYN* or a *FIN*.

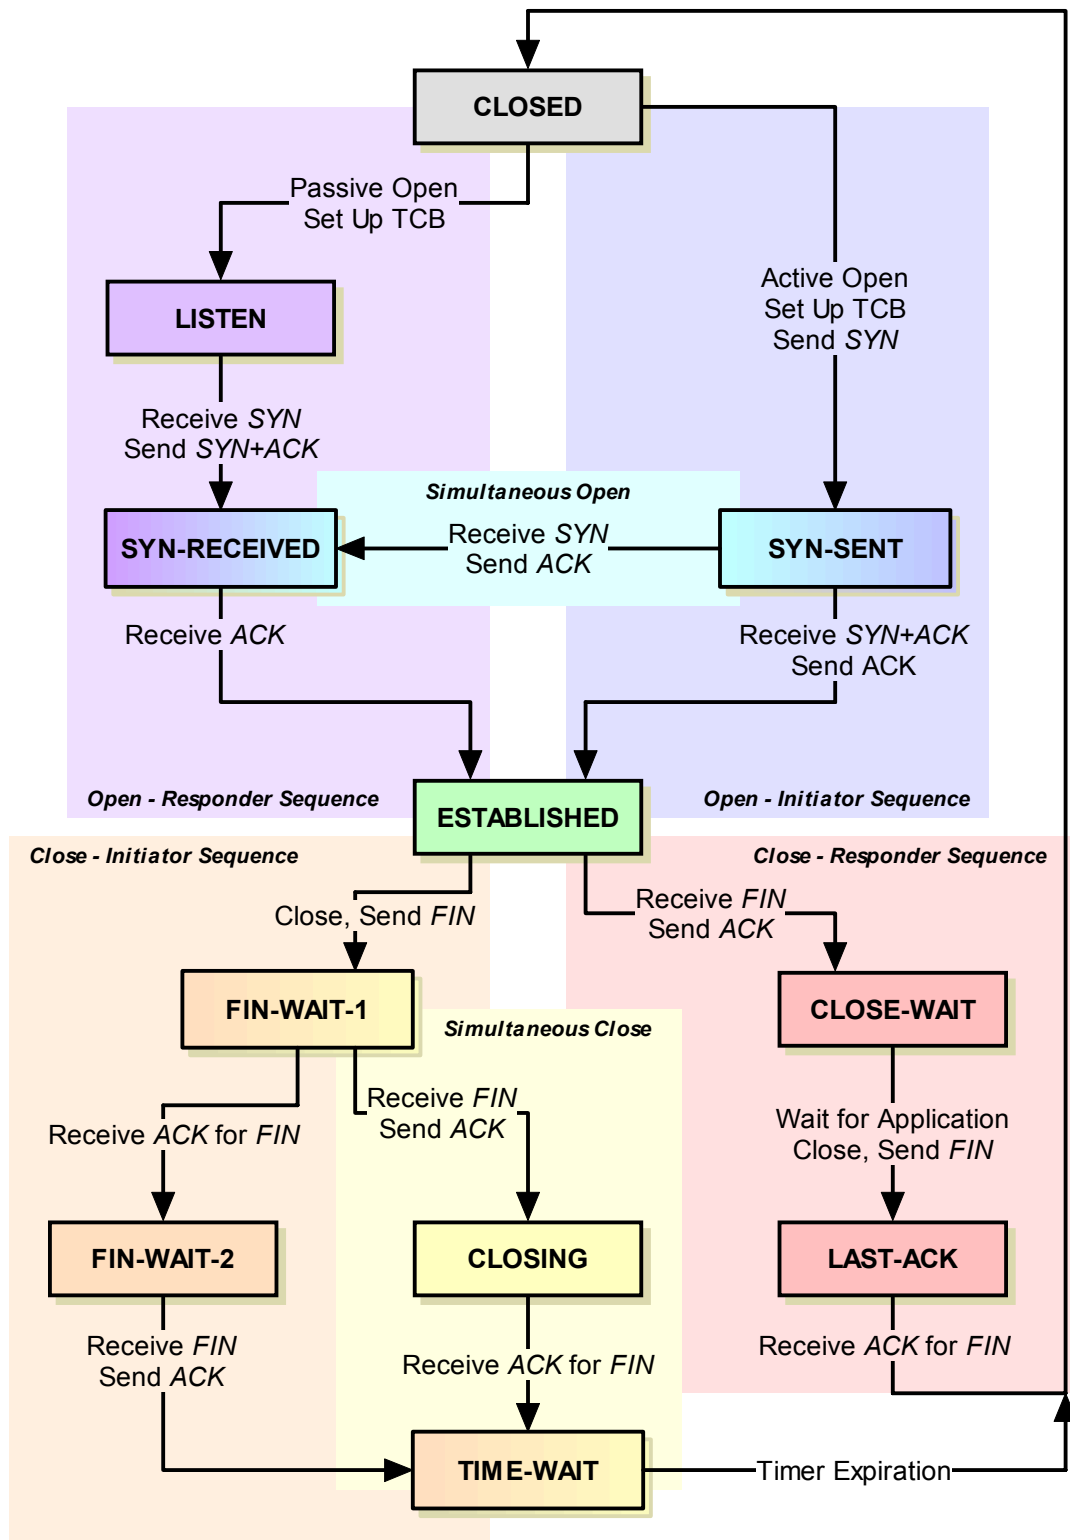

Again, I have not shown every possible transition, just the ones normally followed in the life of a connection. Error conditions also cause transitions but including these would move us well beyond a “simplified” state machine. The FSM is also illustrated in [Figure 210](#), which you may find easier for seeing how state transitions occur.

**Table 152: TCP Finite State Machine (FSM) States, Events and Transitions**  
(Page 1 of 2)

State	State Description	Event and Transition
<b>CLOSED</b>	This is the default state that each connection starts in before the process of establishing it begins. The state is called “fictional” in the standard. The reason is that this state represents the situation where there is no connection between devices—it either hasn't been created yet, or has just been destroyed. If that makes sense. ☺	<b>Passive Open:</b> A server begins the process of connection setup by doing a passive open on a TCP port. At the same time, it sets up the data structure ( <a href="#">transmission control block or TCB</a> ) needed to manage the connection. It then transitions to the <i>LISTEN</i> state.
		<b>Active Open, Send SYN:</b> A client begins connection setup by sending a <i>SYN</i> message, and also sets up a TCB for this connection. It then transitions to the <i>SYN-SENT</i> state.
<b>LISTEN</b>	A device (normally a server) is waiting to receive a <i>synchronize (SYN)</i> message from a client. It has not yet sent its own <i>SYN</i> message.	<b>Receive Client SYN, Send SYN+ACK:</b> The server device receives a <i>SYN</i> from a client. It sends back a message that contains its own <i>SYN</i> and also acknowledges the one it received. The server moves to the <i>SYN-RECEIVED</i> state.
<b>SYN-SENT</b>	The device (normally a client) has sent a <i>synchronize (SYN)</i> message and is waiting for a matching <i>SYN</i> from the other device (usually a server).	<b>Receive SYN, Send ACK:</b> If the device that has sent its <i>SYN</i> message receives a <i>SYN</i> from the other device but not an <i>ACK</i> for its own <i>SYN</i> , it acknowledges the <i>SYN</i> it receives and then transitions to <i>SYN-RECEIVED</i> to wait for the acknowledgment to its <i>SYN</i> .
		<b>Receive SYN+ACK, Send ACK:</b> If the device that sent the <i>SYN</i> receives both an acknowledgment to its <i>SYN</i> and also a <i>SYN</i> from the other device, it acknowledges the <i>SYN</i> received and then moves straight to the <i>ESTABLISHED</i> state.
<b>SYN-RECEIVED</b>	The device has both received a <i>SYN</i> (connection request) from its partner and sent its own <i>SYN</i> . It is now waiting for an <i>ACK</i> to its <i>SYN</i> to finish connection setup.	<b>Receive ACK:</b> When the device receives the <i>ACK</i> to the <i>SYN</i> it sent, it transitions to the <i>ESTABLISHED</i> state.

**Table 152: TCP Finite State Machine (FSM) States, Events and Transitions**  
(Page 2 of 2)

State	State Description	Event and Transition
<b>ESTABLISHED</b>	The “steady state” of an open TCP connection. Data can be exchanged freely once both devices in the connection enter this state. This will continue until the connection is closed for one reason or another.	<b>Close, Send <i>FIN</i>:</b> A device can close the connection by sending a message with the <i>FIN</i> ( <i>finish</i> ) bit sent and transition to the <i>FIN-WAIT-1</i> state.
		<b>Receive <i>FIN</i>:</b> A device may receive a <i>FIN</i> message from its connection partner asking that the connection be closed. It will acknowledge this message and transition to the <i>CLOSE-WAIT</i> state.
<b>CLOSE-WAIT</b>	The device has received a close request ( <i>FIN</i> ) from the other device. It must now wait for the application on the local device to acknowledge this request and generate a matching request.	<b>Close, Send <i>FIN</i>:</b> The application using TCP, having been informed the other process wants to shut down, sends a close request to the TCP layer on the machine upon which it is running. TCP then sends a <i>FIN</i> to the remote device that already asked to terminate the connection. This device now transitions to <i>LAST-ACK</i> .
<b>LAST-ACK</b>	A device that has already received a close request and acknowledged it, has sent its own <i>FIN</i> and is waiting for an <i>ACK</i> to this request.	<b>Receive <i>ACK</i> for <i>FIN</i>:</b> The device receives an acknowledgment for its close request. We have now sent our <i>FIN</i> and had it acknowledged, and received the other device's <i>FIN</i> and acknowledged it, so we go straight to the <i>CLOSED</i> state.
<b>FIN-WAIT-1</b>	A device in this state is waiting for an <i>ACK</i> for a <i>FIN</i> it has sent, or is waiting for a connection termination request from the other device.	<b>Receive <i>ACK</i> for <i>FIN</i>:</b> The device receives an acknowledgment for its close request. It transitions to the <i>FIN-WAIT-2</i> state.
		<b>Receive <i>FIN</i>, Send <i>ACK</i>:</b> The device does not receive an <i>ACK</i> for its own <i>FIN</i> , but receives a <i>FIN</i> from the other device. It acknowledges it, and moves to the <i>CLOSING</i> state.
<b>FIN-WAIT-2</b>	A device in this state has received an <i>ACK</i> for its request to terminate the connection and is now waiting for a matching <i>FIN</i> from the other device.	<b>Receive <i>FIN</i>, Send <i>ACK</i>:</b> The device receives a <i>FIN</i> from the other device. It acknowledges it and moves to the <i>TIME-WAIT</i> state.
<b>CLOSING</b>	The device has received a <i>FIN</i> from the other device and sent an <i>ACK</i> for it, but not yet received an <i>ACK</i> for its own <i>FIN</i> message.	<b>Receive <i>ACK</i> for <i>FIN</i>:</b> The device receives an acknowledgment for its close request. It transitions to the <i>TIME-WAIT</i> state.
<b>TIME-WAIT</b>	The device has now received a <i>FIN</i> from the other device and acknowledged it, and sent its own <i>FIN</i> and received an <i>ACK</i> for it. We are done, except for waiting to ensure the <i>ACK</i> is received and prevent potential overlap with new connections. (See <a href="#">the topic describing connection termination</a> for more details on this state.)	<b>Timer Expiration:</b> After a designated wait period, device transitions to the <i>CLOSED</i> state.

**Figure 210: The TCP Finite State Machine (FSM)**

This diagram illustrates the simplified TCP FSM. The color codings are not an official part of the definition of the FSM; I have added them to show more clearly the sequences taken by the two devices to open and close a link. For both establishment and termination there is a regular sequence, where the initiating and responding devices go through different states, and a *simultaneous* sequence where each uses the same sequence.

---

Tap tap... still awake? Okay, I guess even with serious simplification, that FSM isn't all that simple. It may seem a bit intimidating at first, but if you take a few minutes with it, you can get a good handle on how TCP works. The FSM will be of great use in making sense of the connection establishment and termination processes later in this section—and conversely, reading those sections will help you make sense of the FSM. So if your eyes have glazed over completely, just carry on and try coming back to this topic later.

### ***Finite State Machine Steps Represent the Stages of a Connection***

It's important to remember that this state machine is followed for **each connection**. This means at any given time TCP may be in one state for one connection to socket X, while in another for its connection to socket Y. Also, the typical movement between states for the two processes in a particular connection is not symmetric, because the roles of the devices are not symmetric: one device initiates a connection, the other responds; one device starts termination, the other replies. There is also an alternate path taken for connection establishment and termination if both devices initiate simultaneously (which is unusual, but can happen). This is shown by the color codings in [Figure 210](#).

Thus, for example, at the start of connection establishment, the two devices will take different routes to get to *ESTABLISHED*: one device (the server usually) will pass through the *LISTEN* state while the other (the client) will go through *SYN-SENT*. Similarly, one device will initiate connection termination and take the path through *FIN-WAIT-1* to get back to *CLOSED*; the other will go through *CLOSE-WAIT* and *LAST-ACK*. However, if both try to open at once, they each proceed through *SYN-SENT* and *SYN-RECEIVED*, and if both try to close at once, they go through *FIN-WAIT-1*, *CLOSING* and *TIME-WAIT* roughly simultaneously.

**Key Concept:** The TCP finite state machine describes the sequence of steps taken by both devices in a TCP session as they establish, manage and close the connection. Each device may take a different path through the states since under normal circumstances the operation of the protocol is not symmetric—one device initiates either connection establishment or termination, and the other responds.

---

### **TCP Connection Preparation: Transmission Control Blocks (TCBs) and Passive and Active Socket *OPENS***

In [the TCP fundamentals topic describing ports and connections](#), I raised an important point about TCP operation: it must be capable of handling many connections simultaneously. It is for this reason that we uniquely identify each connection using the *quadruple* of the socket identifiers (IP address and port number) for each of the two devices on the connection. The process of setting up, managing and terminating a connection is performed independently for each connection.

---

## Storing Connection Data: the Transmission Control Block

Since each connection is distinct, we must maintain data about each connection separately. TCP uses a special data structure for this purpose, called a *transmission control block* (TCB). The TCB contains all the important information about the connection, such as the two socket numbers that identify it and pointers to buffers where incoming and outgoing data are held. The TCB is also used to implement the sliding window mechanism. It holds variables that keep track of the number of bytes received and acknowledged, bytes received and not yet acknowledged, current window size and so forth. Of course, each device maintains its own TCB for the connection.

Before the process of setting up a TCP connection can begin, the devices on each end must perform some “prep work”. One of the tasks required to prepare for the connection is to set up the TCB that will be used to hold information about it. This is done right at the very start of the connection establishment process, when each device just transitions out of the *CLOSED* state.

### Active and Passive OPENs

TCP/IP is based on the client/server model of operation, and TCP connection setup is based on the existence of these roles as well. The client and server each prepare for the connection by performing an *OPEN* operation. However, there are two different kinds of *OPEN*:

- ☉ **Active OPEN:** A client process using TCP takes the “active role” and initiates the connection by actually sending a TCP message to start the connection (a *SYN* message).
- ☉ **Passive OPEN:** A server process designed to use TCP, however, takes a more “laid-back” approach. It performs a *passive OPEN* by contacting TCP and saying “I am here, and I am waiting for clients that may wish to talk to me to send me a message on the following port number”. The *OPEN* is called *passive* because aside from indicating that the process is listening, the server process does nothing.

A passive *OPEN* can in fact specify that the server is waiting for an active *OPEN* from a specific client, though not all TCP/IP APIs support this capability. More commonly, a server process is willing to accept connections from all comers. Such a passive *OPEN* is said to be *unspecified*.

**Key Concept:** A client process initiates a TCP connection by performing an active *OPEN*, sending a *SYN* message to a server. A server process using TCP prepares for an incoming connection request by performing a passive *OPEN*. Both devices create for each TCP session a data structure used to hold important data related to the connection, called a *transmission control block* (TCB).

---

---

## ***Preparation For Connection***

Both the client and the server create the TCB for the connection at the time that they perform the *OPEN*. The client already knows the IP addresses and port numbers for both the client process and the server process it is trying to reach, so it can use these to uniquely identify the connection and the TCB that goes with it.

For the server, the concept of a TCB at this stage of the game is a bit more complex. If the server is in fact waiting for a particular client, it can identify the connection using its own socket and the socket of the client for which it is waiting. Normally, however, the server doesn't know what client is trying to reach it. In fact, it could be contacted by more than one client nearly at the same time.

In this case, the server creates a TCB with an unspecified (zero) client socket number, and waits for an active *OPEN* to be received. It then *binds* the socket number of the client to the TCB for the passive *OPEN* as part of the connection process. To allow it to handle multiple incoming connections, the server process may in fact perform several unspecified passive *OPENs* simultaneously.

The transmission control block for a connection is maintained throughout the connection and destroyed when the connection is completely terminated and the device returns to the *CLOSED* state. TCP does include a procedure to handle the situation where both devices perform an active *OPEN* simultaneously. This is discussed in more detail in [the next topic on the connection establishment process](#).

## **TCP Connection Establishment Process: The "Three-Way Handshake"**

We have discussed in earlier topics in this section the connection orientation of TCP and its operation. Before TCP can be employed for any actually useful purpose—that is, sending data—a connection must be set up between the two devices that wish to communicate. This process, usually called *connection establishment*, involves an exchange of messages that transitions both devices from their initial connection state (*CLOSED*) to the normal operating state (*ESTABLISHED*).

### ***Connection Establishment Functions***

The connection establishment process actually accomplishes several things as it creates a connection suitable for data exchange:

- ☉ **Contact and Communication:** The client and server make contact with each other and establish communication by sending each other messages. The server usually doesn't even know what client it will be talking to before this point, so it discovers this during connection establishment.
- ☉ **Sequence Number Synchronization:** Each device lets the other know what [initial sequence number](#) it wants to use for its first transmission.
- ☉ **Parameter Exchange:** Certain [parameters that control the operation of the TCP connection are exchanged](#) by the two devices.

---

## Control Messages Used for Connection Establishment: SYN and ACK

TCP uses control messages to manage the process of contact and communication. There aren't, however, any special TCP control message types; all TCP messages use [the same segment format](#). A set of control flags in the TCP header indicates whether a segment is being used for control purposes or just to carry data. As I introduced in [the discussion of the TCP finite state machine](#), two control message types are used in connection setup, which are specified by setting the following two flags:

- ☉ **SYN:** This bit indicates that the segment is being used to initialize a connection. *SYN* stands for *synchronize*, in reference to the sequence number synchronization I mentioned above.
- ☉ **ACK:** This bit indicates that the device sending the segment is conveying an *acknowledgment* for a message it has received (such as a *SYN*).

There are also other control bits (*FIN*, *RST*, *PSH* and *URG*), which aren't important to connection establishment, so we will set them aside for now. We'll discuss them in other topics. In common TCP parlance, a message with a control bit set is often named for that bit. For example, if the *SYN* control bit is set the segment is often called "a *SYN* message". Similarly, one with the *ACK* bit set is "an *ACK* message" or even just "an *ACK*".

## Normal Connection Establishment: The "Three Way Handshake"

To establish a connection, each device must send a *SYN* and receive an *ACK* for it from the other device. Thus, conceptually, we need to have four control messages pass between the devices. However, it's inefficient to send a *SYN* and an *ACK* in separate messages when one could communicate both simultaneously. Thus, in the normal sequence of events in connection establishment, one of the *SYNs* and one of the *ACKs* is sent together by setting both of the relevant bits (a message sometimes called a *SYN+ACK*). This makes a total of three messages, and for this reason the connection procedure is called a *three-way handshake*.

**Key Concept:** The normal process of establishing a connection between a TCP client and server involves three steps: the client sends a *SYN* message; the server sends a message that combines an *ACK* for the client's *SYN* and contains the server's *SYN*; and then the client sends an *ACK* for the server's *SYN*. This is called the *TCP three-way handshake*.

---

[Table 153](#) describes in detail how the three-way handshake works (including a summary of [the preparation discussed in the previous topic](#)). It is adapted from [the table describing the TCP finite state machine](#), but shows what happens for both the server and the client over time. Each row shows the state the device begins in, what action it takes in that state and the state to which it transitions. The transmit and receive parts of each of the three steps of the handshake process are shown in the table, as well as in [Figure 211](#).

**Table 153: TCP “Three-Way Handshake” Connection Establishment Procedure**

Client			Server		
Start State	Action	Move To State	Start State	Action	Move To State
<b>CLOSED</b>	The client cannot do anything until the server has performed a passive <i>OPEN</i> and is ready to accept a connection. (Well, it can try, but nothing will be accomplished until the server is ready.)	—	<b>CLOSED</b>	The server performs a passive <i>OPEN</i> , creating a transmission control block (TCB) for the connection and readying itself for the receipt of a connection request ( <i>SYN</i> ) from a client.	<b>LISTEN</b>
<b>CLOSED</b>	<b>Step #1 Transmit:</b> The client performs an active <i>OPEN</i> , creating a transmission control block (TCB) for the connection and sending a <i>SYN</i> message to the server.	<b>SYN-SENT</b>	<b>LISTEN</b>	The server waits for contact from a client.	—
<b>SYN-SENT</b>	The client waits to receive an <i>ACK</i> to the <i>SYN</i> it has sent, as well as the server's <i>SYN</i> .	—	<b>LISTEN</b>	<b>Step #1 Receive, Step #2 Transmit:</b> The server receives the <i>SYN</i> from the client. It sends a single <i>SYN+ACK</i> message back to the client that contains an <i>ACK</i> for the client's <i>SYN</i> , and the server's own <i>SYN</i> .	<b>SYN-RECEIVED</b>
<b>SYN-SENT</b>	<b>Step #2 Receive, Step #3 Transmit:</b> The client receives from the server the <i>SYN+ACK</i> containing the <i>ACK</i> to the client's <i>SYN</i> , and the <i>SYN</i> from the server. It sends the server an <i>ACK</i> for the server's <i>SYN</i> . The client is now done with the connection establishment.	<b>ESTABLISHED</b>	<b>SYN-RECEIVED</b>	The server waits for an <i>ACK</i> to the <i>SYN</i> it sent previously.	—
<b>ESTABLISHED</b>	The client is waiting for the server to finish connection establishment so they can operate normally.		<b>SYN-RECEIVED</b>	<b>Step #3 Receive:</b> The server receives the <i>ACK</i> to its <i>SYN</i> and is now done with connection establishment.	<b>ESTABLISHED</b>
<b>ESTABLISHED</b>	The client is ready for normal data transfer operations.		<b>ESTABLISHED</b>	The server is ready for normal data transfer operations.	

**Figure 211: TCP “Three-Way Handshake” Connection Establishment Procedure**

This diagram illustrates how a conventional connection is established between a client and server, showing the three messages sent during the process and how each device transitions from the *CLOSED* state through intermediate states until the session is *ESTABLISHED*.

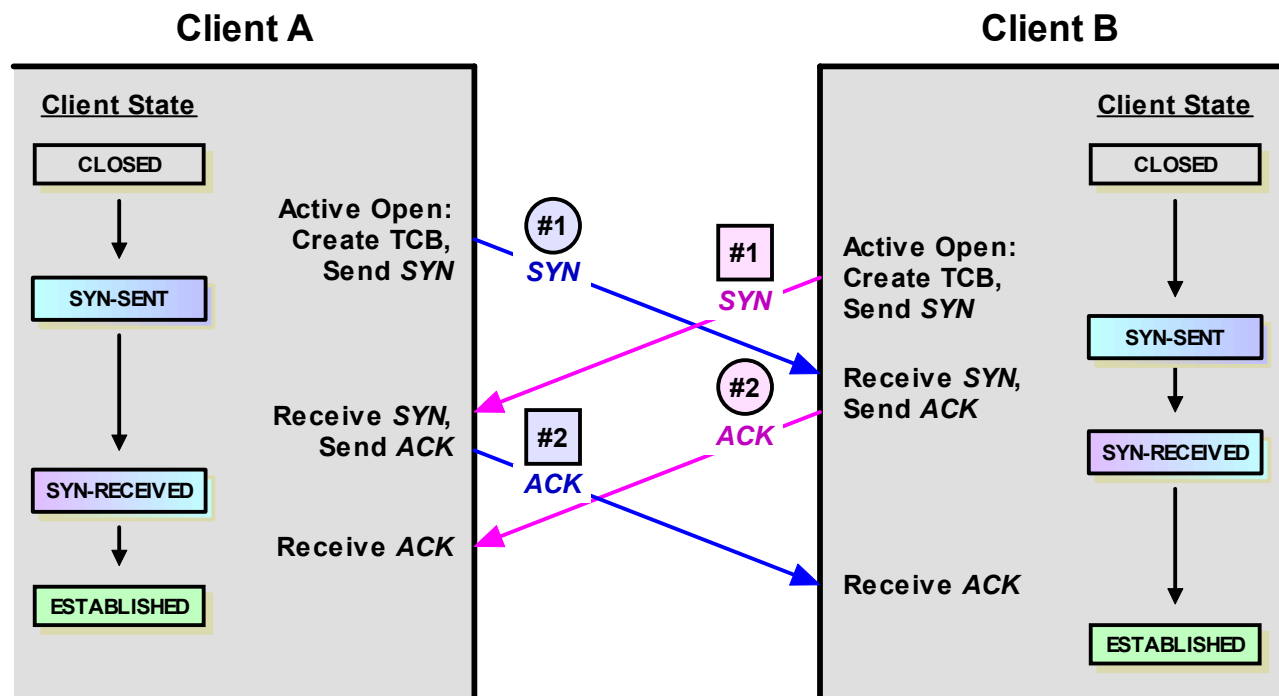

### ***Simultaneous Open Connection Establishment***

TCP is also set up to handle the situation where both devices perform an active *OPEN* instead of one doing a passive *OPEN*. This may occur if two clients are trying to reach each other instead of a client and a server. It is uncommon, however, and only happens under certain circumstances. Simultaneous connection establishment can also only happen if a well-known port is used as the source port for one of the devices.

In this case, the steps are different for both devices. Each client will perform an active *OPEN* and then proceed through both the *SYN-SENT* and *SYN-RECEIVED* states until their *SYNs* are acknowledged. This means there isn't a “three-way handshake” any more as shown in [Table 153](#). Instead, it is like two simultaneous “two-way handshakes”. Each client sends a *SYN*, receives the other's *SYN* and *ACKs* it, and then waits for its own *ACK*. The transaction, simplified, is described in [Table 154](#) and [Figure 212](#).

**Table 154: TCP Simultaneous Open Connection Establishment Procedure**

Client A			Client B		
Start State	Action	Move To State	Start State	Action	Move To State
<b>CLOSED</b>	<b>Client A Step #1</b> <b>Transmit:</b> Client A performs an active <i>OPEN</i> , creating a TCB and sending a <i>SYN</i> message to the server.	<b>SYN-SENT</b>	<b>CLOSED</b>	<b>Client B Step #1</b> <b>Transmit:</b> Client B performs an active <i>OPEN</i> , creating a TCB and sending a <i>SYN</i> to the server.	<b>SYN-SENT</b>
<b>SYN-SENT</b>	<b>Client B Step #1</b> <b>Receive and Step #2</b> <b>Transmit:</b> Client A receives Client B's <i>SYN</i> and sends it an <i>ACK</i> . It is still waiting for an <i>ACK</i> to its own <i>SYN</i> .	<b>SYN-RECEIVED</b>	<b>SYN-SENT</b>	<b>Client A Step #1</b> <b>Receive and Step #2</b> <b>Transmit:</b> Client B receives Client A's <i>SYN</i> and sends it an <i>ACK</i> . It is still waiting for an <i>ACK</i> to its own <i>SYN</i> .	<b>SYN-RECEIVED</b>
<b>SYN-RECEIVED</b>	<b>Client A Step #2</b> <b>Receive:</b> Client A receives the <i>ACK</i> from Client B for its <i>SYN</i> and is done with connection establishment.	<b>ESTAB-LISHED</b>	<b>SYN-RECEIVED</b>	<b>Client B Step #2</b> <b>Receive:</b> Client B receives the <i>ACK</i> from Client A for its <i>SYN</i> and is done with connection establishment.	<b>ESTAB-LISHED</b>

**Figure 212: TCP Simultaneous Open Connection Establishment Procedure**

This diagram shows what happens when two devices try to open a connection to each other at the same time. In this case instead of a three-way handshake, each sends a *SYN* and receives an *ACK*. They each follow the same sequence of states, which differs from both sequences in the normal three-way handshake.

---

To keep the table size down, I have shown the activities performed by the two devices occurring simultaneously (in the same row). In “real life” the actions don’t need to occur at exactly the same time, and probably won’t. All that has to happen for the simultaneous procedure to be followed is that each device receives a SYN before getting an ACK for their own SYN, as [Figure 212](#) shows.

**Key Concept:** If one device setting up a TCP connection sends a SYN and then receives a SYN from the other one before its SYN is acknowledged, the two devices perform a *simultaneous open*, which consists of the exchange of two independent SYN and ACK message sets. The end result is the same as the conventional three-way handshake, but the process of getting to the *ESTABLISHED* state is different.

---

## TCP Connection Establishment Sequence Number Synchronization and Parameter Exchange

The [TCP three-way handshake](#) describes the mechanism of message exchange that allows a pair of TCP devices to move from a closed state to a ready-to-use, established connection. Connection establishment is about more than just passing messages between devices to establish communication. The TCP layers on the devices must also exchange information about the sequence numbers each device wants to use for its first data transmission, as well as parameters that will control how the connection operates. The former of these two data exchange functions is usually called *sequence number synchronization*, and is such an important part of connection establishment that the messages that each device sends to start the connection are called SYN (*synchronization*) messages.

You may recall from the TCP fundamentals section that [TCP refers to each byte of data individually](#), and [uses sequence numbers to keep track of which bytes have been sent and received](#). Since each byte has a sequence number, we can acknowledge each byte, or more efficiently, use a single number to acknowledge a range of bytes received.

### ***The Problem With Starting Every Connection Using the Same Sequence Number***

In the example I gave in [the topic describing the sliding windows system](#), I assumed for “simplicity” (ha ha, was that simple?) that each device would start a connection by giving the first byte of data sent sequence number 1. A valid question is, why wouldn’t we ***always*** just start off each TCP connection by sending the first byte of data with a sequence number of 1? The sequence numbers are arbitrary, after all, and this is the simplest method.

In an ideal world, this would probably work, but we don’t live in an ideal world. ☹ The problem with starting off each connection with a sequence number of 1 is that it introduces the possibility of segments from different connections getting mixed up. Suppose we established a TCP connection and sent a segment containing bytes 1 through 30. However, there was a problem with the internetwork that caused this segment to be delayed, and eventually, the TCP connection itself to be terminated. We then started up a new

---

connection and again used a starting sequence number of 1. As soon as this new connection was started, however, the old segment with bytes labeled 1 to 30 showed up. The other device would erroneously think those bytes were part of the **new** connection.

This is but one of several similar problems that can occur. To avoid them, each TCP device, at the time a connection is initiated, chooses a 32-bit *initial sequence number (ISN)* for the connection. Each device has its own ISN, and they will normally not be the same.

### **Selecting the Initial Sequence Number**

Traditionally, each device chose the ISN by making use of a timed counter, like a clock of sorts, that was incremented every 4 microseconds. This counter was initialized when TCP started up and then its value increased by 1 every 4 microseconds until it reached the largest 32-bit value possible (4,294,967,295) at which point it “wrapped around” to 0 and resumed incrementing. Any time a new connection is set up, the ISN was taken from the current value of this timer. Since it takes over 4 hours to count from 0 to 4,294,967,295 at 4 microseconds per increment, this virtually assured that each connection will not conflict with any previous ones.

One issue with this method is that it makes ISNs predictable. A malicious person could write code to analyze ISNs and then predict the ISN of a subsequent TCP connection based on the ISNs used in earlier ones. This represents a security risk, which has been exploited in the past (such as in the case of the famous Mitnick attack). To defeat this, implementations now use a random number in their ISN selection process.

### **TCP Sequence Number Synchronization**

Once each device has chosen its ISN, it sends this value to the other device in the *Sequence Number* field in its initial *SYN* message. The device receiving the *SYN* responds with an *ACK* message acknowledging the *SYN* (which may also contain its own *SYN*, as in step #2 of the three-way handshake). In the *ACK* message, the *Acknowledgment Number* field is set to the value of the ISN received from the other device **plus one**. This represents the next sequence number the device expects to receive from its peer; the ISN actually thus represents the sequence number of the last byte received (fictitious in this case, since the connection is new and nothing yet has been received). We'll see later on that [this is consistent with how these two fields are used for normal data exchange](#).

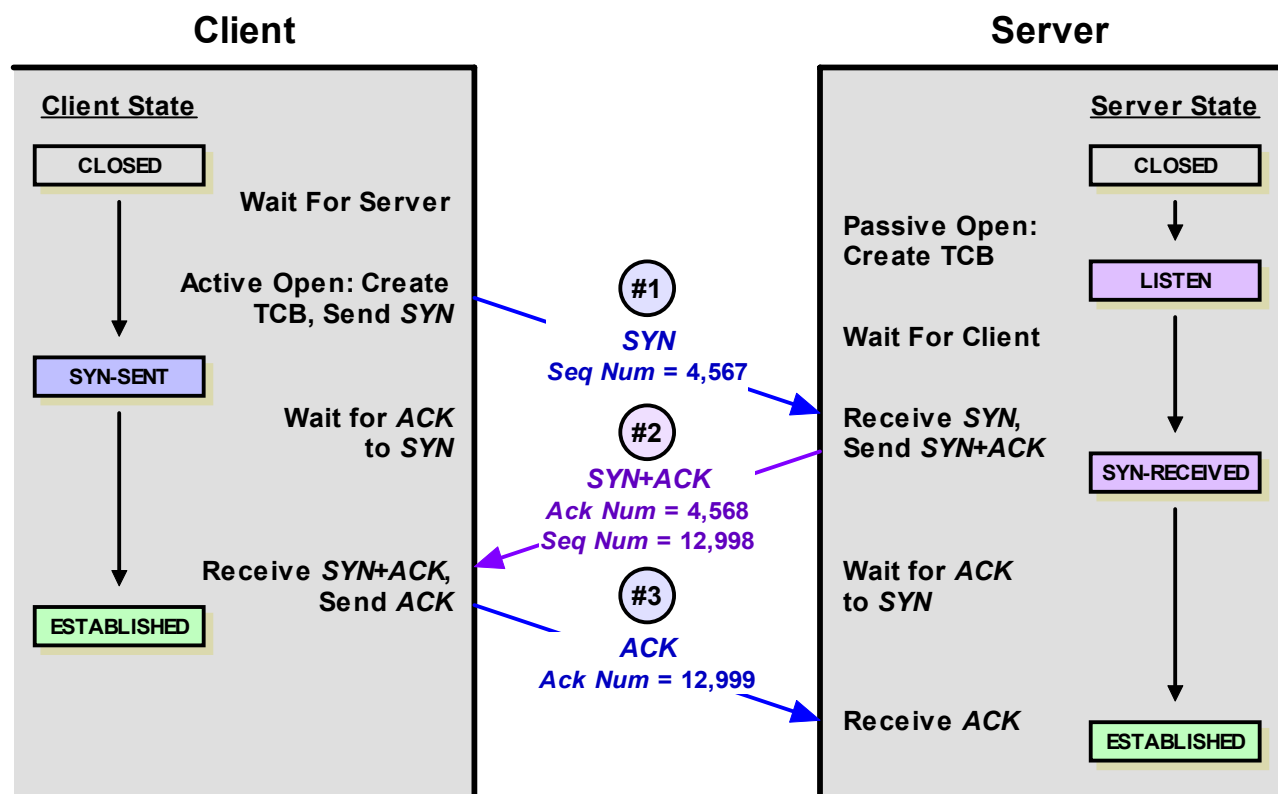

**Key Concept:** As part of the process of connection establishment, each of the two devices in a TCP connection informs the other of the sequence number it plans to use for its first data transmission by putting the preceding sequence number in the *Sequence Number* field of its *SYN* message. The other device confirms this by incrementing that value and putting it into the *Acknowledgment Number* field of its *ACK*, telling the other device that is the sequence number it is expecting for the first data transmission. This process is called *sequence number synchronization*.

---

Here's a simplified example of the three-way handshake steps showing how this is done (see [Figure 213](#) as well). I chose small ISNs for readability but remember that they can be any 32-bit number:

1. **Connection Request By Client:** The client chooses an ISN for its transmissions of 4,567. It sends a *SYN* with the *Sequence Number* field set to 4,567.
2. **Acknowledgment and Connection Request By Server:** The server chooses an ISN for its transmissions of 12,998. It receives the client's *SYN*. It sends a *SYN+ACK* with an *Acknowledgment Number* field value of 4,568 (one more than the client's ISN). This message has a *Sequence Number* field value of 12,998.
3. **Acknowledgment By Client:** The client sends an *ACK* with the *Acknowledgment Number* field set to 12,999.

**Figure 213: TCP Sequence Number Synchronization**

This diagram illustrates the same three-way handshake connection establishment procedure introduced in [Figure 211](#), except this time I have shown the *Sequence Number* and *Acknowledgment Number* fields in each message so you can see how they are used by each of the two devices to establish initial sequence numbers for data exchange.

With the connection now established, the client will send data whose first byte will be given sequence number 4,568. The server's first byte of data will be numbered 12,999.

---

## TCP Parameter Exchange

In addition to initial sequence numbers, *SYN* messages also are designed to convey important parameters about how the connection should operate. TCP includes a flexible scheme for carrying these parameters, in the form of a variable-length *Options* field in the TCP segment format that can be expanded to carry multiple parameters. Only a single parameter is defined in TCP 793 to be exchanged during connection setup: *Maximum Segment Size (MSS)*. [The significance of this parameter is explained in the TCP data transfer section.](#)

Each device sends the other the MSS that it wants to use for the connection, if it wishes to use a non-default value. When receiving the *SYN*, the server records the MSS value that the client sent, and will never send a segment larger than that value to the client. The client does the same for the server. The client and server MSS values are independent, so a connection can be established where the client can receive larger segments than the server or vice-versa.

Later RFCs have defined additional parameters that may be exchanged during connection setup. Some of these include:

- ☉ **Window Scale Factor:** Allows a pair of devices to specify larger window sizes than would normally be possible given the 16-bit size of the TCP *Window* field.
- ☉ **Selective Acknowledgment Permitted:** Allows a pair of devices to use [the optional selective acknowledgment feature](#) to allow only certain lost segments to be retransmitted.
- ☉ **Alternate Checksum Method:** Lets devices specify an alternative method of performing checksums than [the standard TCP mechanism](#).

## TCP Connection Management and Problem Handling, the Connection Reset Function, and TCP "Keepalives"

Once both of the devices in a TCP connection have completed connection setup and have entered the *ESTABLISHED* state, the TCP software is in its normal operating mode. Bytes of data will be packaged into segments for transmission using the mechanisms described in [the section on message formatting and data transfer](#). The [sliding windows scheme](#) will be used to control segment size and to provide flow control, congestion handling and retransmissions as needed.

Once in this mode, both devices can remain there indefinitely. Some TCP connections can be very long-lived indeed—in fact, some users maintain certain connections like [Telnet sessions](#) for hours or even days at a time. There are two circumstances that can cause a connection to move out of the *ESTABLISHED* state:

- ☉ **Connection Termination:** Either of the devices decides to terminate the connection. This involves [a specific procedure that is covered in the next topic in this section](#).
- ☉ **Connection Disruption:** A problem of some sort occurs that causes the connection to be interrupted.

---

## ***The TCP Reset Function***

To allow TCP to live up to its job of being a reliable and robust protocol, it includes intelligence that allows it to detect and respond to various problems that can occur during an established connection. One of the most common is the *half-open connection*. This situation occurs when due to some sort of problem, one device closes or aborts the connection without the other one knowing about it. This means one device is in the *ESTABLISHED* state while the other may be in the *CLOSED* state (no connection) or some other transient state. This could happen if, for example, one device had a software crash and was restarted in the middle of a connection, or if some sort of glitch caused the states of the two devices to become unsynchronized.

To handle half-open connections and other problem situations, TCP includes a special *reset function*. A reset is a TCP segment that is sent with the *RST* flag set to one in its header. Generally speaking, a reset is generated whenever something happens that is “unexpected” by the TCP software. Some of the most common specific cases in which a reset is generated include:

- ① Receipt of any TCP segment from any device with which the device receiving the segment does not currently have a connection (other than a *SYN* requesting a new connection.)
- ② Receipt of a message with an invalid or incorrect *Sequence Number* or *Acknowledgment Number* field, indicating the message may belong to a prior connection or is spurious in some other way.
- ③ Receipt of a *SYN* message on a port where there is no process listening for connections.

## ***Handling Reset Segments***

When a device receives a segment with the *RST* bit sent, it tells the device to reset the connection so it can be re-established. Like all segments, the reset itself must be checked to ensure that it is valid (by looking at the value of its *Sequence Number* field). This prevents a spurious reset from shutting down a connection. Assuming the reset is valid, the handling of the message depends on the state of the device that receives it:

- ① If the device is in the *LISTEN* state, the reset is ignored and it remains in that state.
- ② If the device is in the *SYN-RECEIVED* state but was previously in the *LISTEN* state (which is the normal course of events for a server setting up a new connection), it returns to the *LISTEN* state.
- ③ In any other situation, the reset causes the connection to be aborted and the device returns to the *CLOSED* state for that connection. The device will advise the higher-layer process using TCP that the connection has been closed.

**Key Concept:** TCP includes a special *connection reset feature* to allow devices to deal with problem situations, such as half-open connections or the receipt of unexpected message types. To use the feature, the device detecting the problem sends a TCP segment with the *RST* (reset) flag set to 1. The receiving device either returns to the *LISTEN* state, if it was in the process of connection establishment, or closes the connection and returns to the *CLOSED* state pending a new session negotiation.

---

### ***Idle Connection Management and "Keepalive" Messages***

One final connection management issue in TCP is how to handle an idle connection; that is, a TCP session that is active but that has no data being transmitted by either device for a prolonged period of time. The TCP standard specifies that the appropriate action to take in this situation is... nothing. The reason is that, strictly speaking, there is no need to do anything to maintain an idle connection in TCP. The protocol is perfectly happy to allow both devices to stop transmitting for a very long period of time, and then simply resume transmissions of data and acknowledgment segments when either has data to send.

However, just as many people become “antsy” when they are on a telephone call and they don’t hear anything for a long while, there was concern on the part of some TCP implementors that a TCP connection that was idle for a very long while might mean that the connection had been broken.

Thus, TCP software often includes an “unofficial” feature that allows a device with a TCP link to periodically send a null segment containing no data to its peer on the connection. If the connection is still valid, the other device responds with a segment containing an acknowledgment; if it is not, the other device will reply with a connection reset segment as described above. These segments sometimes called TCP “*keepalive*” messages, or just “*keepalives*”. They are analogous to [BGP Keepalive messages](#).

The use of these messages is quite controversial, and therefore, not universal. Those who are opposed to them argue that they are not really necessary, and that sending them represents a waste of internetwork bandwidth and a possible additional cost on metered links (those that charge for each datagram sent.) Their key point is that if the connection is not presently being used, it doesn’t matter if it is still valid or not; as soon as the connection is used again, if it has broken in the mean time, TCP can handle that using the reset function mentioned above.

Worse, sending a “keepalive” can in theory cause a good TCP session to be unnecessarily broken. This may happen if the “keepalive” is sent during a time when there is an intermittent failure between the client and server, a failure that might otherwise have corrected itself by the time the next piece of “real” data must be sent. In addition, some TCP implementations may not properly deal with the receipt of these segments.

---

Those in favor of using “keepalives” point out that each TCP connection consumes a certain amount of resources, and this can be an issue especially for busy servers. If many clients connect to such a server and don’t terminate the TCP connection properly, the server may sit for a long time with an idle connection, using system memory and other resources that could be applied elsewhere.

Since there is no wide acceptance on the use of this feature, devices implementing it include a way to disable it if necessary. Devices are also programmed so they will not terminate a connection simply as a result of not receiving a response to a single “keepalive”. They may do so if they do not receive a reply after several such messages have been sent over a period of time.

## **TCP Connection Termination**

As the saying goes, “all good things must come to an end”... and so it is with TCP connections. The link between a pair of devices can remain open for a considerable period of time, assuming that a problem doesn't [force the connection to be aborted](#). Eventually, however, one or both of the processes in the connection will run out of data to send and will shut down the TCP session, or will be instructed by the user to do so.

### ***Requirements and Issues In Connection Termination***

Just as TCP follows [an ordered sequence of operations to establish a connection](#), it includes a specific procedure for terminating a connection. As with connection establishment, each of the devices moves from one state to the next to terminate the connection. This process is more complicated than one might imagine it needs to be. In fact, an examination of the [TCP finite state machine](#) shows that there are more distinct states involved in shutting down a connection than in setting one up.

The reason that connection termination is complex is that during normal operation, both of the devices are sending and receiving data simultaneously. Usually, connection termination begins with the process on just one device indicating to TCP that it wants to close the connection. The matching process on the other device may not be aware that its peer wants to end the connection at all. Several steps are required to ensure that the connection is shut down gracefully by both devices, and that no data is lost in the process.

Ultimately, shut down of a TCP connection requires that the application processes on both ends of the connection recognize that “the end is nigh” for the connection and stop sending data. For this reason, connection termination is implemented so that each device terminates its end of the connection separately. The act of closing the connection by one device means that device will no longer send data, but can continue to receive it until the other device has decided to stop sending. This allows all data that is pending to be sent by both sides of the communication to be flushed before the connection is ended.

---

## Normal Connection Termination

In the normal case, each side terminates its end of the connection by sending a special message with the *FIN* (*finish*) bit set. This message, sometimes called a *FIN*, serves as a connection termination request to the other device, while also possibly carrying data like a regular segment. The device receiving the *FIN* responds with an acknowledgment to the *FIN* to indicate that it was received. The connection as a whole is not considered terminated until both sides have finished the shut down procedure by sending a *FIN* and receiving an *ACK*.

Thus, termination isn't a three-way handshake like establishment: it is a pair of two-way handshakes. The states that the two devices in the connection move through during a normal connection shutdown are different because the device initiating the shutdown must behave differently than the one that receives the termination request. In particular, the TCP on the device receiving the initial termination request must inform its application process and wait for a signal that the process is ready to proceed. The initiating device doesn't need to do this, since the application is what started the ball rolling in the first place.

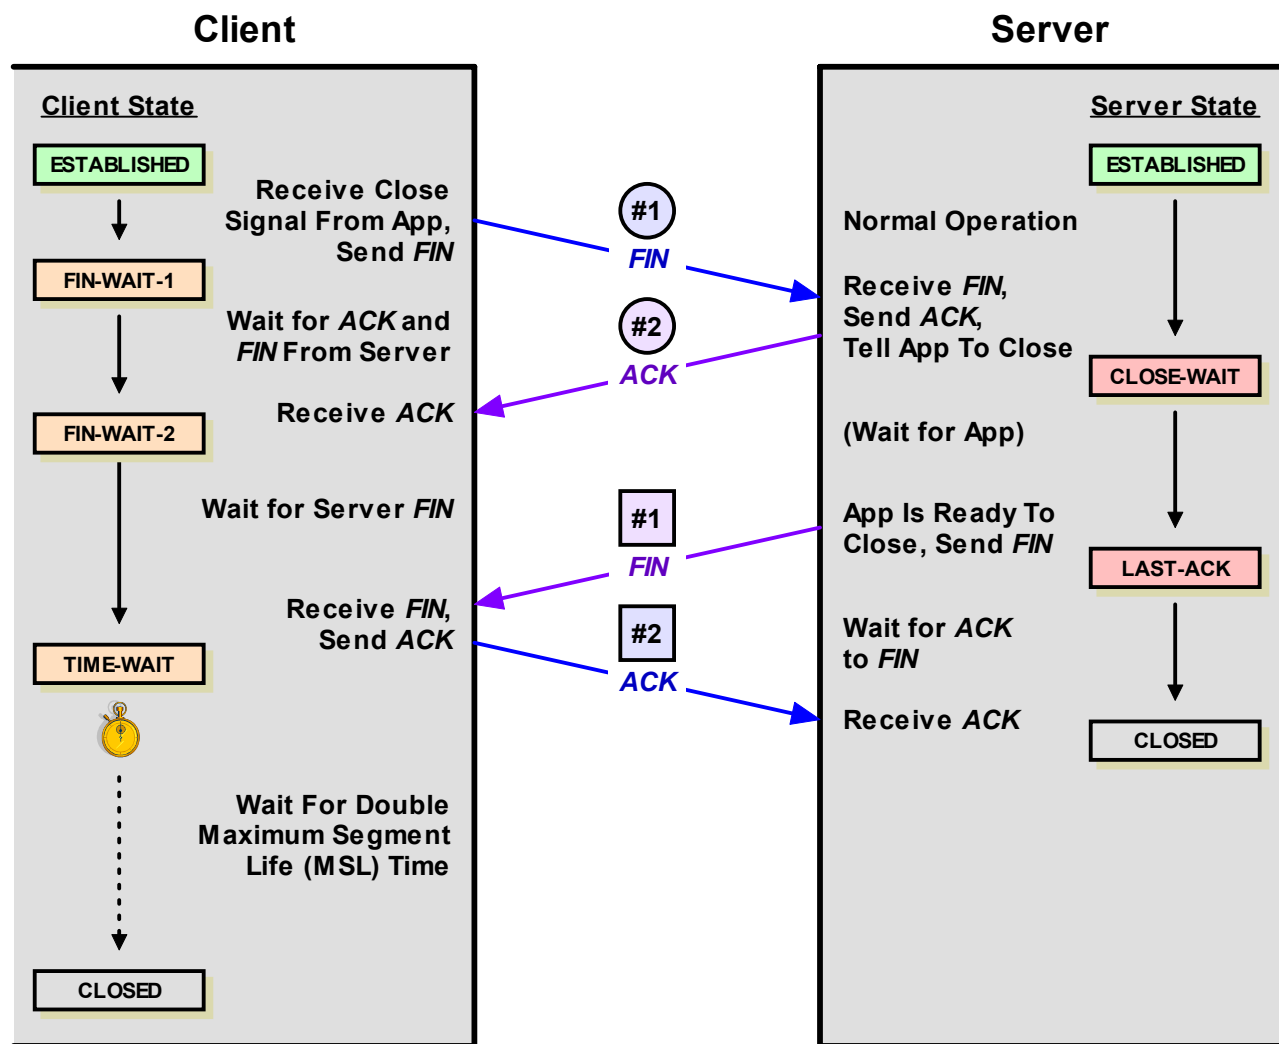

**Key Concept:** A TCP connection is normally terminating using a special procedure where each side independently closes its end of the link. It normally begins with one of the application processes signalling to its TCP layer that the session is no longer needed. That device sends a *FIN* message to tell the other device that it wants to end the connection, which is acknowledged. When the responding device is ready, it too sends a *FIN* that is acknowledged; after waiting a period of time for the *ACK* to be received, the session is closed.

---

[Table 155](#) describes in detail how the connection termination process works; the progression of states and messages exchanged can also be seen in [Figure 214](#). The table is adapted from [Table 152](#), describing the TCP finite state machine, but shows what happens for both the server and the client over time during connection shutdown. Either device can initiate connection termination; in this example I am assuming the client does it. Each row shows the state each device begins in, what action it takes in that state and what state to which it transitions. I have also shown the send and receive stages of both of the steps for each of the client and server's close operations.

**Table 155: TCP Connection Termination Procedure**

Client			Server		
Start State	Action	Transitions To State	Start State	Action	Transitions To State
<b>ESTABLISHED</b>	<b>Client Close Step #1</b> <b>Transmit:</b> The application using TCP signals that the connection is no longer needed. The client TCP sends a segment with the <i>FIN</i> bit set to request that the connection be closed.	<b>FIN-WAIT-1</b>	<b>ESTABLISHED</b>	At this stage the server is still in normal operating mode.	—
<b>FIN-WAIT-1</b>	The client, having sent a <i>FIN</i> , is waiting for it to both be acknowledged and for the server to send its own <i>FIN</i> . In this state the client can still receive data from the server but will no longer accept data from its local application to be sent to the server.	—	<b>ESTABLISHED</b>	<b>Client Close Step #1</b> <b>Receive and Step #2</b> <b>Transmit:</b> The server receives the client's <i>FIN</i> . It sends an <i>ACK</i> to acknowledge the <i>FIN</i> . The server must wait for the application using it to be told the other end is closing, so the application here can finish what it is doing.	<b>CLOSE-WAIT</b>
<b>FIN-WAIT-1</b>	<b>Client Close Step #2</b> <b>Receive:</b> The client receives the <i>ACK</i> for its <i>FIN</i> . It must now wait for the server to close.	<b>FIN-WAIT-2</b>	<b>CLOSE-WAIT</b>	The server waits for the application process on its end to signal that it is ready to close.	—
<b>FIN-WAIT-2</b>	The client is waiting for the server's <i>FIN</i> .	—	<b>CLOSE-WAIT</b>	<b>Server Close Step #1</b> <b>Transmit:</b> The server's TCP receives notice from the local application that it is done. The server sends its <i>FIN</i> to the client.	<b>LAST-ACK</b>
<b>FIN-WAIT-2</b>	<b>Server Close Step #1</b> <b>Receive and Step #2</b> <b>Transmit:</b> The client receives the server's <i>FIN</i> and sends back an <i>ACK</i> .	<b>TIME-WAIT</b>	<b>LAST-ACK</b>	The server is waiting for an <i>ACK</i> for the <i>FIN</i> it sent.	—
<b>TIME-WAIT</b>	The client waits for a period of time equal to double the maximum segment life (MSL) time, to ensure the <i>ACK</i> it sent was received.	—	<b>LAST-ACK</b>	<b>Server Close Step #2</b> <b>Receive:</b> The server receives the <i>ACK</i> to its <i>FIN</i> and closes the connection.	<b>CLOSED</b>
<b>TIME-WAIT</b>	The timer expires after double the MSL time.	<b>CLOSED</b>	<b>CLOSED</b>	The connection is closed on the server's end.	
<b>CLOSED</b>	The connection is closed.		<b>CLOSED</b>	The connection is closed.	

**Figure 214: TCP Connection Termination Procedure**

This diagram shows the conventional termination procedure for a TCP session, with one device initiating termination and the other responding. In this case the client initiates; it sends a *FIN* which is acknowledged by the server. The server waits for the server process to be ready to close and then sends its *FIN*, which is acknowledged by the client. The client waits for a period of time to ensure that its *ACK* is received, before proceeding to the *CLOSED* state.

### The *TIME-WAIT* State

The device receiving the initial *FIN* may have to wait a fairly long time (in networking terms) in the *CLOSE-WAIT* state for the application it is serving to indicate that it is ready to shut down. TCP cannot make any assumptions about how long this will take. During this period of time, the server in our example above may continue sending data, and the client will receive it. However, the client will not send data to the server.

---

Eventually, the second device (the server in our example) will send a *FIN* to close its end of the connection. The device that originally initiated the close (the client above) will send an *ACK* for this *FIN*. However, the client cannot immediately go to the *CLOSED* state right after sending that *ACK*. The reason is that it must allow time for the *ACK* to travel to the server. Normally this will be quick, but delays might result in it being slowed down somewhat.

The *TIME-WAIT* state is required for two main reasons. The first is to provide enough time to ensure that the *ACK* is received by the other device, and to retransmit it if it is lost. The second is to provide a “buffering period” between the end of this connection and any subsequent ones. If not for this period, it is possible that packets from different connections could be mixed, creating confusion.

The standard specifies that the client should wait double a particular length of time called the *maximum segment lifetime (MSL)* before finishing the close of the connection. The TCP standard defines MSL as being a value of 120 seconds (2 minutes). In modern networks this is an eternity, so TCP allows implementations to choose a lower value if it is believed that will lead to better operation.

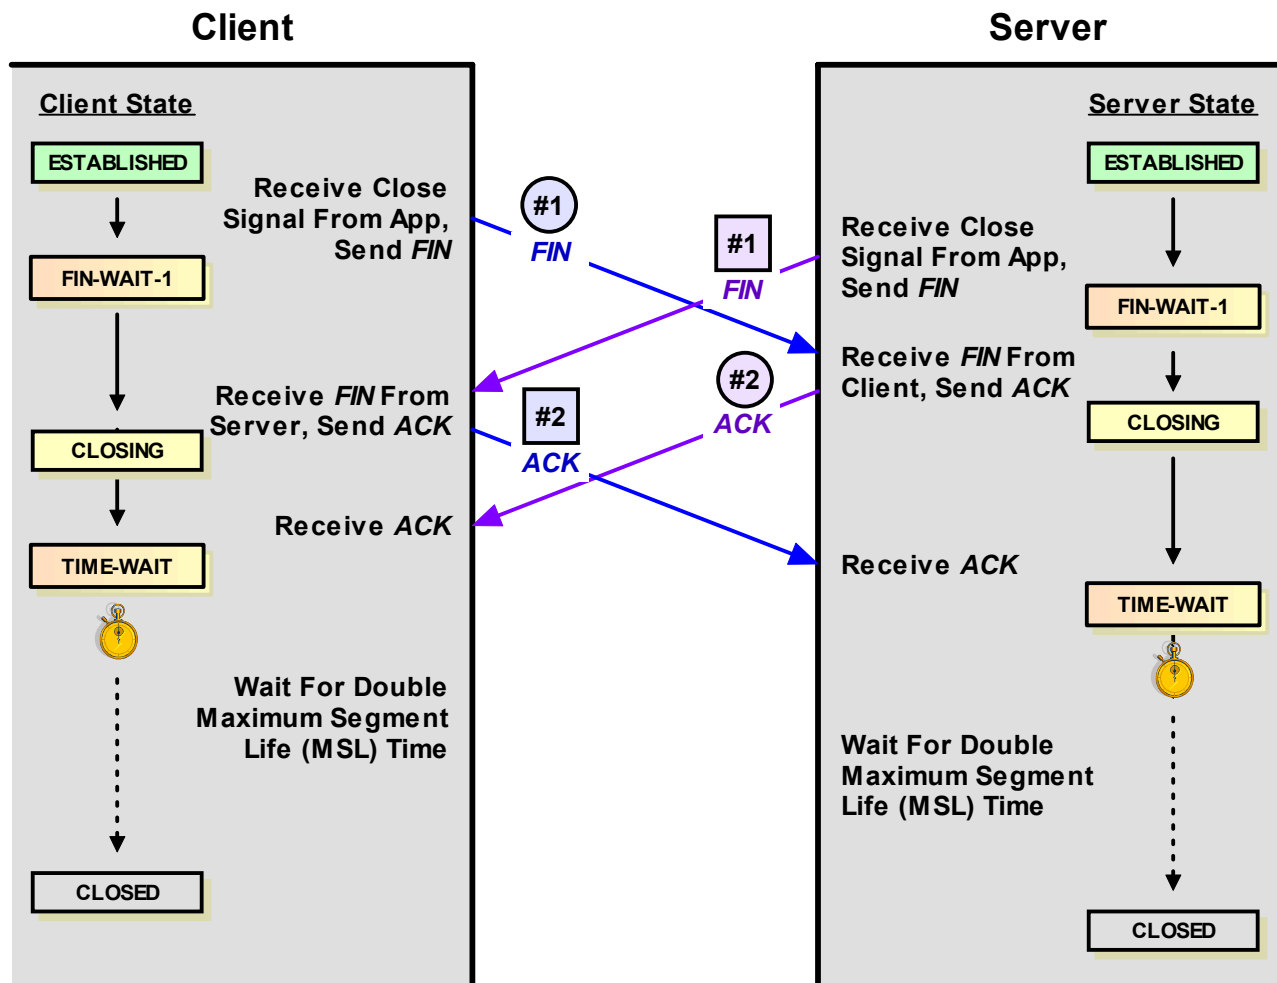

### ***Simultaneous Connection Termination***

Just as it is possible for the normal connection establishment process to be changed if two devices decide to actively *OPEN* a connection to each other, it is also possible for two devices to try to terminate a connection simultaneously. This term “simultaneously” doesn’t mean that they both decide to shut down at exactly the same time—variances in network delays mean nothing can be simultaneous on an internetwork anyway. It simply means that, in the example above, the client decides to shut down and sends a *FIN*, but the server sends its own *FIN* before the client’s *FIN* shows up at the server. In that case, a different procedure is followed, as described in [Table 156](#) and [Figure 215](#).

As you can see, the process is much more symmetric in this case, with both devices transitioning through the same states. In either case the end result is the same, with the connection in the *CLOSED* state—meaning no connection. Each TCP will make sure all outstanding data is sent to the application, sometimes referred to as an implied “push” ([see the description of the “push” function for an explanation of this term](#)). The transmission control blocks (TCBs) established for the connection in both devices are destroyed when the connection is closed down.

**Table 156: TCP Simultaneous Connection Termination Procedure**

Client			Server		
Start State	Action	Transitions To State	Start State	Action	Transitions To State
<b>ESTABLISHED</b>	<b>Client Close Step #1</b> <b>Transmit:</b> The application using TCP signals that the connection is no longer needed. The TCP on the client sends the next segment with the <i>FIN</i> bit set, indicating a request to close the connection.	<b>FIN-WAIT-1</b>	<b>ESTABLISHED</b>	<b>Server Close Step #1</b> <b>Transmit:</b> Before the server can receive the <i>FIN</i> sent by the client, the application on the server also signals a close. The server also sends a <i>FIN</i> .	<b>FIN-WAIT-1</b>
<b>FIN-WAIT-1</b>	<b>Server Close Step #1</b> <b>Receive and Step #2</b> <b>Transmit:</b> The client has sent a <i>FIN</i> and is waiting for it to be acknowledged. Instead, it receives the <i>FIN</i> sent by the server. It acknowledges the server's close request with an <i>ACK</i> and continues to wait for its own <i>ACK</i> .	<b>CLOSING</b>	<b>FIN-WAIT-1</b>	<b>Client Close Step #1</b> <b>Receive and Step #2</b> <b>Transmit:</b> The server has sent a <i>FIN</i> and is waiting for it to be acknowledged. Instead, it receives the <i>FIN</i> sent by the client. It acknowledges the client's close request with an <i>ACK</i> and continues to wait for its own <i>ACK</i> .	<b>CLOSING</b>
<b>CLOSING</b>	<b>Client Close Step #2</b> <b>Receive:</b> The client receives the <i>ACK</i> for its <i>FIN</i> .	<b>TIME-WAIT</b>	<b>CLOSING</b>	<b>Server Close Step #2</b> <b>Receive:</b> The server receives the <i>ACK</i> for its <i>FIN</i> .	<b>TIME-WAIT</b>
<b>TIME-WAIT</b>	The client waits for a period of time equal to double the maximum segment life (MSL) time. This gives enough time to ensure the <i>ACK</i> it sent to the server was received.	—	<b>TIME-WAIT</b>	The server waits for a period of time equal to double the maximum segment life (MSL) time. This gives enough time to ensure the <i>ACK</i> it sent to the client was received.	—
<b>TIME-WAIT</b>	The timer expires after double the MSL time.	<b>CLOSED</b>	<b>TIME-WAIT</b>	The timer expires after double the MSL time.	<b>CLOSED</b>
<b>CLOSED</b>	The connection is closed.	—	<b>CLOSED</b>	The connection is closed.	—

**Figure 215: TCP Simultaneous Connection Termination Procedure**

Under certain circumstances both devices may decide to terminate a connection simultaneously, or nearly simultaneously. In this case each sends a *FIN* and before getting an *ACK* for it, receives the other device's *FIN*. Each acknowledges the other's *FIN* and waits for a period of time before closing the connection. Note the transition through the **CLOSING** state, which is only used as part of simultaneous termination.

**Key Concept:** Just as two devices can simultaneously open a TCP session, they can terminate it simultaneously as well. In this case a different state sequence is followed, with each device responding to the other's *FIN* with an *ACK*, waiting for receipt of its own *ACK*, and pausing for a period of time to ensure that its *ACK* is received by the other device before ending the connection.

---

## **TCP Message Formatting and Data Transfer**

The [previous section](#) described how two devices using the Transmission Control Protocol establish a TCP connection, as well as how that connection is managed and eventually terminated. While connections are a key part of how TCP works, they are really a means to the ultimate end of the protocol: sending data. Employing the TCP sliding window mechanism, a special segment format and several features, TCP devices are able to package and send data over the connection, enabling applications to communicate.

In this section, I describe the actual mechanism by which TCP messages are formatted and data is transferred between devices. I begin with a look at the important TCP segment format, which describes the fields in each TCP message and how they are used. I provide a description of the method used to calculate the checksum in TCP (as well as UDP) messages, and the reason why a special “pseudo header” is used. I discuss the Maximum Segment Size (MSS) parameter and its significance. I then talk about exactly how the sliding window mechanism is used to transfer and acknowledge data. I conclude with a description of two special data transfer features: the “push” feature for immediate data transfer, and the “urgent” feature for priority data transfer.

**Background Information:** This section assumes that you are already familiar with TCP concepts such as sequence numbers, segments, and the basics of the TCP sliding window mechanism. If you are not, I'd strongly recommend reading [the TCP fundamentals section](#) before proceeding here.

---

### **TCP Message (Segment) Format**

In [the TCP fundamentals section](#), I described one of the most interesting jobs that TCP performs: it allows an application to send data as an unstructured sequence of bytes, transparently packaging that data in distinct messages as required by the underlying protocol that TCP uses (normally the Internet Protocol, of course). TCP messages are called *segments*, the name referring to the fact that each segment is a portion of the overall data stream passing between the devices.

#### ***Roles Performed by TCP Segments***

TCP segments are very much “jack of all trade” messages—they are flexible and serve a variety of purposes. A single field format is used for all segments, with a number of header fields that implement the many functions and features for which TCP is responsible. One of the most notable characteristics of TCP segments is that they are designed to carry both control information and data simultaneously. This reduces the number of segments sent, since they can perform more than one function.

For example, there is no need to send separate acknowledgments in TCP because each TCP message includes a field for an acknowledgment byte number. Similarly, one can request that a connection be closed while sending data in the same message. The nature of

---

each TCP segment is indicated through the use of several special control bits. More than one bit can be sent to allow a segment to perform multiple functions, such as when a bit is used to specify an initial sequence number and acknowledge receipt of another such segment at the same time.

### **TCP Header Field Functions**

The price we pay for this flexibility is that the TCP header is large: 20 bytes for regular segments and more for those carrying options. This is one of the reasons why some protocols prefer to use UDP if they don't need TCP's features. The TCP header fields are used for the following general purposes:

- ☉ **Process Addressing:** The processes on the source and destination devices are identified using port numbers.
- ☉ **Sliding Window System Implementation:** Sequence numbers, acknowledgment numbers and window size fields implement the [TCP sliding window system](#).
- ☉ **Control Bits and Fields:** Special bits that implement various control functions, and fields that carry pointers and other data needed for them.
- ☉ **Carrying Data:** The *Data* field carries the actual bytes of data being sent between devices.
- ☉ **Miscellaneous Functions:** A checksum for data protection and options for connection setup.

### **TCP Segment Format**

The format for TCP messages (segments) is described fully in [Table 157](#) and [Figure 216](#).

**Table 157: TCP Segment Format (Page 1 of 3)**

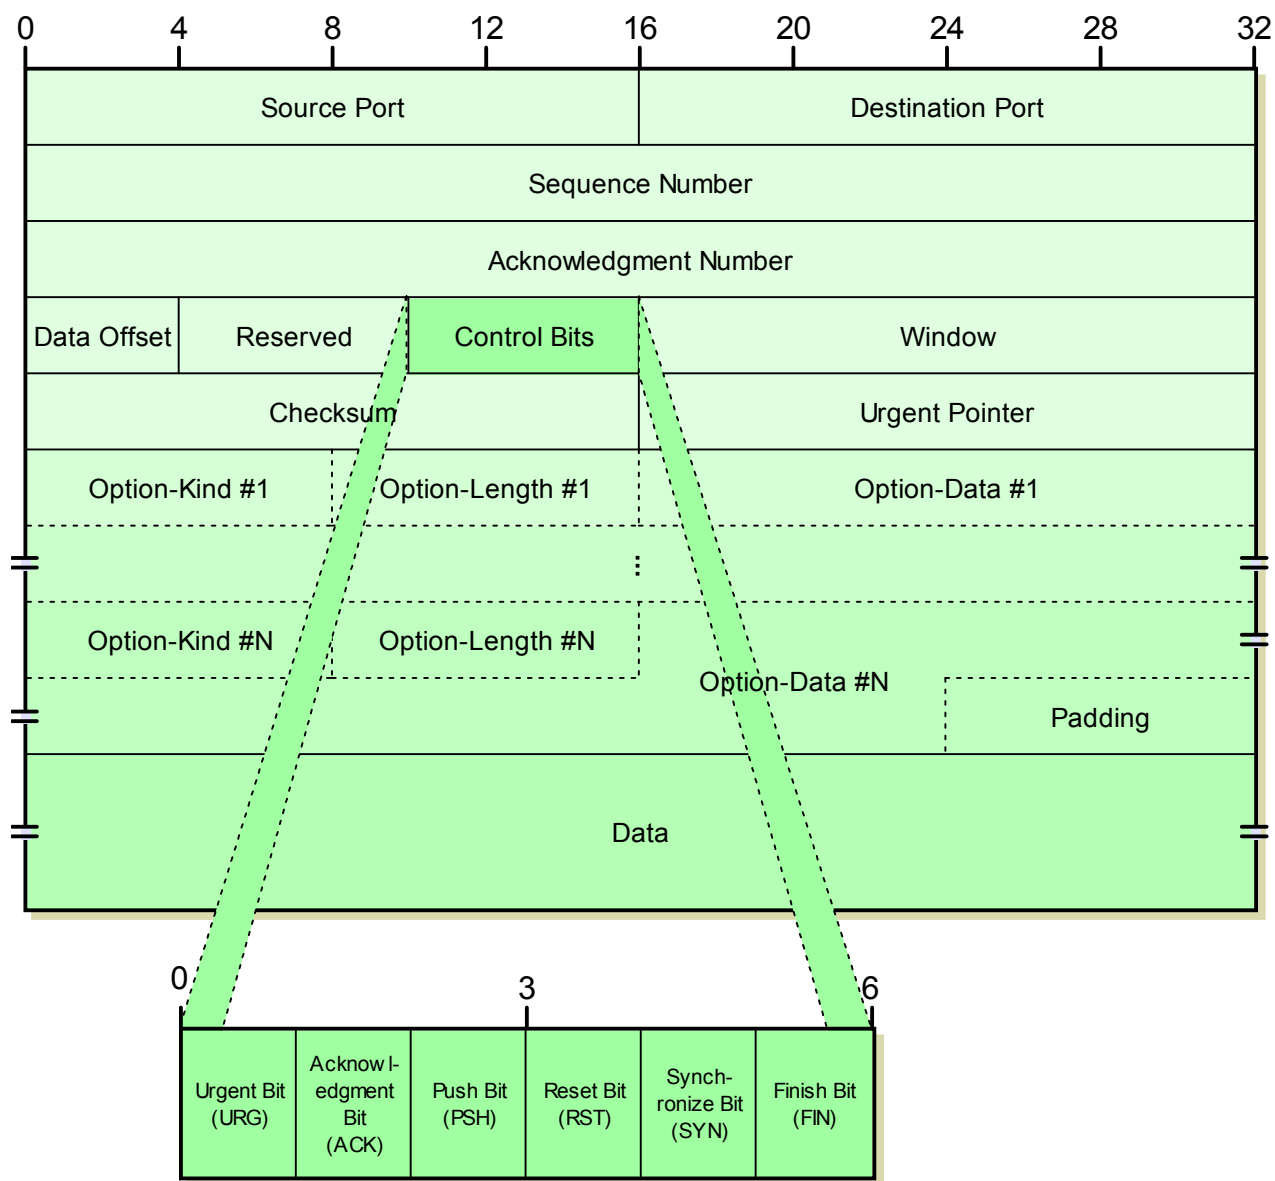

Field Name	Size (bytes)	Description
<b>Source Port</b>	2	<b>Source Port:</b> The 16-bit port number of the process that originated the TCP segment on the source device. This will normally be an <a href="#">ephemeral (client) port number</a> for a request sent by a client to a server, or a <a href="#">well-known/registered (server) port number</a> for a reply from a server to a client.
<b>Destination Port</b>	2	<b>Destination Port:</b> The 16-bit port number of the process that is the ultimate intended recipient of the message on the destination device. This will usually be a <a href="#">well-known/registered (server) port number</a> for a client request, or an <a href="#">ephemeral (client) port number</a> for a server reply.
<b>Sequence Number</b>	4	<b>Sequence Number:</b> For normal transmissions, the sequence number of the first byte of data in this segment. In a connection request (SYN) message, this carries the initial sequence number (ISN) of the source TCP. The first byte of data will be given the next sequence number after the contents of this field, as described in <a href="#">the topic on sequence number synchronization</a> .

Table 157: TCP Segment Format (Page 2 of 3)

Field Name	Size (bytes)	Description																					
<b>Acknowledgment Number</b>	4	<b>Acknowledgment Number:</b> When the <i>ACK</i> bit is set, this segment is serving as an acknowledgment (in addition to other possible duties) and this field contains the sequence number the source is next expecting the destination to send. <a href="#">See the topic describing TCP data transfer for details.</a>																					
<b>Data Offset</b>	1/2 (4 bits)	<b>Data Offset:</b> Specifies the number of 32-bit words of data in the TCP header. In other words, this value times four equals the number of bytes in the header, which must always be a multiple of four. It is called a “data offset” since it indicates by how many 32-bit words the start of the data is offset from the beginning of the TCP segment.																					
<b>Reserved</b>	3/4 (6 bits)	<b>Reserved:</b> 6 bits reserved for future use; sent as zero.																					
<b>Control Bits</b>	3/4 (6 bits)	<p><b>Control Bits:</b> As mentioned, TCP does not use a separate format for control messages. Instead, certain bits are set to indicate the communication of control information. The six bits are:</p> <table> <tr> <th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr> <tr> <td><b>URG</b></td><td>1/8 (1 bit)</td><td><b>Urgent Bit:</b> When set to 1, indicates that the <a href="#">priority data transfer feature</a> has been invoked for this segment, and that the <i>Urgent Pointer</i> field is valid.</td></tr> <tr> <td><b>ACK</b></td><td>1/8 (1 bit)</td><td><b>Acknowledgment Bit:</b> When set to 1, indicates that this segment is carrying an acknowledgment, and the value of the <i>Acknowledgment Number</i> field is valid and carrying the next sequence expected from the destination of this segment.</td></tr> <tr> <td><b>PSH</b></td><td>1/8 (1 bit)</td><td><b>Push Bit:</b> The sender of this segment is using the <a href="#">TCP push feature</a>, requesting that the data in this segment be immediately pushed to the application on the receiving device.</td></tr> <tr> <td><b>RST</b></td><td>1/8 (1 bit)</td><td><b>Reset Bit:</b> The sender has encountered a problem and wants to <a href="#">reset the connection</a>.</td></tr> <tr> <td><b>SYN</b></td><td>1/8 (1 bit)</td><td><b>Synchronize Bit:</b> This segment is a request to <a href="#">synchronize sequence numbers</a> and <a href="#">establish a connection</a>; the <i>Sequence Number</i> field contains the initial sequence number (ISN) of the sender of the segment.</td></tr> <tr> <td><b>FIN</b></td><td>1/8 (1 bit)</td><td><b>Finish Bit:</b> The sender of the segment is <a href="#">requesting that the connection be closed</a>.</td></tr> </table>	Subfield Name	Size (bytes)	Description	<b>URG</b>	1/8 (1 bit)	<b>Urgent Bit:</b> When set to 1, indicates that the <a href="#">priority data transfer feature</a> has been invoked for this segment, and that the <i>Urgent Pointer</i> field is valid.	<b>ACK</b>	1/8 (1 bit)	<b>Acknowledgment Bit:</b> When set to 1, indicates that this segment is carrying an acknowledgment, and the value of the <i>Acknowledgment Number</i> field is valid and carrying the next sequence expected from the destination of this segment.	<b>PSH</b>	1/8 (1 bit)	<b>Push Bit:</b> The sender of this segment is using the <a href="#">TCP push feature</a> , requesting that the data in this segment be immediately pushed to the application on the receiving device.	<b>RST</b>	1/8 (1 bit)	<b>Reset Bit:</b> The sender has encountered a problem and wants to <a href="#">reset the connection</a> .	<b>SYN</b>	1/8 (1 bit)	<b>Synchronize Bit:</b> This segment is a request to <a href="#">synchronize sequence numbers</a> and <a href="#">establish a connection</a> ; the <i>Sequence Number</i> field contains the initial sequence number (ISN) of the sender of the segment.	<b>FIN</b>	1/8 (1 bit)	<b>Finish Bit:</b> The sender of the segment is <a href="#">requesting that the connection be closed</a> .
Subfield Name	Size (bytes)	Description																					
<b>URG</b>	1/8 (1 bit)	<b>Urgent Bit:</b> When set to 1, indicates that the <a href="#">priority data transfer feature</a> has been invoked for this segment, and that the <i>Urgent Pointer</i> field is valid.																					
<b>ACK</b>	1/8 (1 bit)	<b>Acknowledgment Bit:</b> When set to 1, indicates that this segment is carrying an acknowledgment, and the value of the <i>Acknowledgment Number</i> field is valid and carrying the next sequence expected from the destination of this segment.																					
<b>PSH</b>	1/8 (1 bit)	<b>Push Bit:</b> The sender of this segment is using the <a href="#">TCP push feature</a> , requesting that the data in this segment be immediately pushed to the application on the receiving device.																					
<b>RST</b>	1/8 (1 bit)	<b>Reset Bit:</b> The sender has encountered a problem and wants to <a href="#">reset the connection</a> .																					
<b>SYN</b>	1/8 (1 bit)	<b>Synchronize Bit:</b> This segment is a request to <a href="#">synchronize sequence numbers</a> and <a href="#">establish a connection</a> ; the <i>Sequence Number</i> field contains the initial sequence number (ISN) of the sender of the segment.																					
<b>FIN</b>	1/8 (1 bit)	<b>Finish Bit:</b> The sender of the segment is <a href="#">requesting that the connection be closed</a> .																					
<b>Window</b>	2	<b>Window:</b> Indicates the number of octets of data the sender of this segment is willing to accept from the receiver at one time. This normally corresponds to the current size of the buffer allocated to accept data for this connection. This field is, in other words, the current receive window size for the device sending this segment, which is also the send window for the recipient of the segment. <a href="#">See the data transfer mechanics topic for details.</a>																					

**Table 157: TCP Segment Format (Page 3 of 3)**

Field Name	Size (bytes)	Description												
<b>Checksum</b>	2	<b>Checksum:</b> A 16-bit checksum for data integrity protection, computed over the entire TCP datagram plus a special “pseudo header” of fields. It is used to protect the entire TCP segment against not just errors in transmission, but also errors in delivery. Optional alternate checksum methods are also supported.												
<b>Urgent Pointer</b>	2	<b>Urgent Pointer:</b> Used in conjunction with the <i>URG</i> control bit for priority data transfer. This field contains the sequence number of the last byte of urgent data. <a href="#">See the priority data transfer topic for details.</a>												
<b>Options</b>	Variable	<p><b>Options:</b> TCP includes a generic mechanism for including one or more sets of optional data in a TCP segment. Each of the options can be either one byte in length or variable in length. The first byte is the <i>Option-Kind</i> subfield, and its value specifies the type of option, which in turn indicates whether the option is just a single byte or multiple bytes. Options that are many bytes consist of three fields:</p> <table> <tr> <th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr> <tr> <td><b>Option-Kind</b></td><td>1</td><td><b>Option-Kind:</b> Specifies the option type.</td></tr> <tr> <td><b>Option-Length</b></td><td>1</td><td><b>Option-Length:</b> The length of the entire option in bytes, including the <i>Option-Kind</i> and <i>Option-Length</i> fields.</td></tr> <tr> <td><b>Option-Data</b></td><td>Variable</td><td><b>Option-Data:</b> The option data itself. In at least one oddball case, this field is omitted (making <i>Option-Length</i> equal to 2).</td></tr> </table>	Subfield Name	Size (bytes)	Description	<b>Option-Kind</b>	1	<b>Option-Kind:</b> Specifies the option type.	<b>Option-Length</b>	1	<b>Option-Length:</b> The length of the entire option in bytes, including the <i>Option-Kind</i> and <i>Option-Length</i> fields.	<b>Option-Data</b>	Variable	<b>Option-Data:</b> The option data itself. In at least one oddball case, this field is omitted (making <i>Option-Length</i> equal to 2).
Subfield Name	Size (bytes)	Description												
<b>Option-Kind</b>	1	<b>Option-Kind:</b> Specifies the option type.												
<b>Option-Length</b>	1	<b>Option-Length:</b> The length of the entire option in bytes, including the <i>Option-Kind</i> and <i>Option-Length</i> fields.												
<b>Option-Data</b>	Variable	<b>Option-Data:</b> The option data itself. In at least one oddball case, this field is omitted (making <i>Option-Length</i> equal to 2).												
<b>Padding</b>	Variable	<b>Padding:</b> If the <i>Options</i> field is not a multiple of 32 bits in length, enough zeroes are added to pad the header so it is a multiple of 32 bits.												
<b>Data</b>	Variable	<b>Data:</b> The bytes of data being sent in the segment.												

**Figure 216: TCP Segment Format**

## TCP Options and Option Field Values

Table 158 shows the main options currently defined for TCP.

Table 158: TCP Options

Option-Kind	Option-Length	Option-Data	Description
0	—	—	<b>End Of Option List:</b> A single byte option that marks the end of all options included in this segment. This only needs to be included when the end of the options doesn't coincide with the end of the TCP header.
1	—	—	<b>No-Operation:</b> A “spacer” that can be included between options to align a subsequent option on a 32-bit boundary if needed.
2	4	Maximum Segment Size Value	<b>Maximum Segment Size:</b> Conveys the size of the largest segment the sender of the segment wishes to receive. Used only in connection request (SYN) messages.
3	3	Window Size Shift Bits	<b>Window Scale:</b> Implements the optional window scale feature, which allows devices to specify much larger window sizes than would be possible with the normal <i>Window</i> field. The value in <i>Option-Data</i> specifies the power of two that the <i>Window</i> field should be multiplied by to get the true window size the sender of the option is using. For example, if the value of <i>Option-Data</i> is 3, this means values in the <i>Window</i> field should be multiplied by 8, assuming both devices agree to use this feature. This allows very large windows to be advertised when needed on high-performance links. See the topic on data transfer for more.
4	2	—	<b>Selective Acknowledgment Permitted:</b> Specifies that this device supports the selective acknowledgment (SACK) feature. This was implemented as a two-byte option with no <i>Option-Data</i> field, instead of a single-byte option like <i>End Of Option List</i> or <i>No-Operation</i> . This was necessary because it was defined after the original TCP specification, so an explicit option length had to be indicated for backwards compatibility.
5	Variable	Blocks Of Data Selectively Acknowledged	<b>Selective Acknowledgment:</b> Allows devices supporting the optional selective acknowledgment feature to specify non-contiguous blocks of data that have been received so they are not retransmitted if intervening segments do not show up and need to be retransmitted.
14	3	Alternate Checksum Algorithm	<b>Alternate Checksum Request:</b> Lets a device request that a checksum generation algorithm other than the standard TCP algorithm be used for this connection. Both devices must agree to the algorithm for it to be used.
15	Variable	Alternate Checksum	<b>Alternate Checksum:</b> If the checksum value needed to implement an alternate checksum is too large to fit in the standard 16-bit Checksum field, it is placed in this option.

I have not shown every TCP option in Table 158, just the basic ones defined in RFC 793 and a few others that are interesting and correspond to features described elsewhere in the Guide. Note that most options are sent only in connection request (SYN) segments. This

---

includes the *Maximum Segment Size*, *Window Scale*, *Selective Acknowledgement Permitted* and *Alternate Checksum Request* options above. In contrast, *Selective Acknowledgment* and *Alternate Checksum* options appear in regular data segments, when used.

## **TCP Checksum Calculation and the TCP "Pseudo Header"**

The Transmission Control Protocol is designed to provide reliable data transfer between a pair of devices on an IP internetwork. Much of the effort required to ensure reliable delivery of data segments is of necessity focused on the problem of ensuring that data is not lost in transit. But there's another important critical impediment to the safe transmission of data: the risk of *errors* being introduced into a TCP segment during its travel across the internetwork.

### ***Detecting Transmission Errors Using Checksums***

If the data gets where it needs to go but is corrupted and we do not detect the corruption, this is in some ways worse than it never showing up at all. To provide basic protection against errors in transmission, TCP includes a 16-bit *Checksum* field in its header. The idea behind a checksum is very straight-forward: take a string of data bytes and add them all together. Then send this sum with the data stream and have the receiver check the sum. In TCP, a special algorithm is used to calculate this checksum by the device sending the segment; the same algorithm is then employed by the recipient to check the data it received and ensure that there were no errors.

The checksum calculation used by TCP is a bit different than a regular checksum algorithm. A conventional checksum is performed over all the bytes that the checksum is intended to protect, and can detect most bit errors in any of those fields. The designers of TCP wanted this bit error protection, but also desired to protect against other type of problems.

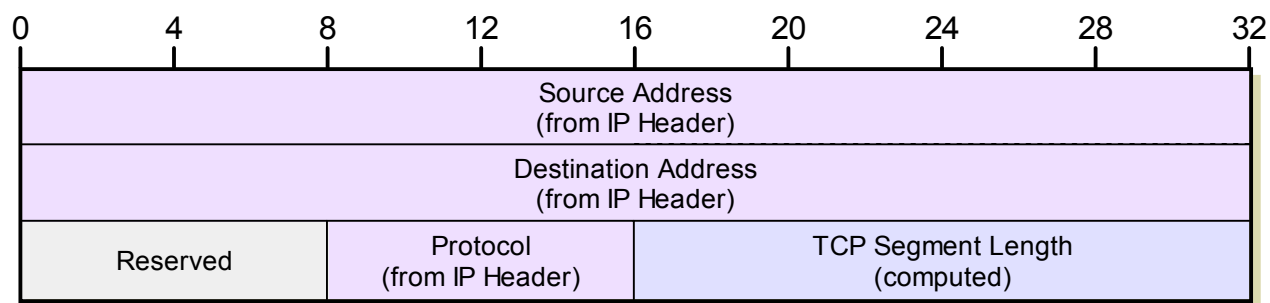

### ***Increasing The Scope of Detected Errors: the TCP Pseudo Header***

To this end, a change was made in how the TCP checksum is computed. This special TCP checksum algorithm was eventually also [adopted for use by the User Datagram Protocol \(UDP\)](#).

Instead of computing the checksum over only the actual data fields of the TCP segment, a 12-byte TCP *pseudo header* is created prior to checksum calculation. This header contains important information taken from fields in both the TCP header and the IP datagram into which the TCP segment will be encapsulated. The TCP pseudo header has the format shown in Table 159 and Figure 217.

**Table 159: TCP “Pseudo Header” For Checksum Calculation**

Field Name	Size (bytes)	Description
<b>Source Address</b>	4	<b>Source Address:</b> The 32-bit IP address of the originator of the datagram, taken from the IP header.
<b>Destination Address</b>	4	<b>Destination Address:</b> The 32-bit IP address of the intended recipient of the datagram, also from the IP header.
<b>Reserved</b>	1	<b>Reserved:</b> 8 bits of zeroes.
<b>Protocol</b>	1	<b>Protocol:</b> The <i>Protocol</i> field from the IP header. This indicates what higher-layer protocol is carried in the IP datagram. Of course, we already know what this protocol is, it's TCP! So, this field will normally have the value 6.
<b>TCP Length</b>	2	<b>TCP Length:</b> The length of the TCP segment, including both header and data. Note that this is not a specific field in the TCP header; it is computed.

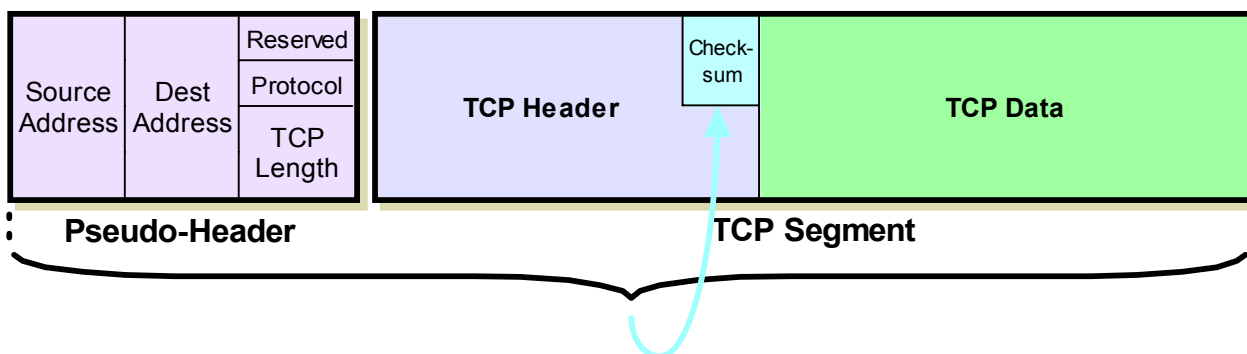

**Figure 217: TCP “Pseudo Header” For Checksum Calculation**

Once this 96-bit header has been formed, it is placed in a buffer, following which the TCP segment itself is placed. Then, the checksum is computed over the entire set of data (pseudo header plus TCP segment). The value of the checksum is placed into the *Checksum* field of the TCP header, and the pseudo header is discarded—it is **not** an actual part of the TCP segment and is not transmitted. This process is illustrated in Figure 218.

**Note:** The *Checksum* field is itself part of the TCP header and thus one of the fields over which the checksum is calculated, creating a “chicken and egg” situation of sorts. This field is assumed to be all zeroes during calculation of the checksum.

### Checksum Calculated Over Pseudo Header and TCP Segment

**Figure 218: TCP Header Checksum Calculation**

To calculate the TCP segment header's Checksum field, the TCP pseudo header is first constructed and placed, logically, before the TCP segment. The checksum is then calculated over both the pseudo header and the TCP segment. The pseudo header is then discarded.

When the TCP segment arrives at its destination, the receiving TCP software performs the same calculation. It forms the pseudo header, prepends it to the actual TCP segment, and then performs the checksum (setting the *Checksum* field to zero for the calculation as before). If there is a mismatch between its calculation and the value the source device put in the *Checksum* field, this indicates that an error of some sort occurred and the segment is normally discarded.

### Advantages of the Pseudo Header Method

So, why bother with this “pseudo header”? The source and destination devices both compute the checksum using the fields in this pseudo header. This means that if, for any reason, the two devices don't use the same values for the pseudo header, the checksum will fail. Now, when we consider what's in the header, we find that this means the checksum now protects against not just errors in the TCP segment fields but also against:

- ☉ **Incorrect Segment Delivery:** If there is a mismatch in the *Destination Address* between what the source specified and what the destination that got the segment used, the checksum will fail. The same will happen if the *Source Address* does not match.
- ☉ **Incorrect Protocol:** If a datagram is routed to TCP that actually belongs to a different protocol for whatever reason, this can be immediately detected.
- ☉ **Incorrect Segment Length:** If part of the TCP segment has been omitted by accident, the lengths the source and destination used won't match and the checksum will fail.

What's clever about the pseudo header is that by using it for the checksum calculation, we can provide this protection without actually needing to send the fields in the pseudo header itself. This eliminates duplicating the IP fields used in the pseudo header within the TCP header, which would be redundant and wasteful of bandwidth. The drawback of the pseudo header method is that it makes checksum calculation take more time and effort (though this is not much of an issue today.)

---

In the context of today's modern, high-speed, highly-reliable networks, the use of the pseudo header sometimes seems “archaic”. How likely is it that a datagram will be delivered to the wrong address? Not very. At the time TCP was created, however, there was significant concern that there might not be proper “end-to-end” checking of the delivery of datagrams at the IP level. Including IP information in the TCP checksum was seen as a useful additional level of protection.

Of course, there is one interesting implication of the TCP pseudo header: it violates the architectural layering principles that the designers of TCP sought to respect in splitting TCP and IP up. For the checksum, TCP must know IP information that technically it “shouldn't”. TCP checksum calculation requires, for example, that the protocol number from the IP header be given to the TCP layer on the receiving device from the IP datagram that carried the segment. The TCP pseudo header is a good example of a case where strict layering was eschewed in favor of practicality.

Finally, TCP also supports an optional method of having two devices agree on an alternative checksum algorithm. This must be negotiated during connection establishment.

**Key Concept:** TCP checksums are computed over not just the TCP segment but also over a TCP *pseudo header* that contains the length of the TCP segment as well as the IP *Source Address*, *Destination Address* and *Protocol* fields. Since these fields are part of the checksum, if the segment is received by the wrong device, or has the incorrect *Protocol* field or segment length, it will be rejected. The technique is clever because the checksum can provide this protection even though the pseudo header itself is not actually transmitted.

---

## TCP Maximum Segment Size (MSS) and Relationship to IP Datagram Size

TCP *segments* are the messages that carry data between TCP devices. The *Data* field is where the actual data being transmitted is carried, and since the length of the *Data* field in TCP is variable, this raises an interesting question: how much data should we put into each segment? With protocols that accept data in blocks from the higher layers there isn't as much of a question, but TCP accepts data as a constant stream from the applications that use it. This means it must decide how many bytes to put into each message that it sends.

A primary determinant of how much data to send in a segment is the current status of the [sliding window mechanism](#) on the part of the receiver. When Device A receives a TCP segment from Device B, it examines value of the *Window* field to know the limit on how much data Device B is allowing Device A to send in its next segment. There are also important issues in the selection and adjustment of window size that impact the operation of the TCP system as a whole, which are discussed in [the reliability section](#).

In addition to the dictates of the current window size, each TCP device also has associated with it a *ceiling* on TCP size—a segment size that will never be exceeded regardless of how large the current window is. This is called the *maximum segment size (MSS)*. When

---

deciding how much data to put into a segment, each device in the TCP connection will choose the amount based on the current window size, in conjunction with the various algorithms described in the reliability section, but it will never be so large that the amount of data exceeds the MSS of the device to which it is sending.

**Note:** I need to point out that the name “maximum segment size” is in fact misleading. The value actually refers to the maximum amount of **data** that a segment can hold—it does not include the TCP headers. So if the MSS is 100, the actual maximum segment size could be 120 (for a regular TCP header) or larger (if the segment includes TCP options).

---

### **Maximum Segment Size Selection**

The selection of the MSS is based on the need to balance various competing performance and implementation issues in the transmission of data on TCP/IP networks. The main TCP standard, RFC 793, doesn't discuss MSS very much, which opened the potential for confusion on how the parameter should be used. RFC 879 was published a couple of years after the TCP standard to clarify this parameter and the issues surrounding it. Some issues with MSS are fairly mundane; for example, certain devices are limited in the amount of space they have for buffers to hold TCP segments, and therefore may wish to limit segment size to a relatively small value. In general, though, the MSS must be chosen by balancing two competing performance issues:

- 🕒 **Overhead Management:** The TCP header takes up 20 bytes of data (or more if options are used); the IP header also uses 20 or more bytes. This means that between them a minimum of 40 bytes are needed for headers, all of which is non-data “overhead”. If we set the MSS too low, this results in very inefficient use of bandwidth. For example, suppose we set it to 40; if we did, a **maximum** of 50% of each segment could actually be data; the rest would just be headers. Many segment datagrams would be even worse in terms of efficiency.
- 🕒 **IP Fragmentation:** TCP segments will be packaged into IP datagrams. As we saw in the section on IP, datagrams have their own size limit issues: the matter of [the maximum transmission unit \(MTU\) of an underlying network](#). If a TCP segment is too large, it will lead to an IP datagram is too large to be sent without fragmentation. Fragmentation reduces efficiency and increases the chances of part of a TCP segment being lost, resulting in the entire segment needing to be retransmitted.

### **TCP Default Maximum Segment Size**

The solution to these two competing issues was to establish a default MSS for TCP that was as large as possible while avoiding fragmentation for most transmitted segments. This was computed by starting with the minimum MTU for IP networks of 576. All networks are required to be able to handle an IP datagram of this size without fragmenting. From this number, we subtract 20 bytes for the TCP header and 20 for the IP header, leaving 536 bytes. This is the standard MSS for TCP.

---

The selection of this value was a compromise of sorts. When this number is used, it means that **most** TCP segments will be sent unfragmented across an IP internetwork. However, if any TCP or IP options are used, this will cause the minimum MTU of 576 to be exceeded and fragmentation to happen. Still, it makes more sense to allow some segments to be fragmented rather than use a much smaller MSS to ensure that none are ever fragmented. If we chose, say, an MSS of 400, we would probably never have fragmentation, but we'd lower the data/header ratio from 536:40 (93% data) to 400:40 (91% data) for **all** segments.

**Key Concept:** TCP is designed to restrict the size of the segments it sends to a certain maximum limit, to cut down on the likelihood that segments will need to be fragmented for transmission at the IP level. The TCP *maximum segment size (MSS)* specifies the maximum number of bytes in the TCP segment's *Data* field, regardless of any other factors that influence segment size. The default MSS for TCP is 536, which results from taking the minimum IP MTU of 576 and subtracting 20 bytes each for the IP and TCP headers.

---

### **Specifying a Non-Default MSS Value**

Naturally, there are likely to be cases where the default MSS is non-ideal, so TCP provides a means for a device to specify that the MSS it wants to use is either smaller or larger than the default value of 536. [A device can inform the other of the MSS it wants to use](#) during the connection establishment process. A device that chooses to do so includes in its SYN message the TCP option called, appropriately, *Maximum Segment Size*. The other device receives this option and records the MSS for the connection. Each device can specify the MSS it wants for the segments it receives independently.

**Note:** The exchange of MSS values during setup is sometimes called *MSS negotiation*. This is actually a misleading term, because it implies that the two devices must agree on a common MSS value, which is not the case. The MSS value used by each may be different, and there is in fact no negotiation at all.

Devices may wish to use a larger MSS if they know for a fact that the MTUs of the networks the segments will pass over are larger than the IP minimum of 576. This is most commonly the case when large amounts of data are sent on a local network; the process of [path MTU discovery](#) is used to determine the appropriate MSS. A smaller MSS might be advisable if it were known that a particular optional feature was in place that would consistently increase the size of the IP header. Employing [IPSec](#) for security would be a good example. The size of the largest

**Key Concept:** Devices can indicate that they wish to use a different MSS value from the default by including a *©Maximum Segment Size* option in the SYN message they use to establish a connection. Each device in the connection may use a different MSS value.

---

## **TCP Sliding Window Data Transfer and Acknowledgement Mechanics**

The [TCP connection establishment process](#) is employed by a pair of devices to create a TCP connection between them. Once all the setup is done, [transmission control blocks \(TCBs\) set up, parameters have been exchanged](#) and so forth, the devices are ready to get down to business: transferring data.

The sending of data between TCP devices on a connection is accomplished using [the sliding window system we explored in the fundamentals section](#). It's now time to take a more detailed look at exactly how sliding windows are implemented to allow data to be sent and received. For ease of explanation, we'll assume that our connection is between a client and a server—this is easier than the whole “Device A / Device B” thing.

### ***Sliding Window Transmit Categories***

Each of the two devices on a connection must keep track of the data it is sending, as well as the data it is receiving from the other device. This is done by conceptually dividing the bytes into the *categories* we saw in the sliding windows overview. For data being transmitted, there are four transmit categories:

1. **Transmit Category #1:** Bytes Sent And Acknowledged
2. **Transmit Category #2:** Bytes Sent But Not Yet Acknowledged
3. **Transmit Category #3:** Bytes Not Yet Sent For Which Recipient Is Ready
4. **Transmit Category #4:** Bytes Not Yet Sent For Which Recipient Is Not Ready

### ***Sliding Window Receive Categories***

For data being received, there is no need to separate into “received and acknowledged” and “received and unacknowledged” the way the transmitter separates its first two categories into “sent and acknowledged” and “sent but not yet acknowledged. The reason, of course, is that the transmitter must wait for acknowledgment of each transmission, while the receiver doesn't need “acknowledgment” that it received something.

Thus, one receive category corresponds to Transmit Categories #1 and #2, while the other two correspond to Transmit Category #3 and Transmit Category #4 respectively, making three receive categories overall. To help make more clear how the categories relate, I am numbering them as follows:

- ☉ **Receive Category #1+2:** Bytes Received And Acknowledged. This is the receiver's complement to Transmit Categories #1 and #2.

- 
- ☉ **Receive Category #3:** Bytes Not Yet Received For Which Recipient Is Ready. This is the receiver's complement to Transmit Category #3.
  - ☉ **Receive Category #4:** Bytes Not Yet Received For Which Recipient Is Not Ready. This is the receiver's complement to Transmit Category #4.

### ***Send (SND) Pointers***

Both the client and server in the connection must keep track of the stream it is transmitting and the one it is receiving from the other device. This is done using a set of special variables called *pointers*, that carve the byte stream into the categories above. The four transmit categories are divided using three pointers. Two of the pointers are absolute (refer to a specific sequence number) while one is an offset that is added to one of the absolute pointers, as follows (refer to [Figure 219](#)):

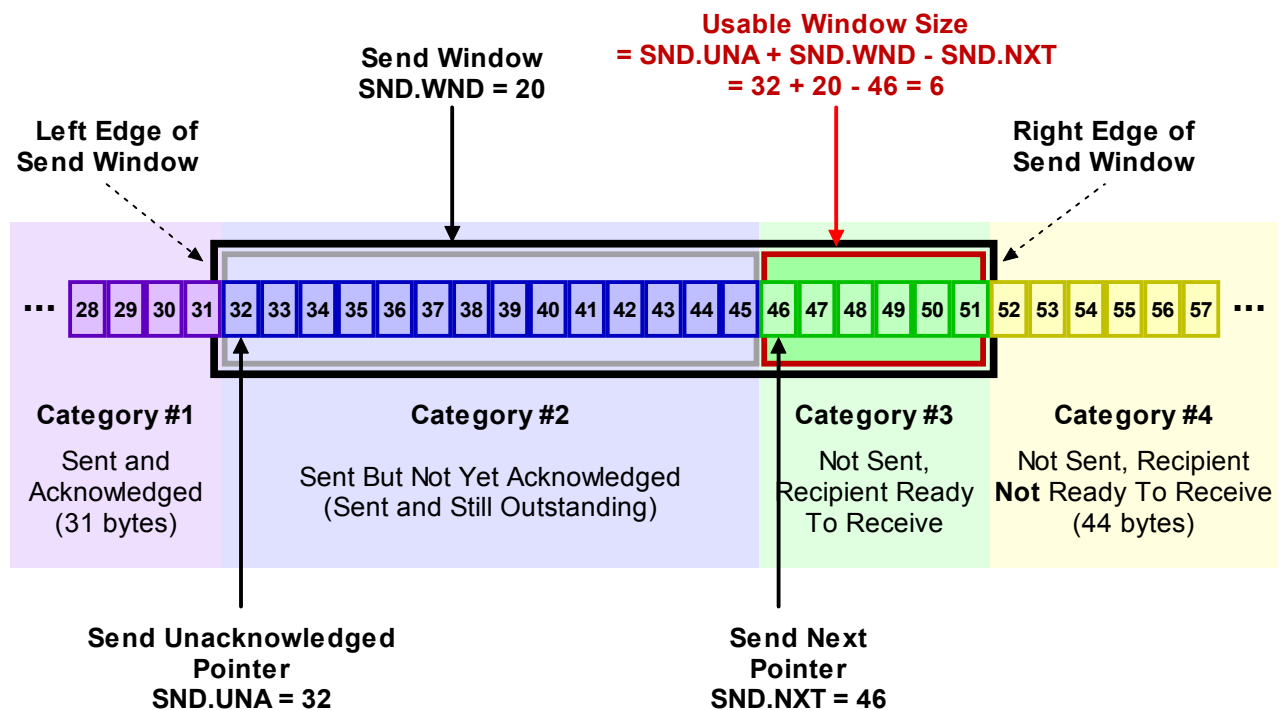

- ☉ **Send Unacknowledged (SND.UNA):** The sequence number of the first byte of data that has been sent but not yet acknowledged. This marks the first byte of Transmit Category #2; all previous sequence numbers refer to bytes in Transmit Category #1.
- ☉ **Send Next (SND.NXT):** The sequence number of the next byte of data to be sent to the other device (the server in this case). This marks the first byte of Transmit Category #3.
- ☉ **Send Window (SND.WND):** The size of the send window. Recall that the window specifies the total number of bytes that any device may have “outstanding” (*unacknowledged*) at any one time. Thus, adding the sequence number of the first unacknowledged byte (*SND.UNA*) and the send window (*SND.WND*) marks the first byte of Transmit Category #4.

Another way of looking at these pointers is how they indicate the number of bytes a transmitting device can send at any point in time; that is, the number of bytes in Transmit Category #3. The start of Transmit Category #3 is marked by *SND.NXT*. The end is marked by the first byte of Transmit Category #4, given by *SND.UNA+SND.WND*. Thus, the number of bytes in Transmit Category #3 is given by the following formula:

$$SND.UNA + SND.WND - SND.NXT$$

This is called the *usable window*, since it indicates how many bytes the transmitter can use at any point in time. When data is acknowledged, this causes bytes to move from Transmit Category #2 to Category #1, by increasing the value of *SND.UNA*. Assuming that the send window size doesn't change, this causes the window to *slide* to the right, permitting more data to be sent.

**Figure 219: TCP Transmission Categories, Send Window and Pointers**

This diagram is the same as [Figure 207](#), but shows the TCP send pointers.  $SND.UNA$  points to the start of Transmit Category #2,  $SND.NXT$  points to the start of Transmit Category #3, and  $SND.WND$  is the size of the send window. The size of the usable window can be calculated as shown from those three pointers.

**Key Concept:** The TCP sliding windows scheme uses three pointers that keep track of which bytes are in each of the four transmit categories.  $SND.UNA$  points to the first unacknowledged byte and indicates the start of Transmit Category #2;  $SND.NXT$  points to the next byte of data to be sent and marks the start of Transmit Category #3.  $SND.WND$  contains the size of the send window; it is added to  $SND.NXT$  to mark the start of Transmit Category #4. Adding  $SND.WND$  to  $SND.UNA$  and then subtracting  $SND.NXT$  yields the current size of the usable transmit window.

## Receive (RCV) Pointers

The three receive categories are divided using two pointers:

- 🕒 **Receive Next (RCV.NXT):** The sequence number of the next byte of data that is expected from the other device. This marks the first byte in Receive Category #3. All previous sequence numbers refer to bytes already received and acknowledged, in Receive Category #1+2.

- ☉ **Receive Window (*RCV.WND*):** The size of the receive window “advertised” to the other device. This refers to the number of bytes the device is willing to accept at one time from its peer, which is usually the size of the buffer allocated for receiving data for this connection. When added to the *RCV.NXT* pointer, marks the first byte of Receive Category #4.

The receive categories and pointers are illustrated in [Figure 220](#).

**Figure 220: TCP Receive Categories and Pointers**

This diagram is the complement of [Figure 219](#), showing how the categories are set up for the receiving device. Categories #1 and #2 have been combined since there is no differentiation between “received and unacknowledged” and “received and acknowledged”. This example shows the state of the receiving device prior to receipt of the 14 bytes that in [Figure 219](#) have already been sent.

**Key Concept:** A set of receive pointers are maintained by each device, which are the complement of the send pointers. A device’s send pointers keep track of its outgoing data and its receive pointers the incoming data. The two receive pointers are *RCV.NXT*, which indicates the number of the next byte of data expected from the other device, and *RCV.WND*, which is the size of the receive window for that device. The *RCV.WND* of one device equals the *SND.WND* of the other device on the connection.

---

## ***The Relationship Between Send and Receive Pointers***

The *SND* and *RCV* pointers are complementary, of course, just as the categories are, with each device managing both the sending of its data and receiving of data from its peer. Assuming we have a client and a server, then:

- ☉ **Client:** The *SND* pointers keep track of the client's outgoing data stream; the *RCV* pointers refer to the data coming in from the server. The client's *SND* categories correspond to the server's *RCV* categories.
- ☉ **Server:** The *SND* pointers keep track of the server's outgoing data stream; the *RCV* pointers refer to the data being received from the client. The server's *SND* categories correspond to the client's *RCV* categories.

## ***TCP Segment Fields Used to Exchange Pointer Information***

Since the *SND* and *RCV* values are complementary, the send window of one device is the receive window of the other, and vice-versa. Note, however, that the values of the pointers do not always line up exactly between the two devices, because at any given time, some bytes may be in transit between the two. [Figure 220](#), for example, shows the receive pointers of the recipient *prior* to receiving bytes 32 to 45, which are shown in transit in [Figure 219](#).

Both *SND* and *RCV* pointers are all maintained in the transmission control block (TCB) for the connection held by each device. As data is exchanged the pointers are updated, and communication about the state of the send and receive streams is exchanged using control fields in the TCP segment format. The three most important ones are:

- ☉ **Sequence Number:** Identifies the sequence number of the first byte of data in the segment being transmitted. This will normally be equal to the value of the *SND.UNA* pointer at the time that data is sent.
- ☉ **Acknowledgment Number:** Acknowledges the receipt of data by specifying the sequence number that the sender of the segment expects in the segment recipient's next transmission. This field will normally be equal to the *RCV.NXT* pointer of the device that sends it.
- ☉ **Window:** The size of the receive window of the device sending the segment (and thus, the send window of the device receiving the segment.)

The *Acknowledgment Number* field is critical because this is what a device uses to tell its peer what segments it has received. The system is **cumulative**: the *Acknowledgment Number* field says “I have received all data bytes with sequence numbers less than this value”. This means if a client receives many segments of data from a server in rapid succession, it can acknowledge all of them using a single number, as long as they are contiguous. If they are not contiguous, then [things get more complicated](#).

**Key Concept:** Three essential fields in the TCP segment format are used to implement the sliding windows system. The *Sequence Number* field indicates the number of the first byte of data being transmitted. The *Acknowledgment Number* is used to acknowledge data received by the device sending this segment. The *Window* field tells the recipient of the segment the size to which it should set its send window.

---

### **Example Illustration of TCP Sliding Window Mechanics**

To see how all of this works, let's consider the example of a client and server using a mythical file retrieval protocol. This protocol specifies that the client sends a request and receives an immediate response from the server. The server then sends the file requested when it is ready.

The two devices will of course first establish a connection and [synchronize sequence numbers](#). For simplicity, let's say the client uses an initial sequence number (ISN) of 0, and the server an ISN of 240. The server will send the client an *ACK* with an *Acknowledgment Number* of 1, indicating it is the sequence number it expects to receive next. Let's say the server's receive window size is set to 350, so this is the client's send window size. The client will send its *ACK* with an *Acknowledgment Number* of 241. Let's say its receive window size is 200 (and the server's client window size is thus 200). Let's assume that both devices maintain the same window size throughout the transaction. This won't normally happen, especially if the devices are busy, but the example is complicated enough. Let's also say the [maximum segment size](#) is 536 bytes in both directions. This means that the MSS won't affect the size of actual segments in this example (since the MSS is larger than the send window sizes for both devices.)

With the background for our example established, we can now follow a sample transaction to show in detail how the send and receive pointers are created and changed as messages are exchanged between client and server. [Table 160](#) describes the process in detail, showing for each step what the send and receive pointers are for both devices. It is rather large, so beware. ☺ The transaction is also graphically illustrated in two figures: [Figure 221](#) and [Figure 222](#). Both illustrate the same exchange of messages, using the step numbers of [Table 160](#), but each from the perspective of one of the devices. [Figure 221](#) shows the

server's send pointers and client's receive pointers; [Figure 222](#) shows the client's send pointers and server's receive pointers. (I would have put them all in one diagram but it wouldn't fit!)

**Table 160: TCP Transaction Example With Send and Receive Pointers (*Page 1 of 3*)**

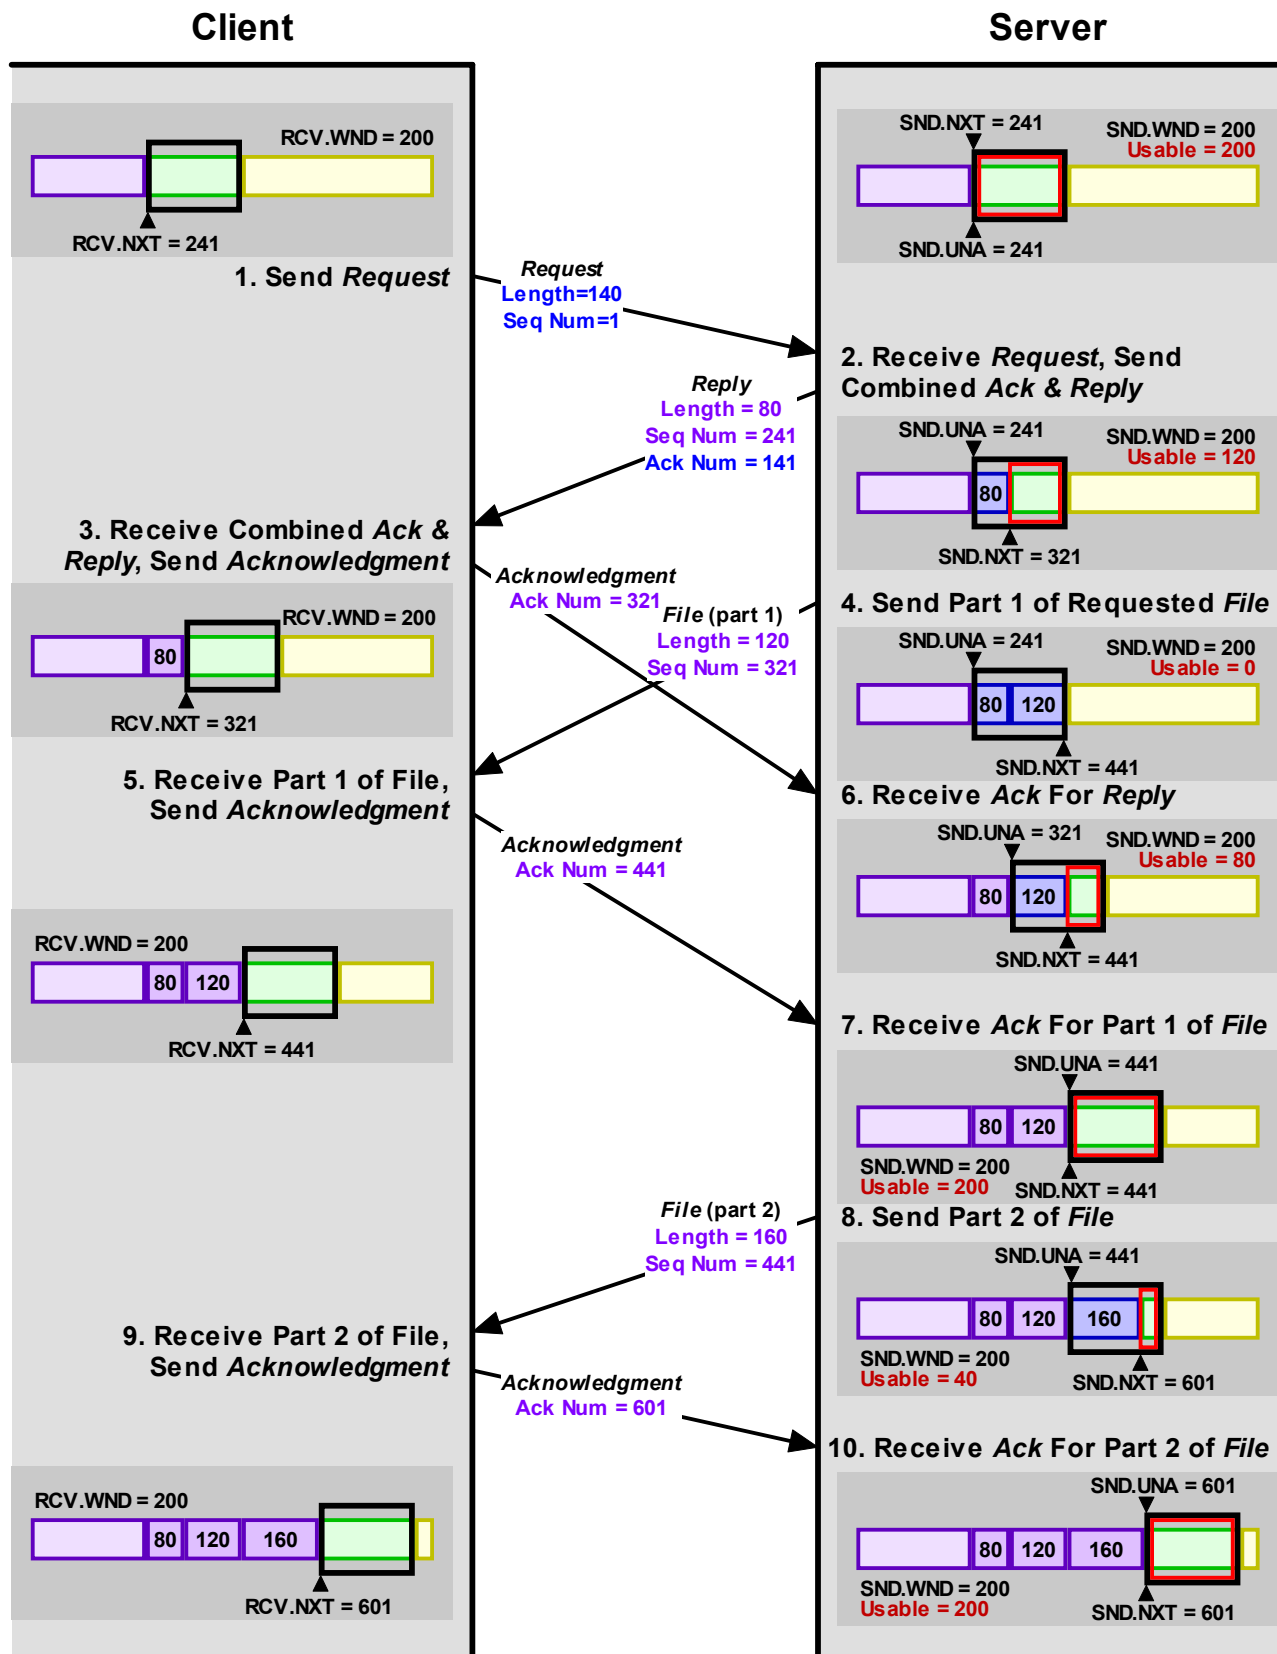

Client						Server					
Process Step	SND. UNA	SND. NXT	SND. WND	RCV. NXT	RCV. WND	Process Step	SND. UNA	SND. NXT	SND. WND	RCV. NXT	RCV. WND
Description						Description					
(setup)	1	1	360	241	200	(setup)	241	241	200	1	360
During connection establishment, the client sets up its pointers based on the parameters exchanged during setup. Notice that the <i>SND.UNA</i> and <i>SND.NXT</i> values are the same — no data has been sent yet so nothing is unacknowledged. <i>RCV.NXT</i> is the value of the first byte of data expected from the server.						The server sets up its pointers just as the client does. Notice how its values are the complement of the client's.					
1. Send Request	1	141	360	241	200	(wait)	241	241	200	1	360
The client transmits a request to the server. Let's say the request is 140 bytes in length. It will form a segment with a data field of this length and transmit it with the <i>Sequence Number</i> set to 1, the sequence number of the first byte. Once this data has been sent, the client's <i>SND.NXT</i> pointer will be incremented to the value 141 to indicate this is the next data to be sent to the server.						The server does nothing, waiting for a request.					
(wait)	1	141	360	241	200	2. Receive Request, Send Ack & Reply	241	321	200	141	360
At this point the client hasn't received an acknowledgment for its request. At present, <i>SND.UNA</i> + <i>SND.WND</i> is 361, while <i>SND.NXT</i> is 141. This means the current usable window is 220 bytes. The the client could send up to 220 more bytes of data before getting back an acknowledgment. For now, let's say it has nothing more to transmit.						The server receives the 140-byte request from the client. The server sends back an 80-byte response that also acknowledges the client's TCP segment. The <i>Sequence Number</i> field will be 241, the first sequence number of the server's 80 bytes of data. The <i>Acknowledgment Number</i> will be 141, telling the client that is the next sequence number the server expects to hear, and thereby implicitly acknowledging receipt of bytes 1 through 140.  The server increases its <i>RCV.NXT</i> pointer to 141 to reflect the 140 bytes of data received. It increases its <i>SND.NXT</i> pointer by 30.					

**Table 160: TCP Transaction Example With Send and Receive Pointers (Page 2 of 3)**

Client						Server					
Process Step	SND. UNA	SND. NXT	SND. WND	RCV. NXT	RCV. WND	Process Step	SND. UNA	SND. NXT	SND. WND	RCV. NXT	RCV. WND
Description						Description					
<b>3. Receive Ack &amp; Reply, Send Ack</b>	141	141	360	321	200	<b>4. Send Part 1 of File</b>	241	441	200	141	360
<p>The client receives the server's response. It sees the Acknowledgment Number of 141 and knows bytes 1 to 140 were successfully received. It increases its <i>SND.UNA</i> to 141, effectively "sliding the send window" by 140.</p> <p>The client also accepts the 80 bytes of data the server sent, increasing its <i>RCV.NXT</i> pointer by 80. Assuming it has no more data to sent, it sends back a TCP segment that is a pure acknowledgment of the server's response. This segment has no data, and an <i>Acknowledgment Number</i> value of 321.</p>						<p>While the client was receiving its response, the server's TCP was supplied with a 280 byte file to be sent to the client. It cannot send this all in one segment however. The current value of <i>SND.UNA+SND.WND</i> is 441, while <i>SND.NXT</i> is 321. Thus, the server's usable window contains 120 bytes of data. It creates a TCP segment with this much data and a <i>Sequence Number</i> of 321. It increases the <i>SND.NXT</i> pointer to 441. The server has now filled the send window.</p> <p>Note that the server does not have to wait for an acknowledgement to the reply it sent in step #2. This is a key factor in TCP's ability to ensure high throughput.</p>					
<b>5. Receive Part 1 of File, Send Ack</b>	141	141	360	441	200	<b>6. Receive Ack for Reply</b>	321	441	200	141	360
<p>The client receives the first 120-byte part of the file the server was sending. It increases the <i>RCV.NXT</i> pointer to 441 and sends an acknowledgment back with an <i>Acknowledgment Number</i> of 441. Again, if it had another request to make of the server it could include it here, but we'll assume it does not.</p>						<p>The server receives the client's acknowledgment of its earlier 80-byte response (sent in step #2). It increases its <i>SND.UNA</i> to 321. Since it just received acknowledgment of 80 bytes (and the client's window didn't change), the server's usable window is now 80 bytes. However, as we will see in <a href="#">the section on TCP performance</a>, sending small segments like this can lead to performance issues. Let's say the server has been programmed to not send segments under 100 bytes when it has a lot of data to transmit. It decides to wait.</p>					
<b>(wait)</b>	141	141	360	441	200	<b>7. Receive Ack for Part 1 of File</b>	441	441	200	141	360
The client waits for the rest of the file.						The server receives the acknowledgment for the first part of the file. It increases <i>SND.UNA</i> to 441. This now restores the full 200 byte window.					

**Table 160: TCP Transaction Example With Send and Receive Pointers (Page 3 of 3)**

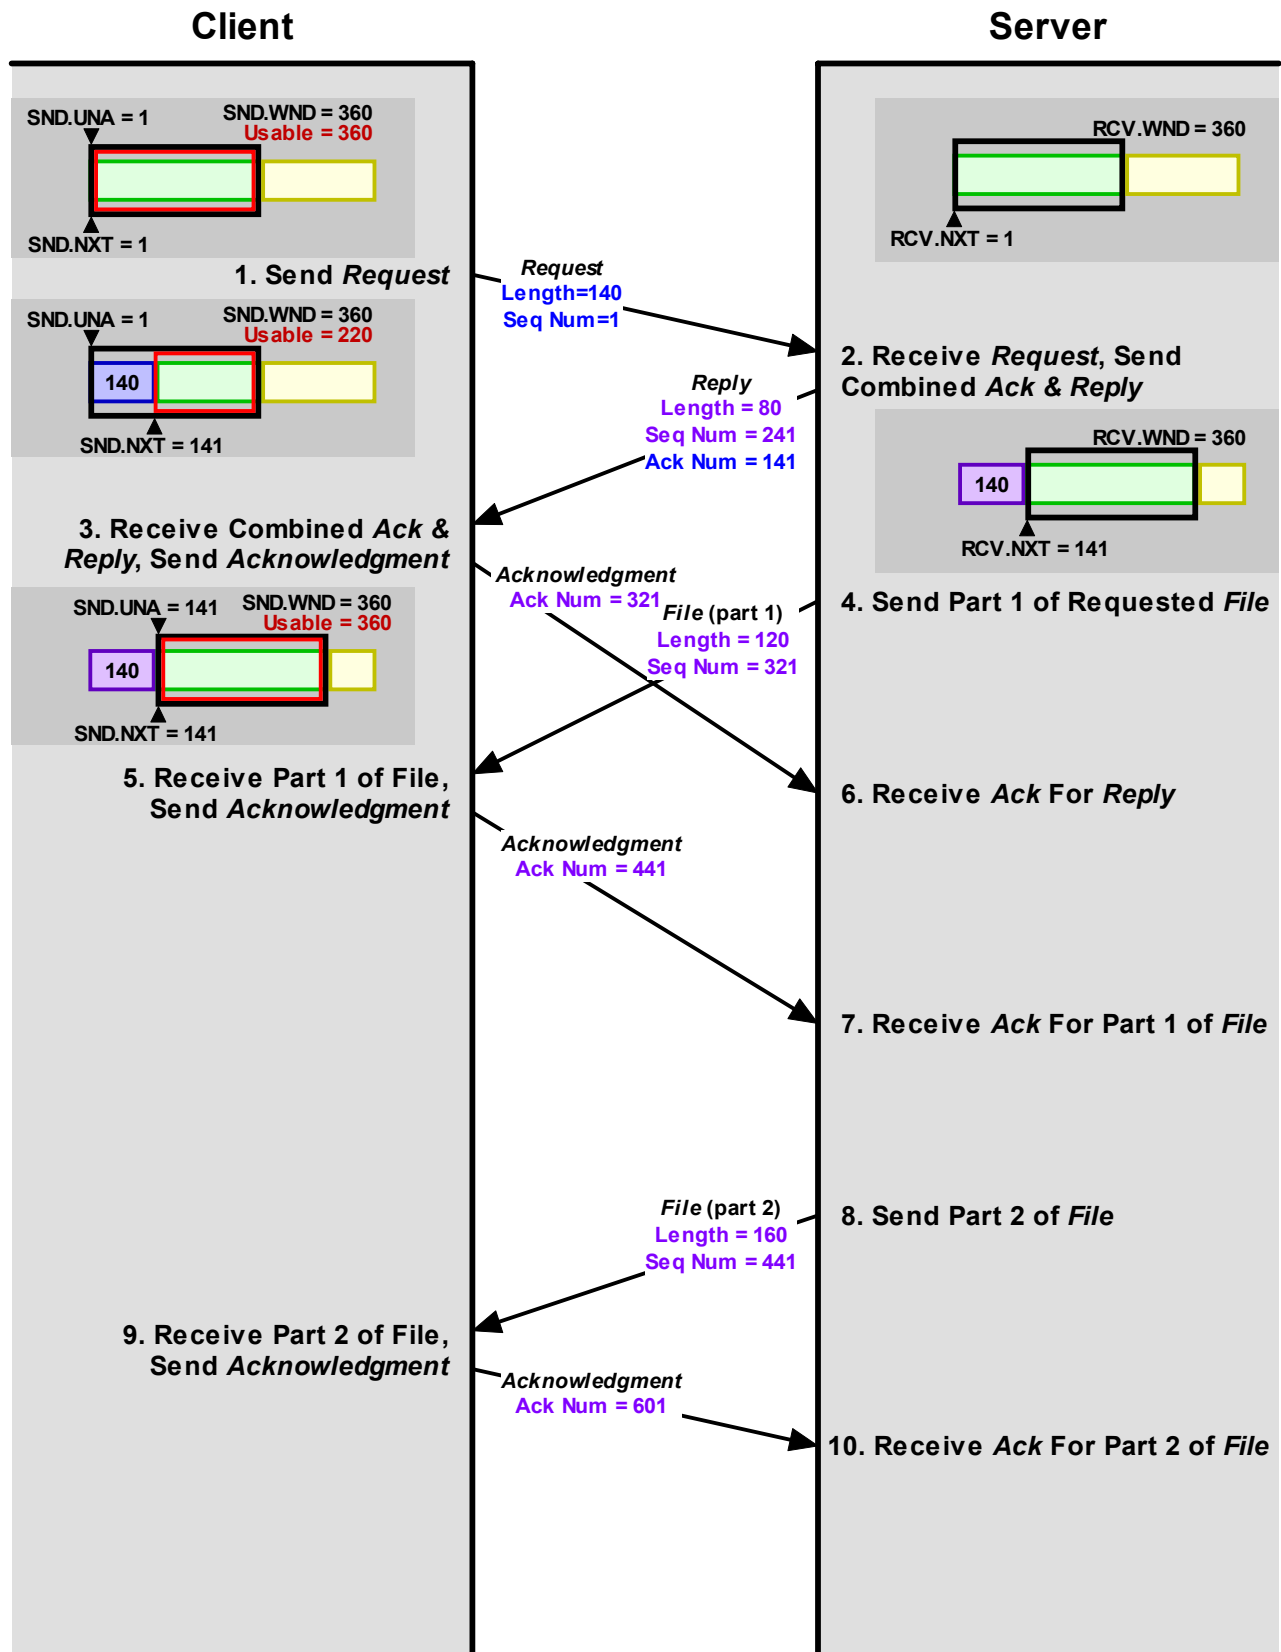

Client						Server					
Process Step	SND. UNA	SND. NXT	SND. WND	RCV. NXT	RCV. WND	Process Step	SND. UNA	SND. NXT	SND. WND	RCV. NXT	RCV. WND
Description						Description					
(still waiting ☺)	141	141	360	441	200	8. Send Part 2 of File	441	601	200	141	360
The client continues to wait for the rest of the file.						The server sends the remaining 160 bytes of data in the file in one segment. It increases <i>SND.NXT</i> by 160, and sends the data with a <i>Sequence Number</i> value of 441.					
9. Receive Part 2 of File, Send Ack	141	141	360	601	200	(wait)	441	601	200	141	360
The client receives the rest of the file and acknowledges it. It increases <i>RCV.NXT</i> to 601 and sends back a segment with an <i>Acknowledgment Number</i> of 601.						The server is done for now; it waits for the acknowledgment of the second part of the file.					
(done)	141	141	360	601	200	10. Receive Ack for Part 2 of File	601	601	200	141	360
The client is done with this exchange.						The server receives the second acknowledgment and slides its send window forward by 160 bytes. The transaction is now completed.					

**Figure 221: TCP Transaction Example Showing Server's Send Pointers**

The transaction of [Table 160](#) from the perspective of the server. See [Figure 222](#) for the client's pointers.

**Figure 222: TCP Transaction Example Showing Client's Send Pointers**

The transaction of [Table 160](#) from the perspective of the client. See [Figure 221](#) for the server's pointers.

---

## Real-World Complications of the Sliding Window Mechanism

I'm sure this seems rather complicated, but in fact, the example is highly **simplified**, to show you how the basic data transfer mechanism works without too much going on. Scary, isn't it? ☺ A real world connection would include several complications:

- ☹ **Overlapping Transmissions:** I intentionally showed only one request from the client and the response from the server. In reality, the client and server could be pumping many requests and responses at each other in rapid-fire succession; the client would be acknowledging segments received from the server with segments that themselves contained new requests, and so on.
- ☹ **Acknowledgment of Multiple Segments:** I also didn't show a case where two segments are received by a device and acknowledged with a single acknowledgment, though this can certainly happen. Suppose that in the example above, the two parts of the 280-byte file were sent at once and received by the client at the same time. The client would acknowledge both by sending a single segment with an *Acknowledgment Number* of 601. Remember, this field is a **cumulative** acknowledgment of all segments containing data through the number preceding it, so this would acknowledge all data up to byte 600.
- ☹ **Fluctuating Window Sizes For Flow Control:** The window sizes in the example above remained constant, but in a real connection this will not always be the case. A very busy server may not be able to process and remove data from its buffer as fast as it acknowledges it. It may need to reduce its receive window to reduce the amount of data the client sends it, and then increase the window when more space becomes available. [This is how TCP implements flow control](#).
- ☹ **Lost Transmissions:** In a real connection, some transmitted segments will be lost and need to be retransmitted. This is handled by [TCP's retransmission scheme](#).
- ☹ **Avoiding Small Window Problems:** I hinted in the table above that we don't necessarily always want to send data as fast as we can, when it means we have to send a very small segment. The reason is that this can lead to performance degradation, including a phenomenon called [silly window syndrome](#). This too will be explored in the section that follows, where we will see how handling it requires that we [change the simple sliding windows scheme](#) we have seen until the point.
- ☹ **Congestion Handling and Avoidance:** The basic sliding window mechanism has been changed over the years to avoid having TCP connections cause internetwork congestion and to have them handle congestion when it is detected. Congestion issues are discussed, you guessed it, [in the next section](#).

## TCP Immediate Data Transfer: "Push" Function

The fact that TCP [takes incoming data from a process as an unstructured stream of bytes](#) gives it great flexibility in meeting the needs of most applications. There is no need for an application to create blocks or messages; it just sends the data to TCP when it is ready for transmission. For its part, TCP has no knowledge or interest in the meaning of the bytes of data in this stream. They are "just bytes" and TCP just sends them without any real concern for their structure or purpose.

---

This has a couple of interesting impacts on how applications work. One is that TCP does not provide any natural indication of the dividing point between pieces of data, such as database records or files. The application must take care of this. Another result of TCP's byte orientation is that TCP cannot decide when to form a segment and send bytes between devices based on the contents of the data. TCP will generally accumulate data sent to it by an application process in a buffer. It chooses when and how to send data based solely on [the sliding window system discussed in the previous topic](#), in combination with logic that helps to ensure efficient operation of the protocol.

This means that while an application can control the rate and timing with which it sends data to TCP, it cannot inherently control the timing with which TCP itself sends the data over the internetwork. Now, if we are sending a large file, for example, this isn't a big problem. As long as we keep sending data, TCP will keep forwarding it over the internetwork. It's generally fine in such a case to let TCP fill its internal transmit buffer with data and form a segment to be sent when TCP feels it is appropriate.

### ***Problems with Accumulating Data for Transmission***

However, there are situations where letting TCP accumulate data before transmitting it can cause serious application problems. The classic example of this is an interactive application such as the [Telnet Protocol](#). When you are using such a program, you want each keystroke to be sent immediately to the other application; you don't want TCP to accumulate hundreds of keystrokes and then send them all at once. The latter may be more “efficient” but it makes the application unusable, which is really putting the cart before the horse.

Even with a more mundane protocol that transfers files, there are many situations in which we need to say “send the data **now**”. For example, many protocols begin with a client sending a request to a server—like the hypothetical one in the example in the preceding topic, or a request for a Web page sent by a Web browser. In that circumstance, we want the client's request sent immediately; we don't want to wait until enough requests have been accumulated by TCP to fill an “optimal-sized” segment.

### ***Forcing Immediate Data Transfer***

Naturally, the designers of TCP realized that a way was needed to handle these situations. When an application has data that it needs to have sent across the internetwork immediately, it sends the data to TCP, and then uses the TCP *push* function. This tells the sending TCP to immediately “push” all the data it has to the recipient's TCP as soon as it is able to do so, without waiting for more data.

When this function is invoked, TCP will create a segment (or segments) that contains all the data it has outstanding, and will transmit it with the *PSH* control bit set to 1. The destination device's TCP software, seeing this bit sent, will know that it should not just take the data in the segment it received and buffer it, but rather push it through directly to the application.

It's important to realize that the push function **only** forces immediate delivery of data. It does not change the fact that TCP provides no boundaries between data elements. It may **seem** that an application could send one record of data and then “push” it to the recipient;

---

then send the second record and “push” that, and so on. However, the application cannot assume that because it sets the *PSH* bit for each piece of data it gives to TCP, that each piece of data will be in a single segment. It is possible that the first “push” may contain data given to TCP earlier that wasn't yet transmitted, and it's also possible that two records “pushed” in this manner may end up in the same segment anyway.

**Key Concept:** TCP includes a special “push” function to handle cases where data given to TCP needs to be sent immediately. An application can send data to its TCP software and indicate that it should be pushed. The segment will be sent right away rather than being buffered. The pushed segment's *PSH* control bit will be set to one to tell the receiving TCP that it should immediately pass the data up to the receiving application.

---

## TCP Priority Data Transfer: "Urgent" Function

TCP treats data to be transmitted as just an unstructured stream of bytes, and this has some important implications on how it is used. One aspect of this characteristic is that since TCP doesn't understand the content of the data it sends, it normally treats all the data bytes in a stream as *equals*. The data is sent to TCP in a particular sequence, and is transmitted in that same order. This makes TCP, in this regard, like those annoying voice mail systems that tell you not to hang up because they will answer calls in the order received.

**Note:** Pet peeve: I hate being told “your call will be answered in the order in which it was received”. I only made one call, so my call wasn't received in any “order”! The phrase should be in the plural: “calls will be answered in the order in which they were received”. ☺

---

## *TCP's Normal Data Processing: First In, First Out*

Of course, while waiting on hold is irritating, this *first in, first out* behavior is usually how we **want** TCP to operate. If we are transmitting a message or a file we want to be able to give TCP the bytes that comprise the file to be sent and have TCP transmit that data in the order we gave it. However, just as special circumstances can require the “push” function we saw in the previous topic, there are cases where we may **not** want to always send all data over in the exact sequence it was given to TCP.

The most common example of this is when it is necessary to *interrupt* an application's data transfer. Suppose we have an application that sends large files in both directions between two devices. The user of the application realizes that the wrong file is being transferred. When he or she tells the application to stop the file being sent, we want this to be communicated to the other end of the TCP connection immediately. We don't want the “abort” command to just be placed at the end of the line after the file we are trying to send!

---

## Prioritizing Data For Transfer

TCP provides a means for a process to prioritize the sending of data in the form of its “urgent” feature. To use it, the process that needs to send urgent data enables the function and sends the urgent data to its TCP layer. TCP then creates a special TCP segment that has the *URG* control bit set to 1. It also sets the *Urgent Pointer* field to an offset value that points to the last byte of urgent data in the segment. So, for example, if the segment contained 400 bytes of urgent data followed by 200 bytes of regular data, the *URG* bit would be set and the *Urgent Pointer* field would have a value of 400.

Upon receipt of a segment with the *URG* flag set to 1, the receiving device looks at the *Urgent Pointer* and from its value determines which data in the segment is urgent. It then forwards the urgent data to the process with an indication that the data is marked as urgent by the sender. The rest of the data in the segment is processed normally.

Since we typically want to send urgent data, well, **urgently**, it makes sense that when such data is given to TCP, the “push” function is usually also invoked. This ensures that the urgent data is sent as soon as possible by the transmitting TCP and also forwarded up the protocol stack right away by the receiving TCP. Again, we need to remember that this does not guarantee the contents of the urgent segment. Using the “push” function **may** mean the segment contains only urgent data with no non-urgent data following, but again, an application cannot assume that this will always be the case.

**Key Concept:** To deal with situations where a certain part of a data stream needs to be sent with a higher priority than the rest, TCP incorporates an “urgent” function. When critical data needs to be sent, the application signals this to its TCP layer, which transmits it with the *URG* bit set in the TCP segment, bypassing any lower-priority data that may have already been queued for transmission.

---

---

## **TCP Reliability and Flow Control Features and Protocol Modifications**

The main task of the Transmission Control Protocol is simple: packaging and sending data. Of course, almost every protocol packages and sends data. What distinguishes TCP from these protocols is [the sliding window mechanism](#) that controls the flow of data between devices. This system not only manages the basic data transfer process, it is also used to ensure that data is sent reliably, and also to manage the flow of data between devices to ensure that data is transferred efficiently without either device sending data faster than the other can receive it.

To enable TCP to provide the features and quality of data transfer that applications require, the protocol had to be enhanced beyond the simplified data transfer mechanism we saw in preceding sections. Extra “smarts” needed to be given to the protocol to handle potential problems, and changes to the basic way that devices send data were implemented to avoid inefficiencies that might otherwise have resulted.

In this section I describe how TCP ensures that devices on a TCP connection communicate in a reliable and efficient manner. I begin with an explanation of the basic method by which TCP detects lost segments and retransmits them. I discuss some of the issues associated with TCP's acknowledgment scheme and an optional feature for improving its efficiency. I then describe the system by which TCP adjusts how long it will wait before deciding that a segment is lost. I discuss how the window size can be adjusted to implement flow control, and some of the issues involved in window size management. This includes a look at the infamous “Silly Window Syndrome” problem, and special heuristics for addressing issues related to small window size that modify the basic sliding windows scheme. I conclude with a discussion of TCP's mechanisms for handling and avoiding congestion.

**Background Information:** This section assumes that you are already familiar with TCP [sequence numbers and segments](#), and [the basics of the TCP sliding window mechanism](#). It also assumes you have already read [the section on TCP message formatting and data transfer](#). If not, you may want to review at least [the topic describing TCP data transfer mechanics](#); several of the topics in this section extend that simplified discussion of TCP data transfer to show what happens in non-ideal conditions.

---

### **TCP Segment Retransmission Timers and the Retransmission Queue**

TCP's basic data transfer and acknowledgment mechanism uses a set of variables maintained by each device to implement the [sliding window acknowledgement system](#). These pointers keep track of the bytes of data sent and received by each device, as well as differentiating between acknowledged and unacknowledged transmissions. In the preceding section [I described this mechanism, and gave a simplified example showing how a client and server uses them for basic data transfer](#).

---

One of the reasons why that example is simplified is that every segment that was transmitted by the server was received by the client, and vice-versa. It would be nice if we could always count on this happening, but as we know, in an Internet environment this is not realistic. Due to any number of conditions, such as hardware failure, corruption of an IP datagram or router congestion, a TCP segment may be sent but never received. To qualify as a reliable transport protocol, TCP must be able detect lost segments and *retransmit* them.

### ***Managing Retransmissions Using the Retransmission Queue***

The method for detecting lost segments and retransmitting them is conceptually simple. Each time we send a segment, we start a *retransmission timer*. This timer starts at a pre-determined value and counts down over time. If the timer expires before an acknowledgment is received for the segment, we retransmit the segment.

TCP uses this basic technique but implements it in a slightly different way. The reason for this is the need to efficiently deal with many segments that may be unacknowledged at once, to ensure that they are each retransmitted at the appropriate time if needed. The TCP system works according to the following specific sequence:

- 🕒 **Placement On Retransmission Queue, Timer Start:** As soon as a segment containing data is transmitted, a copy of the segment is placed in a data structure called the *retransmission queue*. A retransmission timer is started for the segment when it is placed on the queue. Thus, **every** segment is at some point placed in this queue. The queue is kept sorted by the time remaining in the retransmission timer, so the TCP software can keep track of which timers have the least time remaining before they expire.
- 🕒 **Acknowledgment Processing:** If an acknowledgment is received for a segment before its timer expires, the segment is removed from the retransmission queue.
- 🕒 **Retransmission Timeout:** If an acknowledgment is **not** received before the timer for a segment expires, a *retransmission timeout* occurs, and the segment is automatically retransmitted.

Of course, we have no more guarantee that a retransmitted segment will be received than we had for the original segment. For this reason, after retransmitting a segment, it remains on the retransmission queue. The retransmission timer is reset, and the countdown begins again. Hopefully an acknowledgment will be received for the retransmission, but if not, the segment will be retransmitted again and the process repeated.

Certain conditions may cause even repeated retransmissions of a segment to fail. We don't want TCP to just keep retransmitting forever, so TCP will only retransmit a lost segment a certain number of times before concluding that there is a problem and terminating the connection.

**Key Concept:** To provide basic reliability for sent data, each device's TCP implementation uses a *retransmission queue*. Each sent segment is placed on the queue and a *retransmission timer* started for it. When an acknowledgment is received for the data in the segment, it is removed from the retransmission queue. If the timer goes off before an acknowledgment is received the segment is retransmitted and the timer restarted.

---

### ***Recognizing When a Segment is Fully Acknowledged***

One issue we have yet to discuss is how we know when a segment has been fully acknowledged. Retransmissions are handled on a segment basis, but TCP acknowledgments, as we have seen, are done on a cumulative basis using sequence numbers. Each time a segment is sent by Device A to Device B, B looks at the value of the *Acknowledgment Number* field in the segment. All bytes with sequence numbers lower than the value of this field have been received by A.

Thus, a segment sent by B to A is considered acknowledged when all of the bytes that were sent in the segment have a lower sequence number than the latest *Acknowledgment Number* sent by B to A. This is determined by calculating the last sequence number of the segment using its first byte number (in the *Sequence Number* field) and length of the segment's *Data* field.

**Key Concept:** TCP uses a *cumulative acknowledgment system*. The *Acknowledgment Number* field in a segment received by a device indicates that all bytes of data with sequence numbers less than that value have been successfully received by the other device. A segment is considered acknowledged when all of its bytes have been acknowledged; in other words, when an *Acknowledgment Number* containing a value larger than the sequence number of its last byte is received.

---

### ***TCP Transaction Example with Retransmission***

Let's use an example to clarify how acknowledgments and retransmissions work in TCP (illustrated in [Figure 223](#), to which you may wish to refer as you read on). Suppose the server in a connection sends out four contiguous segments (numbered starting with 1 for clarity):

1. **Segment #1:** *Sequence Number* field is 1 and segment length is 80. So the last sequence number in Segment #1 is 80.
2. **Segment #2:** *Sequence Number* field is 81 and segment length is 120. The last sequence number in Segment #2 is 200.
3. **Segment #3:** *Sequence Number* field is 201 and segment length is 160. The last sequence number in Segment #3 is 360.

- 
4. **Segment #4:** *Sequence Number* field is 361 and segment length is 140. The last sequence number in Segment #4 is 500.

Again, these can be sent one after the other without having to wait for each preceding transmission to be acknowledged; this is a major benefit of TCP's sliding window mechanism.

Now let's say the client receives the first two transmissions. It will send back an acknowledgment with an *Acknowledgment Number* field value of 201. This tells the server that the first two segments have been successfully received by the client; they will be removed from the retransmission queue (and the server's send window will slide 200 bytes to the right). Segment #3 will remain on the retransmission queue until a segment with an *Acknowledgment Number* field value of 361 or higher is received; Segment #4 requires an acknowledgment value of 501 or greater.

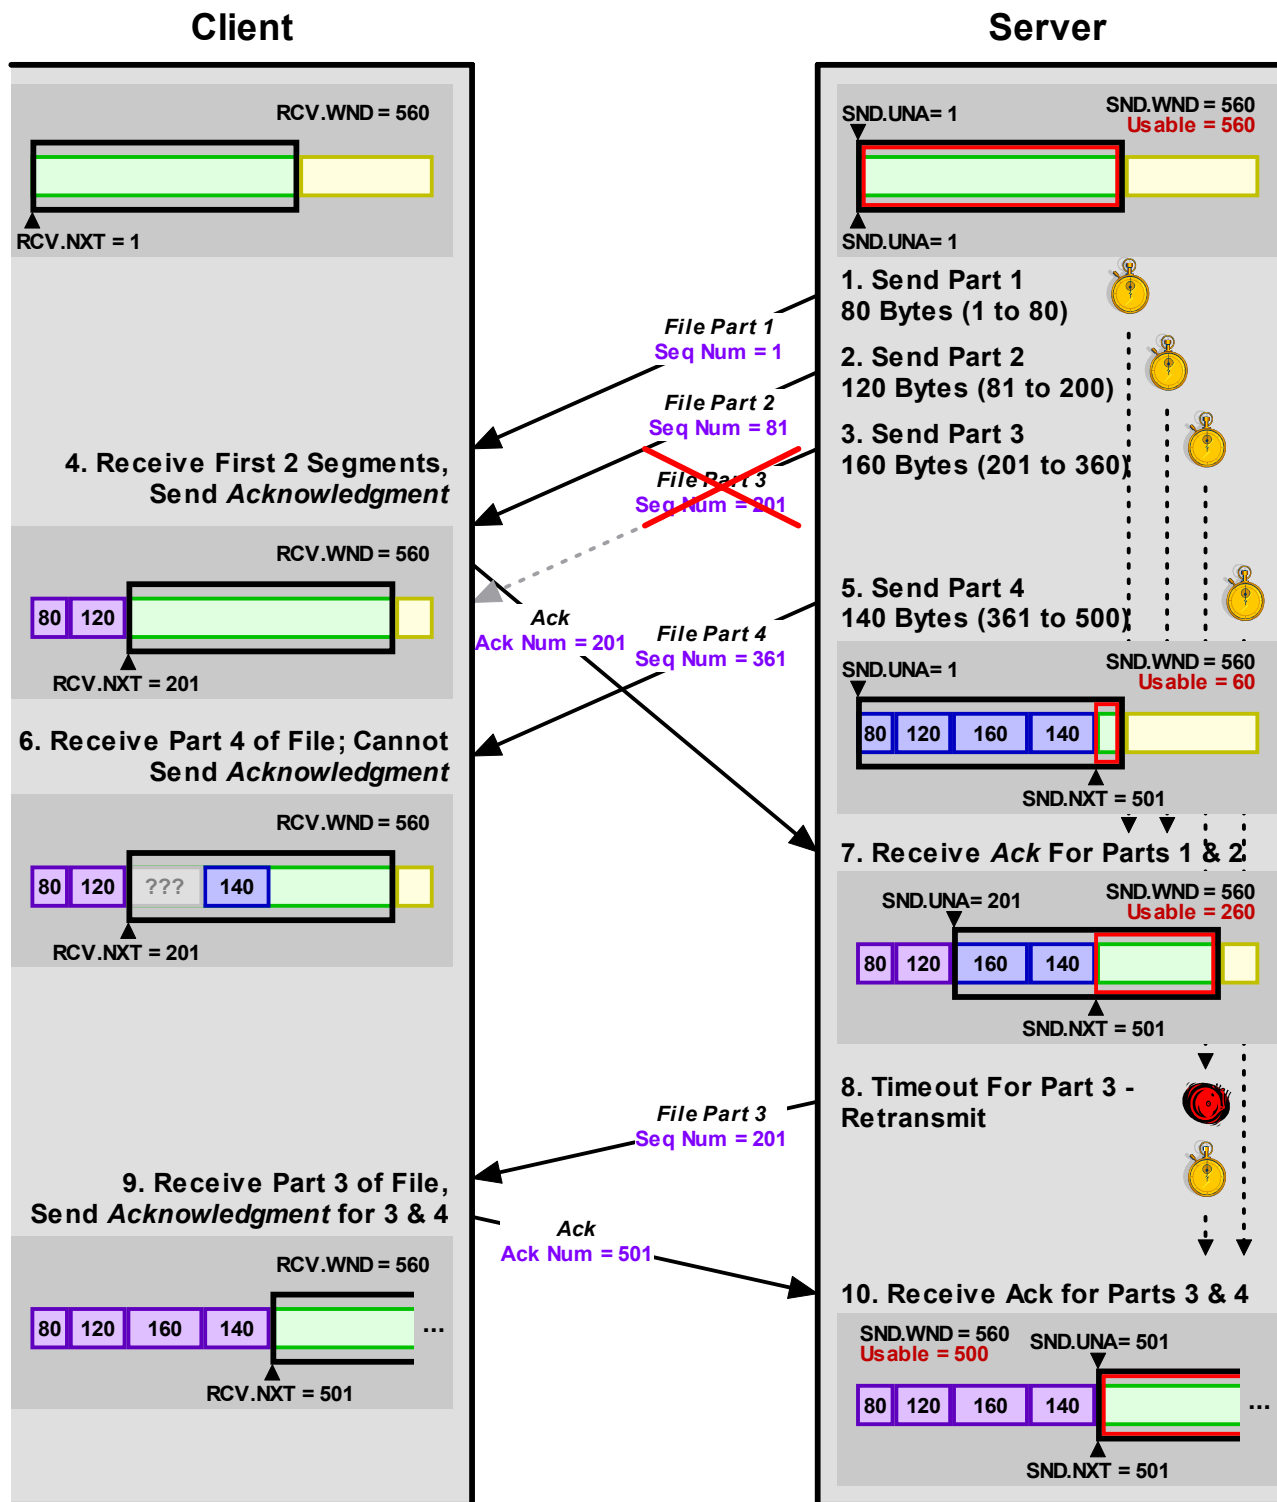

Now, let's further suppose in this example that Segment #3 gets lost in transit, but Segment #4 is received. The client will store Segment #4 in its receive buffer, but will not be able to acknowledge it, because of TCP's cumulative acknowledgment system—acknowledging #4 would imply receipt of #3 as well, which never showed up. So the client will have to simply wait for #3. Eventually, the retransmission timer that the server started for Segment #3 will expire. The server will then retransmit Segment #3. It will be received by the client, which will then be able to acknowledge both #3 and #4 to the server.

There's another important issue here, however: how exactly the server should handle Segment #4. While the client is waiting for the missing Segment #3, the server is receiving no feedback; it doesn't know that #3 is lost, and it also doesn't know what happened to #4 (or any subsequent transmissions.) It is possible that the client has already received Segment #4 but just couldn't acknowledge it. Then again, maybe Segment #4 got lost as well. Some implementations may choose to only re-send Segment #3, while some may choose to re-send both Segment #3 and Segment #4. [This is an important issue that is discussed in more detail in the next topic.](#)

A final issue is what value we should use for the retransmission timer when we put a segment on the retransmission queue. If it is set too low, excessive retransmissions occur; if set too high, performance is reduced due to extraneous delays in re-sending lost segments. In fact, TCP cannot use a single number for this value; it must determine it dynamically using a process called [adaptive retransmission](#).

## **TCP Non-Contiguous Acknowledgment Handling and Selective Acknowledgment (SACK)**

Computer science people sometimes use the term “elegant” to describe a simple but effective solution to a problem or need. I think the term applies fairly well to the cumulative acknowledgment method that is part of the TCP sliding window system. With a single number, returned in the *Acknowledgment Number* field of a TCP segment, the device sending the segment can acknowledge not just a single segment it has received from its connection peer, but possibly several of them. We saw how this works in [the topic on the fundamentals of sliding windows](#), and again in [the previous topic on retransmissions](#).

**Figure 223: TCP Transaction Example With Retransmission**

This diagram illustrates a simple transaction and shows the server's send pointers and client's receive pointers. The server sends three segments to the client in rapid succession, setting a retransmission timer for each. Parts 1 and 2 are received and the client sends an *Acknowledgment* for them; upon receipt of this ACK, 1 and 2 are taken off the retransmission queue. However, Part 3 is lost in transit. When Part 4 is received, the client cannot acknowledge it; this would imply receipt of the missing Part 3. Eventually the retransmission timer for Part 3 expires and it is retransmitted, at which time both Part 3 and Part 4 are acknowledged.

---

## ***The Main Weakness of the TCP Sliding Window System: Handling Non-Contiguous Acknowledgments***

Even the most elegant technique has certain weaknesses, however. In the case of the TCP acknowledgment system, it is the inability to effectively deal with the receipt of *non-contiguous* TCP segments. The *Acknowledgment Number* specifies that **all** sequence numbers lower than its value have been received by the device sending that number. If we receive bytes with sequence numbers in two non-contiguous ranges, there is no way to specify this with a single number.

This can lead to potentially serious performance problems, especially on internetworks that operate at high speed or over inherently unreliable physical networks. To see what the problem is, let's go back to the example in the previous topic. There, the server sent four segments, and received back an acknowledgment with an *Acknowledgment Number* value of 201. Segment #1 and Segment #2 were thus considered acknowledged. They would be removed from the retransmission queue, and this would also allow the server's send window to slide 80+120 bytes to the right, allowing 200 more bytes of data to be sent.

However, let's again imagine that Segment #3, starting with sequence number 201, “disappears”. Since the client never receives this segment, it can never send back a acknowledgment with an *Acknowledgment Number* higher than 201. This causes the sliding window system to get “stuck”. The server can continue to send additional segments until it fills up the client's receive window, but until the client sends another acknowledgment, the server's send window will not slide.

The other problem we saw is that if Segment #3 gets lost, the client has no way to tell the server that it has in fact received any **subsequent** segments. It's entirely possible that the client does receive the server's Segment #4, and in addition, later segments sent until the window filled up. But the client can't send an acknowledgment with a value of 501 to indicate receipt of Segment #4, *because this implies receipt of Segment #3 as well*.

**Note:** In some cases the client may still send an acknowledgment upon receipt of Segment #4, but only containing a repeated acknowledgment of the bytes up to the end of Segment #2. [See the topic on congestion avoidance for an explanation.](#)

---

And here we see the drawback of the single-number, cumulative acknowledgment system of TCP. We could imagine a “worst-case scenario” in which the server is told it has a window of 10,000 bytes, and sends 20 segments of 500 bytes each. The first segment is lost and the other 19 received. But since it is the first segment that never showed up, none of the other 19 segments can be acknowledged!

**Key Concept:** TCP's acknowledgment system is *cumulative*. This means that if a segment is lost in transit, no subsequent segments can be acknowledged until the missing one is retransmitted and successfully received.

---

### ***Policies For Dealing with Retransmission When Unacknowledged Segments Exist***

This then leads to an important question: how do we handle retransmissions when there are subsequent segments outstanding beyond the lost segment? In our example above, when the server experiences a retransmission timeout on Segment #3, it must decide what to do about Segment #4, when it simply doesn't know whether or not the client received it. In our “worst-case scenario”, we have 19 segments that may or may not have shown up at the client after the first one that was lost.

We have two different possible ways to handle this situation.

#### **Retransmit Only Timed-Out Segments**

This is the more “conservative”, or if you prefer, “optimistic” approach. We retransmit only the segment that timed out, hoping that the other segments beyond it were successfully received.

This method is best if the segments after the timed-out segment actually showed up. It doesn't work so well if they did not. In the latter case, each segment would have to time out individually and be retransmitted. Imagine that in our “worst-case scenario” that all 20 500-byte segments were lost. We would have to wait for Segment #1 to time out and be retransmitted. This retransmission would be acknowledged (hopefully) but then we would get stuck waiting for Segment #2 to time out and be resent. We would have to do this many times.

#### **Retransmit All Outstanding Segments**

This is the more “aggressive” or “pessimistic” method. Whenever a segment times out we re-send not only it but all other segments that are still unacknowledged.

This method ensures that any time there is a hold up with acknowledgments, we “refresh” all outstanding segments to give the other device an extra chance at receiving them in case they too were lost. In the case where all 20 segments were lost, this saves substantial amounts of time over the “optimistic” approach. The problem here is that these retransmissions may not be necessary. If the first of 20 segments was lost and the other 19 were actually received, we'd be re-sending 9,500 bytes of data (plus headers) for no reason.

---

## There Is No Ideal Answer

Since TCP doesn't know whether these other segments showed up, it cannot know which method is better. It must simply make an “executive decision” to use one approach or the other, and hope for the best. In the example of the previous topic, as shown in [Figure 223](#), I demonstrated the “conservative” approach—only the lost segment of the file was retransmitted. In contrast, [Figure 224](#) shows the “aggressive” approach to retransmission.

**Key Concept:** There are two approaches to handling retransmission in TCP. In the more “conservative” approach, only the segments whose timers expire are retransmitted; this saves bandwidth but may cause performance degradation if many segments in a row are lost. The alternative is that when a segment’s retransmission timer expires, both it and all subsequent unacknowledged segments are retransmitted. This provides better performance if many segments are lost but may waste bandwidth on unnecessary retransmissions.

---

## A Better Solution: Selective Acknowledgment (SACK)

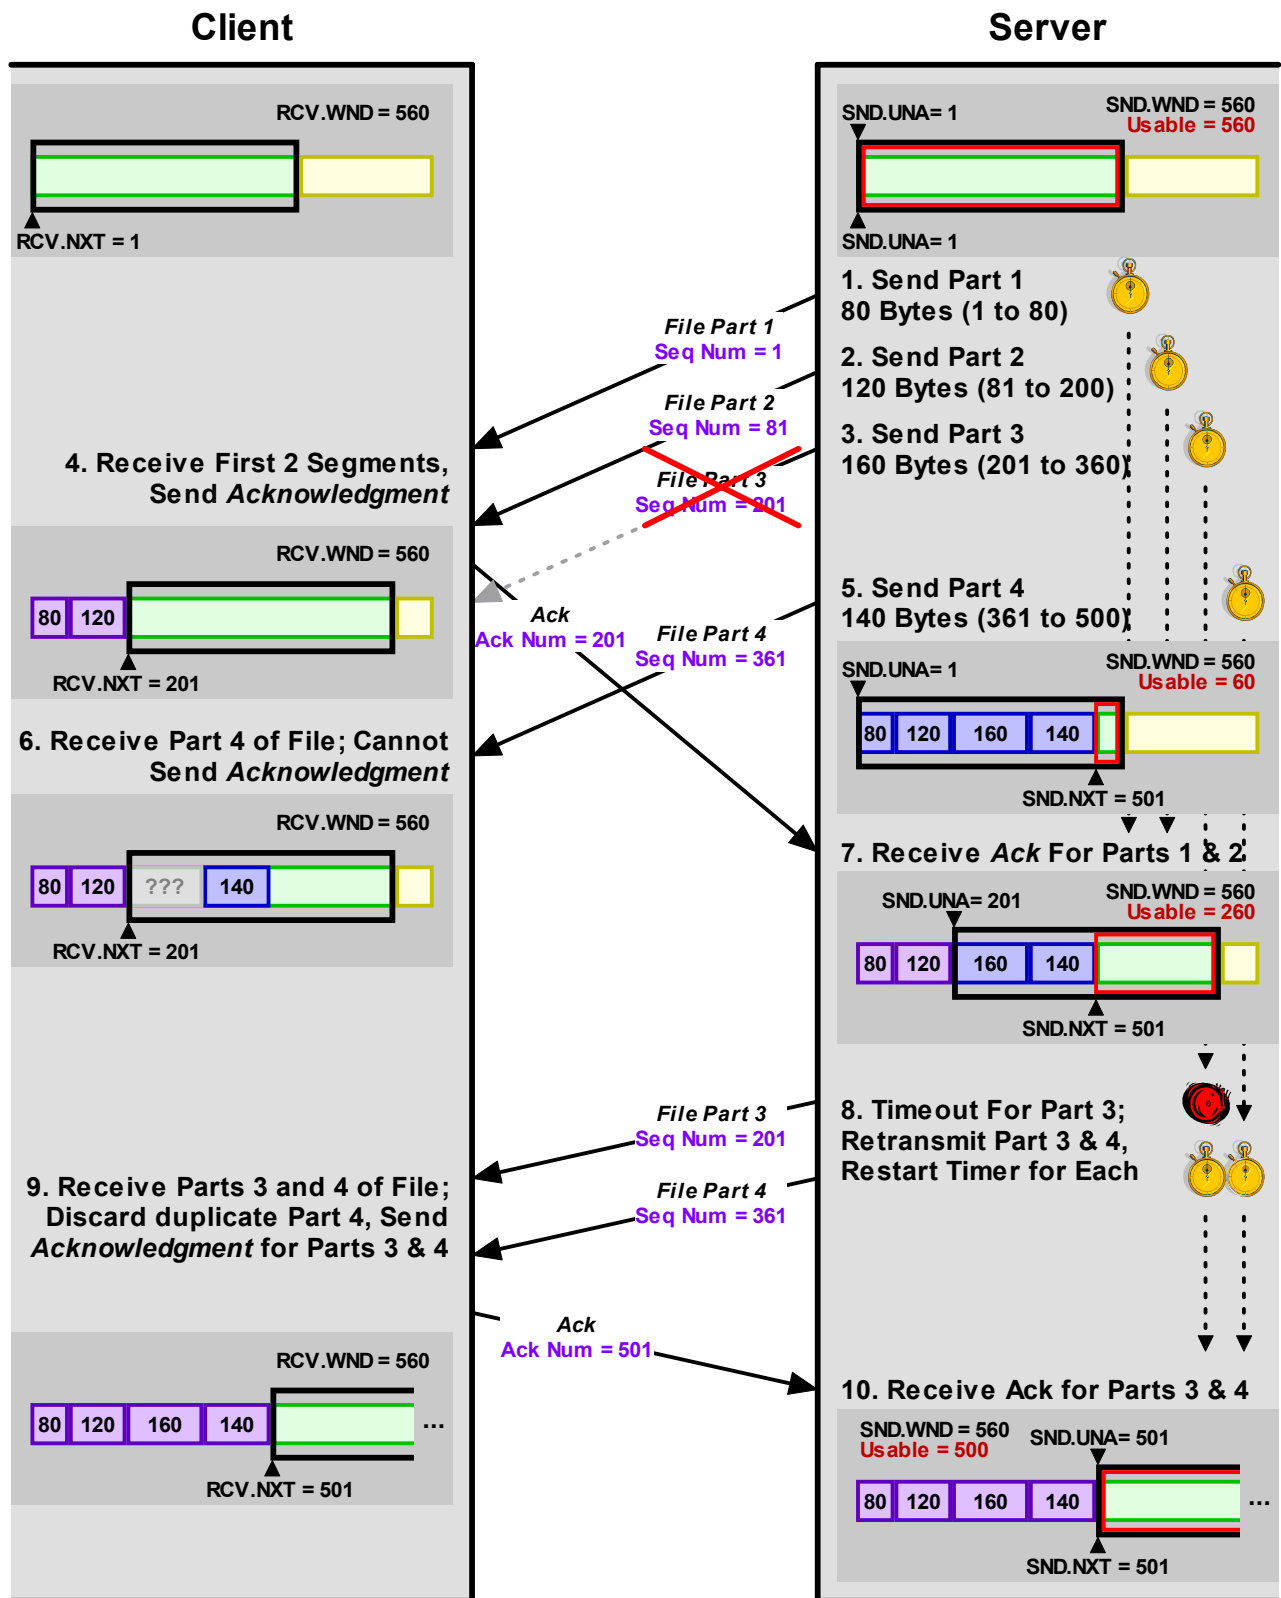

It is in fact this lack of knowledge about non-contiguous segments that is the core of the problem with non-contiguous segments. The solution is to extend the basic TCP sliding window algorithm with an optional feature that allows a device to acknowledge non-contiguous segments individually. This feature, introduced in RFC 1072 and refined in RFC 2018, is called TCP *selective acknowledgment*, abbreviated **SACK**.

To use SACK, the two devices on the connection must both support the feature, and must enable it by [negotiating](#) the *Selective Acknowledge Permitted (SACK-Permitted)* option in the SYN segment they use to establish the connection. Assuming this is done, either device is then permitted to include in a regular TCP segment a *Selective Acknowledgment (SACK)* option. This option contains a list of sequence number ranges of segments of data that have been received but have not been acknowledged since they are non-contiguous.

Each device modifies its retransmission queue so that each segment includes a flag that is set to 1 if the segment has been selectively acknowledged—the **SACK** bit. The device then uses a modified version of the “aggressive” method above, where upon retransmission of a segment all later segments are also retransmitted **unless** their SACK bits are set to 1.

For example, in our four-segment case, if the client receives Segment #4 but not Segment #3, when it sends back a segment with an *Acknowledgment Number* field value of 201 (for #1 and #2), it can include a SACK option that specifies “I have received bytes 361 through 500, but they are not yet acknowledged”. This can also be done in a second acknowledgment segment if Segment #4 arrives well after #1 and #2. The server recognizes this as the range of bytes for Segment #4, and turns on the SACK bit for Segment #4. When Segment #3 is retransmitted, the server sees the SACK bit for Segment #4 on and does not retransmit it. This is illustrated in [Figure 225](#).

**Figure 224: TCP "Aggressive" Retransmission Example**

This example is the same as that of [Figure 223](#) except that here the server is taking an "aggressive" approach to retransmitting lost segments. When segment #3 times out, both #3 and #4 are retransmitted and their retransmission timers restarted. (In this case #4 already arrived so this extra transmission was not useful.)

---

After Segment #3 is retransmitted, the SACK bit for Segment #4 is cleared. This is done for robustness, to handle cases where for whatever reason the client “changes its mind” about having received Segment #4. The client **should** send an acknowledgment with an *Acknowledgment Number* of 501 or higher, indicating “official” receipt of Segments #3 and #4. If this does not happen, the server must receive another selective acknowledge for Segment #4 to turn its SACK bit back on. Otherwise it will be automatically re-sent when its timer expires, or when Segment #3 is retransmitted.

**Key Concept:** The optional TCP *selective acknowledgment* feature provides a more elegant way of handling subsequent segments when a retransmission timer expires. When a device receives a non-contiguous segment it includes a special *Selective Acknowledgment (SACK)* option in its regular acknowledgment that identifies non-contiguous segments that have already been received, even if they are not yet acknowledged. This saves the original sender from having to retransmit them.

---

## **TCP Adaptive Retransmission and Retransmission Timer Calculations**

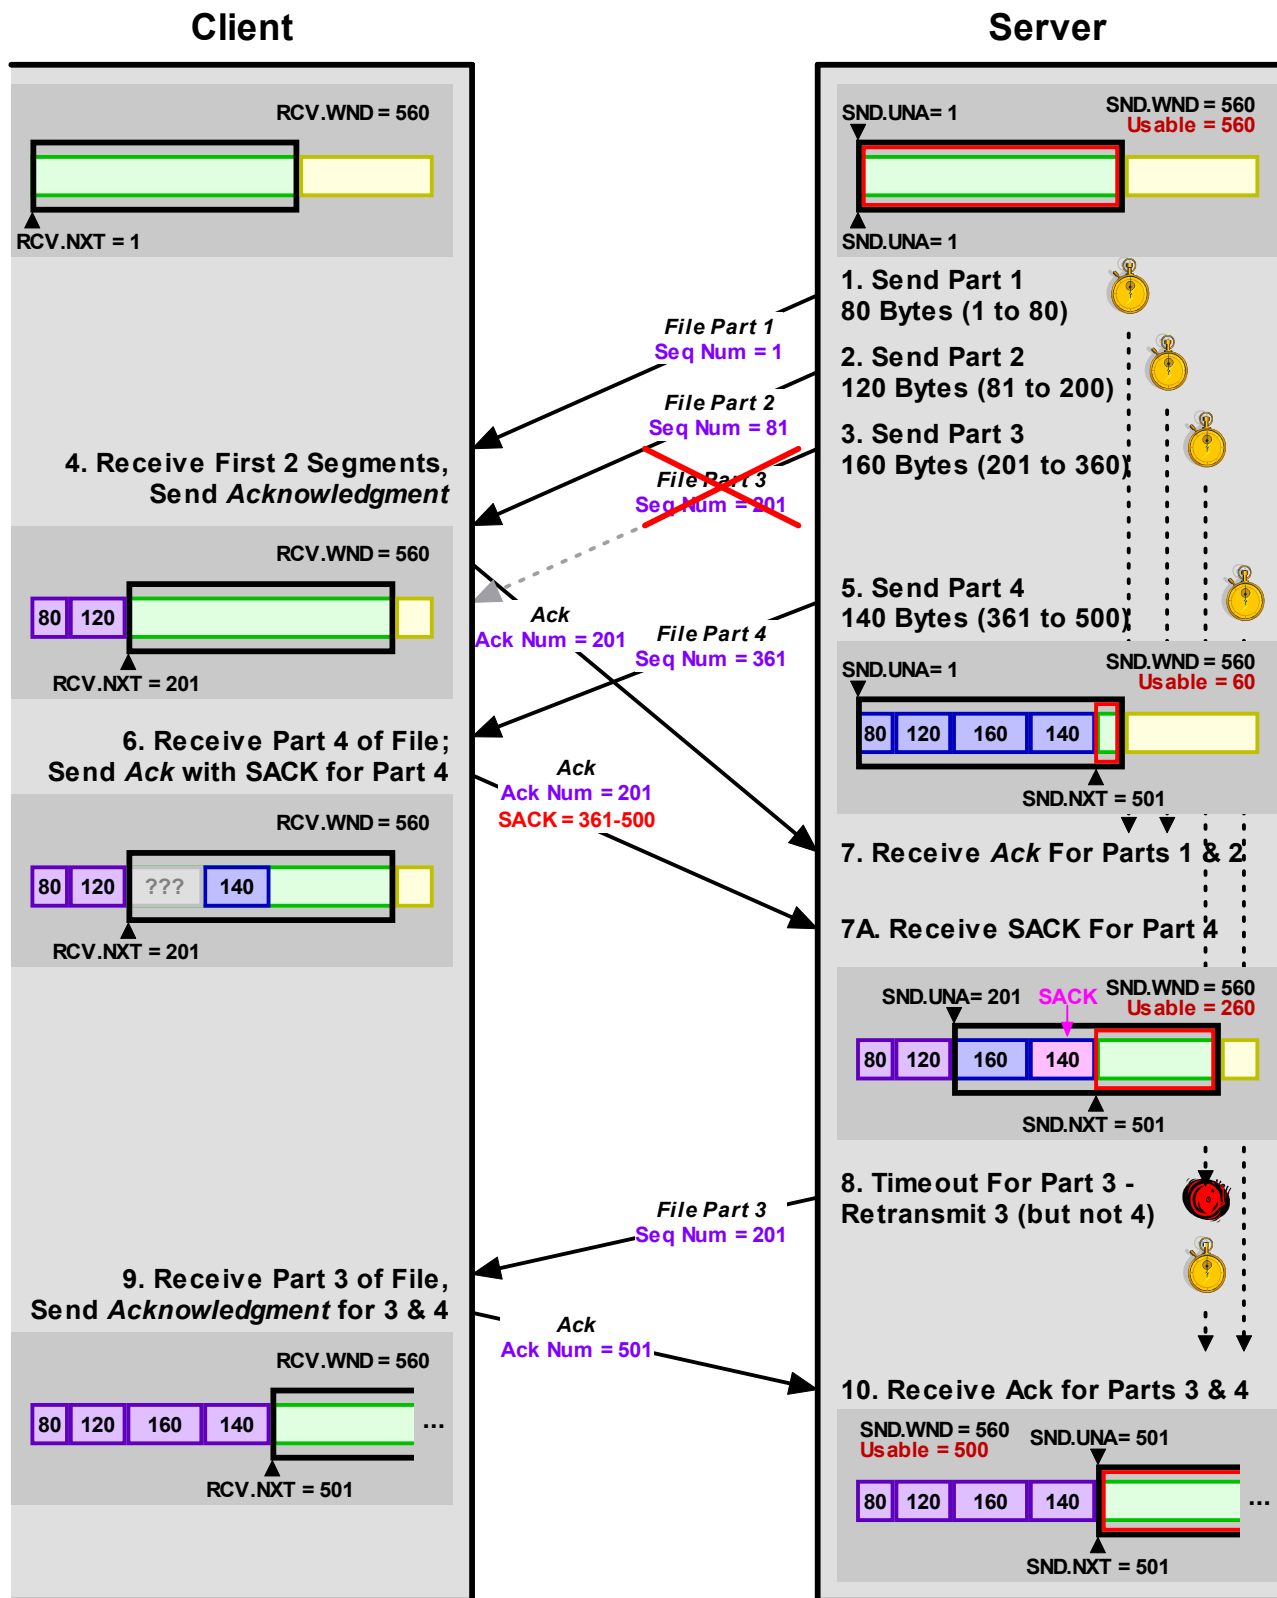

Whenever a TCP segment is transmitted, a copy of it is also placed on the [retransmission queue](#). When the segment is placed on the queue, a retransmission timer is started for the segment, which starts from a particular value and counts down to zero. It is this timer that controls how long a segment can remain unacknowledged before the sender gives up, concludes that it is lost and sends it again.

The length of time we use for retransmission timer is thus very important. If it is set too low, we might start retransmitting a segment that was actually received, because we didn't wait long enough for the acknowledgment of that segment to arrive. Conversely, if we set the timer too long, we waste time waiting for an acknowledgment that will never arrive, reducing overall performance.

### ***Difficulties in Choosing the Duration of the Retransmission Timer***

Ideally, we would like to set the retransmission timer to a value just slightly larger than the *round-trip time (RTT)* between the two TCP devices, that is, the typical time it takes to send a segment from a client to a server and the server to send an acknowledgment back to the client (or the other way around, of course). The problem is that there **is** no such “typical” round-trip time. There are two main reasons for this:

- ☉ **Differences In Connection Distance:** Suppose you are at work in the United States, and during your lunch hour you are transferring a large file between your workstation and a local server connection using 100 Mbps Fast Ethernet, at the same time you are downloading a picture of your nephew from your sister's personal Web site—which is connected to the Internet using an analog modem to an ISP in a small town near Lima, Peru. Would you want both of these TCP connections to use the same retransmission timer value? I certainly hope not!

**Figure 225: TCP Retransmission With Selective Acknowledgment (SACK)**

This is the example from [Figure 223](#) and [Figure 224](#), changed to use the optional *selective acknowledge* feature. After receiving Parts 1, 2 and 4 of the file, the client sends an Acknowledgment for 1 and 2 that includes a SACK for Part 4. This tells the server not to re-send Part 4 when Part 3's timer expires.

- 
- ☉ **Transient Delays and Variability:** The amount of time it takes to send data between any two devices will vary over time due to various happenings on the internet: fluctuations in traffic, router loads and so on. To see an example of this for yourself, try typing “ping www.tcpipguide.com” from the command line of an Internet-connected PC and you'll see how the reported times can vary.

### ***Adaptive Retransmission Based on Round-Trip Time Calculations***

It is for these reasons that TCP does not attempt to use a static, single number for its retransmission timers. Instead, TCP uses a dynamic, or *adaptive* retransmission scheme. TCP attempts to determine the approximate round-trip time between the devices, and adjusts it over time to compensate for increases or decreases in the average delay. The practical issues of how this is done are important, but are not covered in much detail in the main TCP standard. RFC 2988, *Computing TCP's Retransmission Timer*, discusses the issue extensively.

Round-trip times can “bounce” up and down, as we have seen, so we want to aim for an *average* RTT value for the connection. This average should respond to consistent movement up or down in the RTT without overreacting to a few very slow or fast acknowledgments. To allow this to happen, the RTT calculation uses a *smoothing* formula:

$$\text{New RTT} = (\alpha * \text{Old RTT}) + ((1-\alpha) * \text{Newest RTT Measurement})$$

Where “ $\alpha$ ” (alpha) is a *smoothing factor* between 0 and 1. Higher values of “ $\alpha$ ” (closer to 1) provide better smoothing and avoiding sudden changes as a result of one very fast or very slow RTT measurement. Conversely, this also slows down how quickly TCP reacts to more sustained changes in round-trip time. Lower values of alpha (closer to 0) make the RTT change more quickly in reaction to changes in measured RTT, but can cause “over-reaction” when RTTs fluctuate wildly.

### ***Acknowledgment Ambiguity***

Measuring the round-trip time between two devices is simple in concept: note the time that a segment is sent, note the time that an acknowledgment is received, and subtract the two. The measurement is more tricky in actual implementation, however. One of the main potential “gotchas” occurs when a segment is assumed lost and is retransmitted. The retransmitted segment carries nothing that distinguishes it from the original. When an acknowledgment is received for this segment, it's unclear as to whether this corresponds to the retransmission or the original segment. (Even though we decided the segment was lost and retransmitted it, it's possible the segment eventually got there, after taking a long time; or that the segment got there quickly but the **acknowledgment** took a long time!)

This is called *acknowledgment ambiguity*, and is not trivial to solve. We can't just decide to assume that an acknowledgment always goes with the oldest copy of the segment sent, because this makes the round-trip time appear too high. We also don't want to just assume an acknowledgment always goes with the latest sending of the segment, as that may artificially lower the average round-trip time.

---

## Refinements to RTT Calculation and Karn's Algorithm

TCP's solution to round-trip time calculation is based on the use of a technique called *Karn's algorithm*, after its inventor, Phil Karn. The main change this algorithm makes is the separation of the calculation of average round-trip time from the calculation of the value to use for timers on retransmitted segments.

The first change made under Karn's algorithm is to not use measured round-trip times for any segments that are retransmitted in the calculation of the overall average round-trip time for the connection. This completely eliminates the problem of acknowledgment ambiguity.

However, this by itself would not allow increased delays due to retransmissions to affect the average round-trip time. For this, we need the second change: incorporation of a *timer backoff* scheme for retransmitted segments. We start by setting the retransmission timer for each newly-transmitted segment based on the current average round-trip time. When a segment is retransmitted, the timer is not reset to the same value it was set for the initial transmission. It is “backed off” (increased) using a multiplier (typically 2) to give the retransmission more time to be received. The timer continues to be increased until a retransmission is successful, up to a certain maximum value. This prevents retransmissions from being sent too quickly and further adding to network congestion.

Once the retransmission succeeds, the round-trip timer is kept at the longer (backed-off) value until a valid round-trip time can be measured on a segment that is sent and acknowledged without retransmission. This permits a device to respond with longer timers to occasional circumstances that cause delays to persist for a period of time on a connection, while eventually having the round-trip time settle back to a long-term average when normal conditions resume.

**Key Concept:** TCP uses an adaptive retransmission scheme that automatically adjusts the amount of time to which retransmission timers are set, based on the average amount of time it takes to send segments between devices. This helps avoid retransmitting potentially lost segments too quickly or too slowly.

---

## TCP Window Size Adjustment and Flow Control

We have seen the importance of the concept of *window size* to TCP's sliding window mechanism. In a connection between a client and a server, the client tells the server the number of bytes it is willing to receive at one time from the server; this is the client's *receive window*, which becomes the server's *send window*. Likewise, the server tells the client how many bytes of data it is willing to take from the client at one time; this is the server's *receive window* and the client's *send window*.

---

The use of these windows is demonstrated in [the topic discussing TCP's basic data transfer and acknowledgment mechanism](#). However, just as the example in that topic was simplified because I didn't show what happens with lost segments, there's another way that it doesn't reflect the real world conditions of an actual Internet: the send and receive window sizes never changed during the course of communication.

### ***Impact of Buffer Management on TCP Window Size***

To understand why the window size may fluctuate, we need to understand what it represents. The simplest way of considering the window size is that it indicates the size of the device's receive buffer for the particular connection. That is, window size represents how much data a device can handle from its peer at one time before it is passed to the application process. Let's consider the aforementioned example. I said that the server's window size was 360. This means the server is willing to take no more than 360 bytes at a time from the client.

When the server receives data from the client, it places it into this buffer. The server must then do two distinct things with this data:

- ☉ **Acknowledgment:** The server must send an acknowledgment back to the client to indicate that the data was received.
- ☉ **Transfer:** The server must process the data, transferring it to the destination application process.

It is critically important that we differentiate between these two activities. Unfortunately, the TCP standards don't do a great job in this regard, which makes them very difficult to understand. The key point is that in the basic sliding windows system, data is acknowledged when received, but ***not necessarily*** immediately transferred out of the buffer. This means that it is possible for the buffer to fill up with received data faster than the receiving TCP can empty it. When this occurs, the receiving device may need to adjust window size to prevent the buffer from being overloaded.

Since the window size can be used in this manner to manage the rate at which data flows between the devices at the ends of the connection, it is the method by which TCP implements *flow control*, one of the “classical” jobs of the transport layer. Flow control is vitally important to TCP, as it is the method by which devices communicate their status to each other. By reducing or increasing window size, the server and client each ensure that the other device sends data just as fast as the recipient can deal with it.

### ***Reducing Send Window Size To Reduce The Rate Data Is Sent***

Let's go back to our earlier example so I can hopefully explain better what I mean, but let's make a few changes. First, to keep things simple, let's just look at the transmissions made from the client to the server, not the server's replies (other than acknowledgments)—this is illustrated in [Figure 222](#). As before, the client sends 140 bytes to the server. After sending the 140 bytes, the client has 220 bytes remaining in its usable window—360 in the send window less the 140 bytes it just sent.

---

Sometime later, the server receives the 140 bytes and puts them in the buffer. Now, in an “ideal world”, the 140 bytes go into the buffer, are acknowledged and immediately removed from the buffer. Another way of thinking of this is that the buffer is of “infinite size” and can hold as much as the client can send. The buffer's free space remains 360 bytes in size, so the same window size can be advertised back to the client. This was the “simplification” in the previous example.

As long as the server can process the data as fast as it comes in, it will keep the window size at 360 bytes. The client, upon receipt of the acknowledgment of 140 bytes and the same window size it had before, “slides” the full 360-byte window 140 bytes to the right. Since there are now 0 unacknowledged bytes, the client can now once again send 360 bytes of data. These correspond to the 220 bytes that were formerly in the usable window, plus 140 new bytes for the ones that were just acknowledged.

In the “real world”, however, that server might be dealing with dozens, hundreds or even thousands of TCP connections. The TCP might not be able to process the data immediately. Alternately, it is possible the application itself might not be ready for the 140 bytes for whatever reason. In either case, the server's TCP may not be able to immediately remove all 140 bytes from the buffer. If so, upon sending an acknowledgment back to the client, will want to change the window size that it advertises to the client, to reflect the fact that the buffer is partially filled.

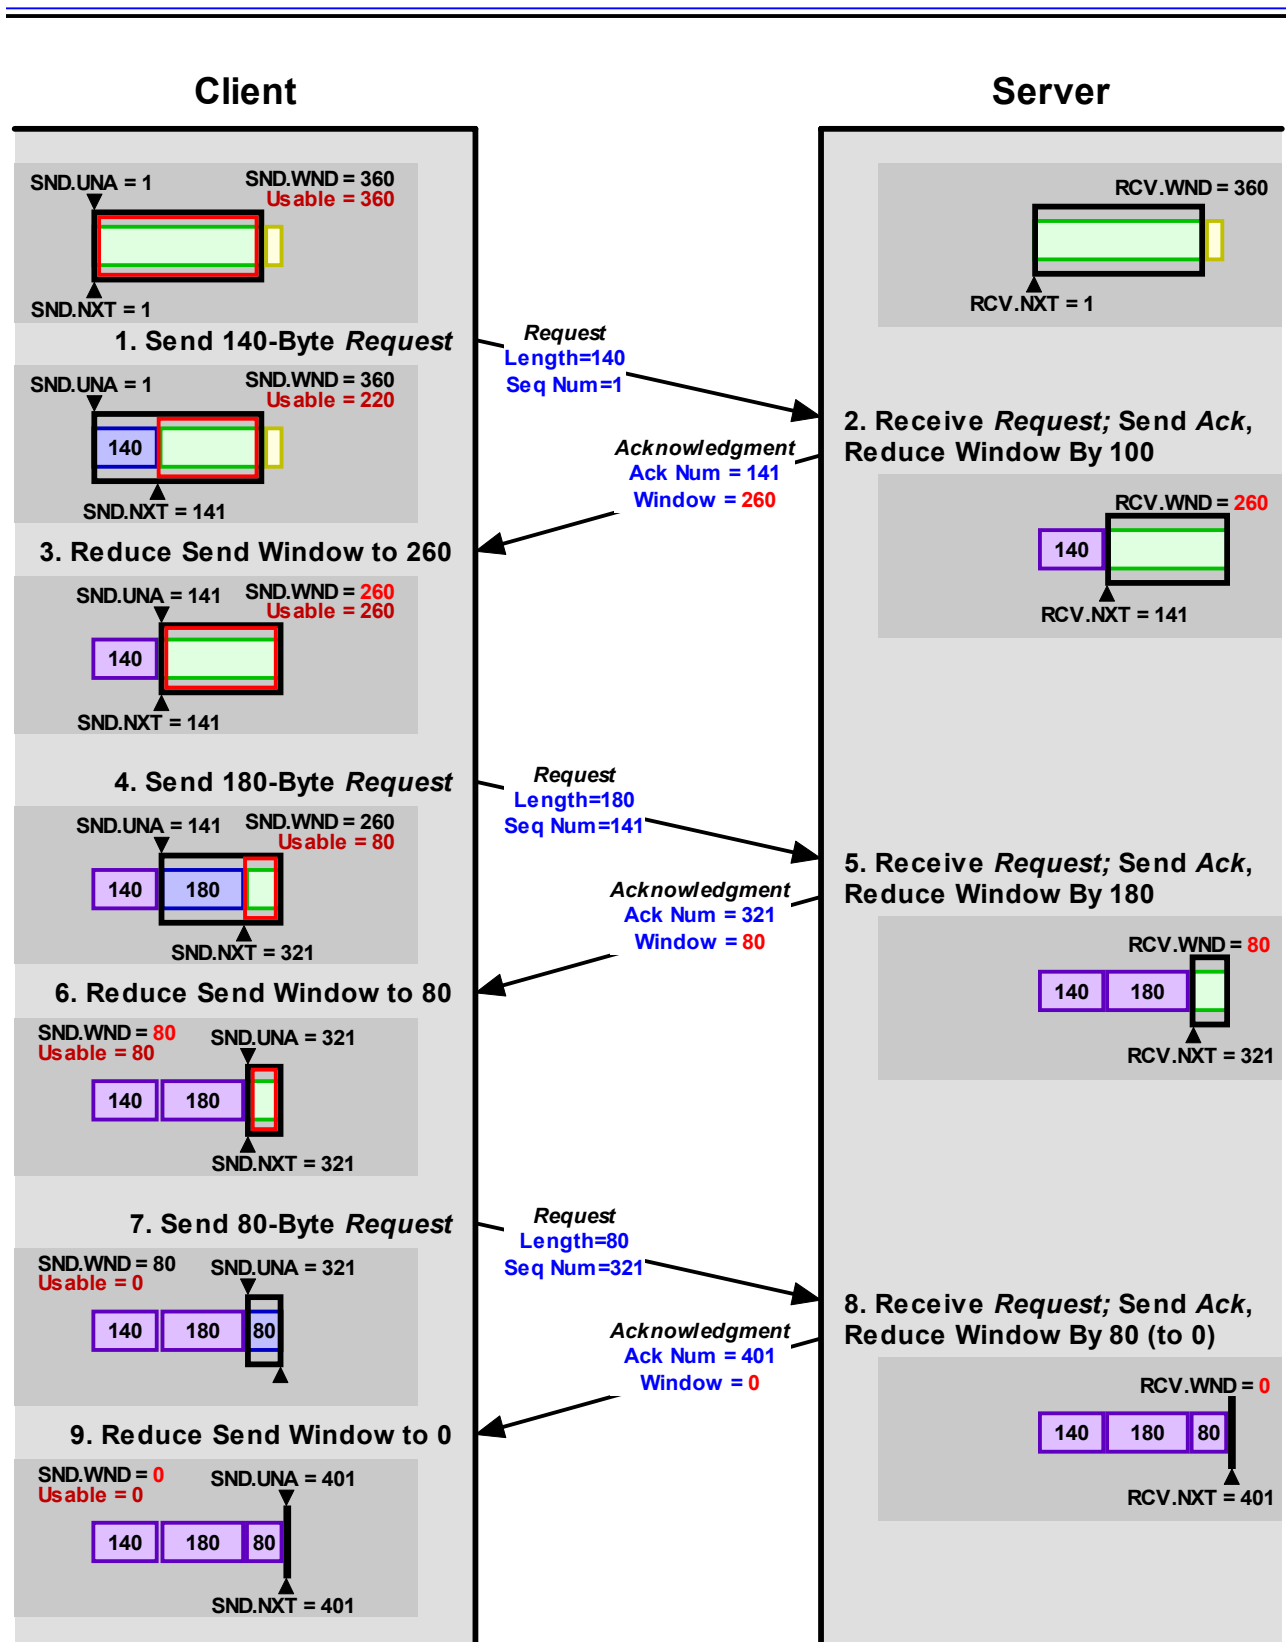

Suppose that we receive 140 bytes as above, but are able to send only 40 bytes to the application, leaving 100 bytes in the buffer. When we send back the acknowledgment for the 140 bytes, the server can reduce its send window by 100, to 260. When the client receives this segment from the server it will see the acknowledgment of the 140 bytes sent and slide its window 140 bytes to the right. However, as it slides this window, it reduces its size to only 260 bytes. We can consider this like sliding the *left edge* of the window 140 bytes, but the *right edge* only 40 bytes. The new, smaller window ensures that the server receives a maximum of 260 bytes from the client, which will fit in the 260 bytes remaining in its receive buffer. This is illustrated in the first exchange of messages (Steps #1 through #3) at the top of [Figure 226](#).

### ***Reducing Send Window Size To Stop The Sending of New Data***

What if the server is so bogged down that it can't process **any** of the bytes received? Let's suppose that the next transmission from the client is 180 bytes in size, but the server is so busy it can't remove any of them. It could buffer the 180 bytes and in the acknowledgment it sends for those bytes, reduce the window size by the same amount: from 260 to 80. When the client received the acknowledgment for 180 bytes it would see the window size had reduced by 180 bytes as well. It would “slide” its window by the same amount as the window size was reduced! This is effectively like the server saying “I acknowledge receipt of 180 bytes, but I am not allowing you to send any new bytes to replace them”.

Another way of looking at this is that the left edge of the window slides 180 bytes while the right edge remained fixed. And as long as the right edge of the window doesn't move, the client can't send any more data than it could before receipt of the acknowledgment. This is the middle exchange (Steps #4 to #6) in [Figure 226](#).

**Figure 226: TCP Window Size Adjustments and Flow Control**

This diagram shows three message cycles, each of which results in the server reducing its receive window. In the first, the server reduces it from 360 to 260, so the client's usable window can only increase by 40 when it gets the server's *Acknowledgment*. In the second and third the server reduces the window size by the amount of data it receives, which temporarily freezes the client's send window size, halting it from sending new data.

---

## Closing the Send Window

The process of window adjustment can continue, and of course, can be done by both devices—we are just only considering the client-sends-to-server side of the equation here. If the server continues to receive data from the client faster than it can pump it out to the application, it will continue to reduce the size of its receive window. To continue our example above, suppose that after the send window is reduced to 80, the client sends a third request, this one 80 bytes in length, but the server is still busy. The server then reduces its window all the way down to 0, which is called *closing* the window. This tells the client the server is very overloaded, and it should stop routine sending of data entirely, as shown in the bottom third of [Figure 226](#). Later on, when the server is less loaded down, it can increase the window size for this connection back up again, permitting more data to be transferred.

While conceptually simple, flow control using window size adjustment can be very tricky. If we aren't careful about how we make changes to window size, we can introduce serious problems in the operation of TCP. There are also special situations that can occur, especially in cases where the window size is made small in response to a device becoming busy. The next two topics explore [window management issues](#), as well as [changes that need to be made to the basic sliding windows system](#) to address them.

**Key Concept:** The TCP sliding window system is used not just for ensuring reliability through acknowledgments and retransmissions—it is also the basis for TCP's *flow control* mechanism. By increasing or reducing the size of its receive window, a device can raise or lower the rate at which its connection partner sends it data. In the case where a device becomes extremely busy, it can even reduce the receive window to zero, closing it; this will halt any further transmissions of data until the window is reopened.

---

## TCP Window Management Issues

Each of the two devices on a TCP connection can adjust the window size it advertises to the other, [to control the flow of data over the connection](#). Reducing the size of the window forces the other device to send less data; increasing the window size lets more data flow. In theory, we should be able to just let the TCP software on each of the devices change the window size as needed to match the speed at which data both enters the buffer and is removed from it to be sent to the receiving application.

### **Problems Associated With "Shrinking" The TCP Window**

Unfortunately, certain changes in window size can lead to undesirable consequences. These can occur both when the size of the window is reduced and when it is increased. For this reason, there are a few issues related to *window size management* that we need to consider. As in previous topics, we'll use for illustration a modification of the same client/server example first shown in [the topic explaining the basic TCP data transfer process](#).

---

One window size management matter is related to just how quickly a device reduces the size of its receive window when it gets busy. Let's say the server starts with a 360 byte receive window, as in the aforementioned example, and receives 140 bytes of data that it acknowledges, but cannot remove from the buffer immediately. The server can respond by reducing the size of the window it advertises back to the client. We even discussed in [the previous topic](#) the case where no bytes can be removed from the buffer at all, so the window size is reduced by the same 140 bytes that were added to the buffer. This “freezes” the right edge of the client's send window so it cannot send any additional data when it gets an acknowledgment.

What if the server were so overloaded that we actually needed to reduce the size of the **buffer** itself? Say memory was short and the operating system said “I know you have 360 bytes allocated for the receive buffer for this connection, but I need to free up memory so now you only have 240”. The server still can't immediately process the 140 bytes it received, so it would need to drop the window size it sent back to the client all the way from 360 bytes down to 100 (240 in the total buffer less the 140 already received).

In effect, doing this actually moves the right edge of the client's send window *back to the left*. It says “not only can't you send more data when you receive this acknowledgment, but you now can send **less**”. In TCP parlance, this is called *shrinking the window*.

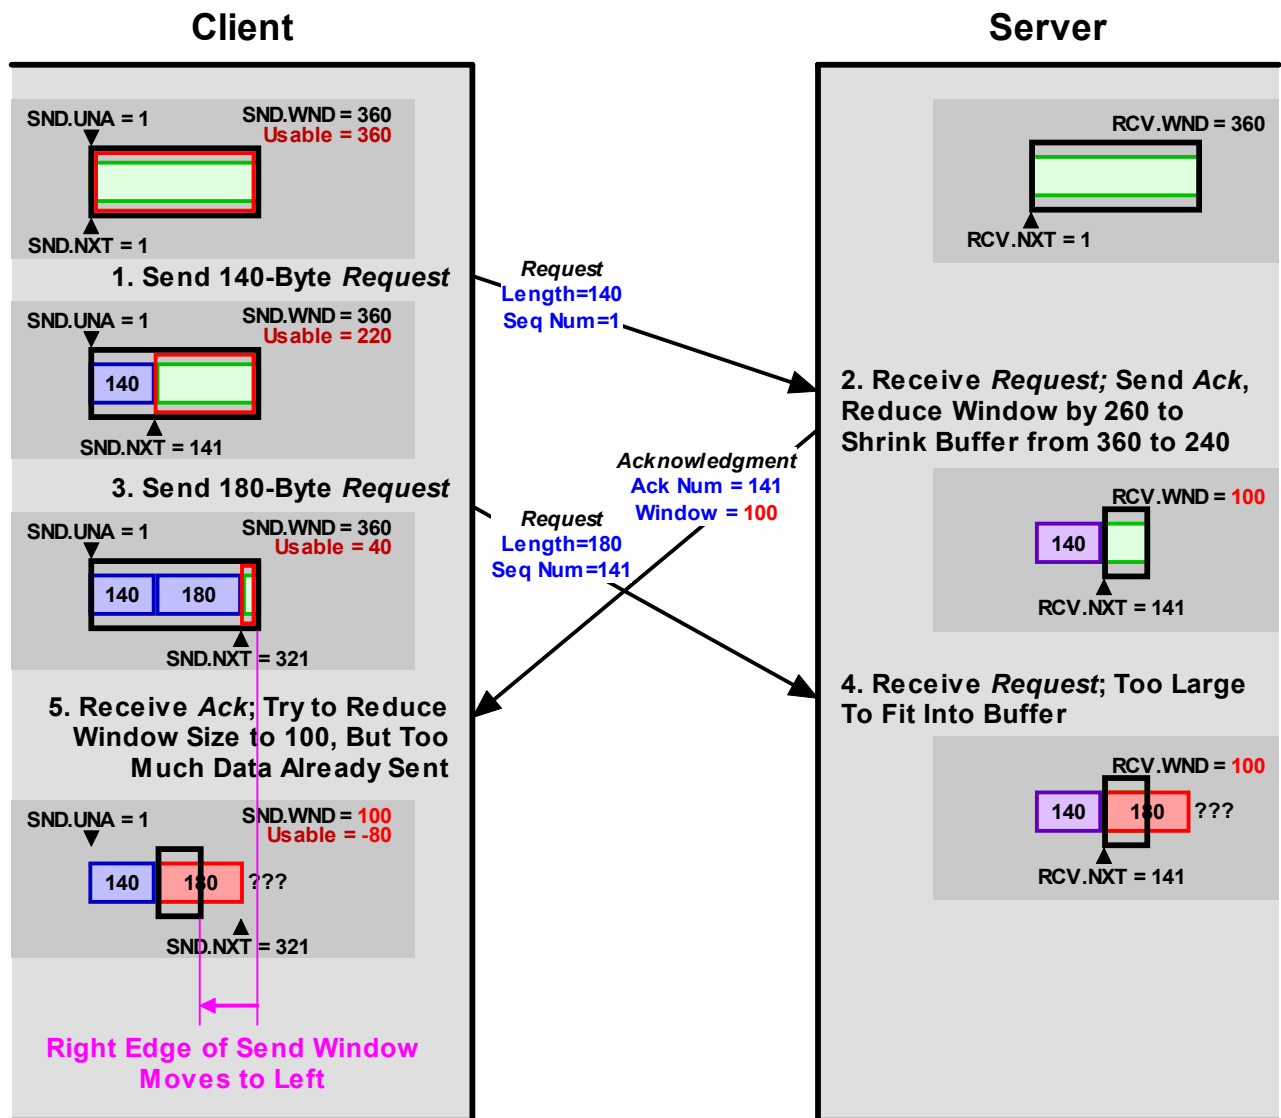

There's a very serious problem with doing this, however: while the original 140 bytes were in transit from the client to the server, the client still thought it had 360 bytes of total window, of which 220 bytes were *usable* (360 less 140). The client may well have already sent some of that 220 bytes of data to the server before it gets notification that the server has shrunk the window! If so, and the server reduces its buffer to 240 bytes with 140 used, when those 220 bytes show up at the server, only 100 will fit and any additional ones will need to be discarded. This will force the client to have to retransmit that data, which is inefficient.

[Figure 227](#) illustrates graphically how this situation would play out.

### ***Reducing Buffer Size Without “Shrinking” the Window***

To prevent this from occurring, TCP adds a simple rule to the basic sliding window mechanism: a device is not allowed to shrink the window. Note that there is a potential terminology ambiguity here. The words “shrinking” and “reducing” are sometimes used synonymously in colloquial discussions. As we've seen, there's nothing wrong with **reducing** the size of the window. The problem of “shrinking the window” only refers to the case where we reduce the window size so much that we contradict a prior window advertisement by *taking back* permission to send a certain number of bytes.

Another way of looking at this is that *shrinking* occurs whenever the server sends back a window size advertisement smaller than what the client considers its usable window size to be at that time. In this case, the server shrunk the window because at the time it was acknowledging the 140 bytes, it sent back a window size of 100, which is less than the 220-byte usable window the client had then.

**Figure 227: The Problem With “Shrinking” The TCP Window**

In this modification of the example of Figure 226, the client begins with a usable window size of 360. It sends a 140-byte segment and then a short time thereafter sends one of 180 bytes. The server is busy, however, and when it receives the first transmission decides to reduce its buffer to 240 bytes. It holds the 140 bytes just received and reduces its receive window all the way down to 100. When the client’s 180-byte segment arrives, there is only room for 100 of the 180 bytes in the server’s buffer. When the client gets the new window size advertisement of 100, it will have a problem because it already has 180 bytes sent but not acknowledged.

Of course, there may well be cases where we *do* need to reduce a buffer, so how should this be handled? Instead of shrinking the window, the server must be more patient. In the example above where the buffer needs to be reduced to 240, the server must send back a window size of 220, freezing the right edge of the client’s send window. The client can still fill the 360 byte buffer, but cannot send more than that. As soon as 120 bytes are removed from the server’s receive buffer, the buffer can then be reduced in size to 240 bytes with no data loss. Then the server can resume normal operation, increasing the window size as bytes are taken from the receive buffer.

**Key Concept:** A phenomenon called *shrinking the window* occurs when a device reduces its receive window so much that its partner device's usable transmit window shrinks in size (meaning that the right edge of its send window moves to the left). Since this can result in data already in transit having to be discarded, devices must instead reduce their receive window size more gradually.

---

### ***Handling a Closed Window and Sending Probe Segments***

Another special window management problem is how to deal with the case where a device must reduce the send window size all the way down to zero. This is called *closing the receive window*. Since the server's receive window is the client's send window, reducing its size to zero means the client cannot send any more data, as we saw at the end of the example in the previous topic. This situation continues until the client receives from the server a new acknowledgment with a non-zero *Window* field, which reopens the window. Then the client is able to send again.

The problem with this situation is that the client is dependent upon receipt of the “window opening” segment from the server. Like all TCP segments, this segment is carried over IP, which is unreliable. Remember, TCP is reliable only because it acknowledges sent data and retransmits lost data if necessary, but it can never **guarantee** that any particular segment gets to its destination. This means that when the server tries to re-open the window with an acknowledgment segment containing a larger *Window* field, it's possible that the client never gets the message. The client might conclude that a problem had occurred and terminate the connection.

To prevent this from happening, the client can regularly send special *probe* segments to the server. The purpose of these probes is to prompt the server to send back a segment containing the current window size. The probe segment can contain either zero or one byte of data, even when the window is closed. The probes will continue to be sent periodically until the window reopens, with the particular implementation determining the rate at which the probes are generated.

When the server decides to reopen the closed window, there is another potential pitfall: opening the window to too small a value. In general, when the receive window is too small, this leads to the generation of many small segments, greatly reducing the overall efficiency of TCP. [The next topic](#) explores this well-known problem and how it is resolved through changes to the basic sliding windows mechanism.

**Key Concept:** A device that reduces its receive window to zero is said to have *closed* the window. The other device's send window is thus closed; it may not send regular data segments. It may, however, send *probe* segments to check the status of the window, thus making sure it does not miss notification when the window reopens.

---

## **TCP "Silly Window Syndrome" and Changes To the Sliding Window System For Avoiding Small-Window Problems**

In [the topic describing TCP's Maximum Segment Size \(MSS\) parameter](#), I explained the trade-off in determining the optimal size of TCP segments. If segments are too large, we risk having them become fragmented at the IP level. Too small, and we get greatly reduced performance because we are sending a small amount of data in a segment with at least 40 bytes of header overhead. We also use up valuable processing time that is required to handle each of these small segments.

The MSS parameter ensures that we don't send segments that are too large—TCP is not allowed to create a segment larger than the MSS. Unfortunately, the basic sliding windows mechanism doesn't provide any *minimum* size of segment that can be transmitted. In fact, not only is it **possible** for a device to send very small, inefficient segments, the simplest implementation of flow control using unrestricted window size adjustments **ensures** that under conditions of heavy load, window size will become small, leading to significant performance reduction!

### ***How Silly Window Syndrome Occurs***

To see how this can happen, let's consider an example that is a variation on the one we've been using so far in this section. We'll assume the MSS is 360 and a client/server pair where again, the server's initial receive window is set to this same value, 360. This means the client can send a "full-sized" segment to the server. As long as the server can keep removing the data from the buffer as fast as the client sends it, we should have no problem. (In reality the buffer size would normally be larger than the MSS.)

Now, imagine that instead, the server is bogged down for whatever reason while the client needs to send it a great deal of data. For simplicity, let's say that the server is only able to remove 1 byte of data from the buffer for every 3 it receives. Let's say it also removes 40 additional bytes from the buffer during the time it takes for the next client's segment to arrive. Here's what will happen:

1. The client's send window is 360, and it has lots of data to send. It immediately sends a 360 byte segment to the server. This uses up its entire send window.
2. When the server gets this segment it acknowledges it. However, it can only remove 120 bytes so the server reduces the window size from 360 to 120. It sends this in the *Window* field of the acknowledgment.
3. The client receives an acknowledgment of 360 bytes, and sees that the window size has been reduced to 120. It wants to send its data as soon as possible, so it sends off a 120 byte segment.
4. The server has removed 40 more bytes from the buffer by the time the 120-byte segment arrives. The buffer thus contains 200 bytes (240 from the first segment, less the 40 removed). The server is able to immediately process one-third of those 120 bytes, or 40 bytes. This means 80 bytes are added to the 200 that already remain in the buffer, so 280 bytes are used up. The server must reduce the window size to 80 bytes.

- 
5. The client will see this reduced window size and send an 80-byte segment.
  6. The server started with 280 bytes and removed 40 to yield 240 bytes left. It receives 80 bytes from the client, removes one third, so 53 are added to the buffer, which becomes 293 bytes. It reduces the window size to 67 bytes (360-293).

This process, which is illustrated in [Figure 228](#), will continue for many rounds, with the window size getting smaller and smaller, especially if the server gets even more overloaded. Its rate of clearing the buffer may decrease even more, and the window may close entirely.

Let's suppose this happens. Now, eventually, the server will remove some of the data from this buffer. Let's say it removes 40 bytes by the time the first closed-window "probe" from the client arrives. The server then reopens the window to a size of 40 bytes. The client is still desperate to send data as fast as possible, so it generates a 40-byte segment. And so it goes, with likely all the remaining data passing from the client to the server in tiny segments until either the client runs out of data, or the server more quickly clears the buffer.

Now imagine the worst-case scenario. This time, it is the application process on the server that is overloaded. It is drawing data from the buffer one byte at a time. Every time it removes a byte from the server's buffer, the server's TCP opens the window with a window size of exactly 1 and puts this in the *Window* field in an acknowledgment to the client. The client then sends a segment with exactly one byte, refilling the buffer until the application draws off the next byte.

### ***The Cause of Silly Window Syndrome: Inefficient Reductions of Window Size***

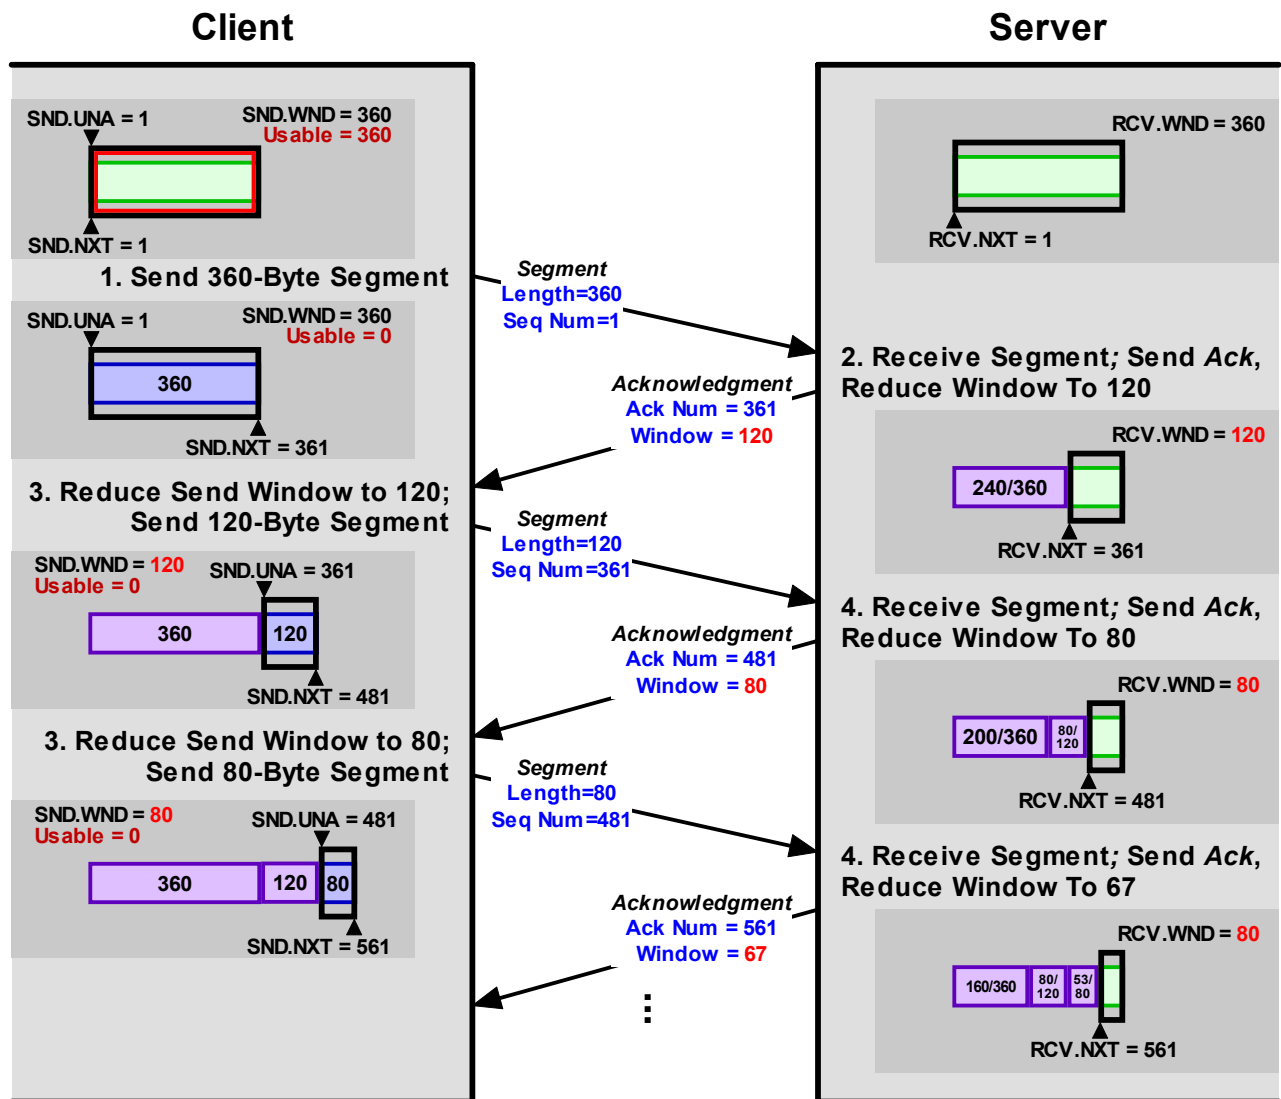

None of what we have seen above represents a *failure* per se of the sliding window mechanism. It is working properly to keep the server's receive buffer filled and to manage the flow of data. The problem is that the sliding window mechanism is only concerned with managing the buffer—it doesn't take into account the inefficiency of the small segments that result when the window size is micromanaged in this way.

In essence, by sending small window size advertisements we are "winning the battles but losing the war". Early TCP/IP researchers who discovered this phenomenon called it *silly window syndrome (SWS)*, a play on the phrase "sliding window system" that expresses their opinion on how it behaves when it gets into this state.

The examples above show how SWS can be caused by the advertisement of small window sizes by a receiving device. It is also possible for SWS to happen if the sending device isn't careful about how it generates segments for transmission, regardless of the state of the receiver's buffers.

For example, suppose the client TCP in the example above was receiving data from the sending application in blocks of 10 bytes at a time. However, the sending TCP was so impatient to get the data to the client that it took each 10-byte block and immediately packaged it into a segment, even though the next 10-byte block was coming shortly thereafter. This would result in a needless swarm of inefficient 10-data-byte segments.

**Figure 228: TCP “Silly Window Syndrome”**

This diagram shows one example of how the phenomenon known as TCP *silly window syndrome* can arise.

The client is trying to send data as fast as possible to the server, which is very busy and cannot clear its buffers promptly. Each time the client sends data the server reduces its receive window. The size of the messages the client sends shrinks until it is only sending very small, inefficient segments.

(Note that in this diagram I have shown the server’s buffer fixed in position, rather than sliding to the right as in the other diagrams in this section. This way you can see the receive window decreasing in size more easily.

**Key Concept:** The basic TCP sliding window system sets no minimum size on transmitted segments. Under certain circumstances, this can result in a situation where many small, inefficient segments are sent, rather than a smaller number of large ones. Affectionately termed *silly window syndrome (SWS)*, this phenomenon can occur either as a result of a recipient advertising window sizes that are too small, or a transmitter being too aggressive in immediately sending out very small amounts of data.

---

### ***Silly Window Syndrome Avoidance Algorithms***

Since SWS is caused by the basic sliding window system not paying attention to the result of decisions that create small segments, dealing with SWS is conceptually simple: change the system so that we avoid small window size advertisements, and at the same time, also avoid sending small segments. Since both the sender and recipient of data contribute to SWS, changes are made to the behavior of both to avoid SWS. These changes are collectively termed *SWS avoidance algorithms*.

#### **Receiver SWS Avoidance**

Let's start with SWS avoidance by the receiver. As we saw in the initial example above, the receiver contributed to SWS by reducing the size of its receive window to smaller and smaller values due its being busy. This caused the right edge of the sender's send window to move by ever-smaller increments, leading to smaller and smaller segments. To avoid SWS, we simply make the rule that the receiver may not update its advertised receive window in such a way that this leaves too little usable window space on the part of the sender. In other words, we restrict the receiver from moving the right edge of the window by too small an amount. The usual minimum that the edge may be moved is either the value of the MSS parameter, or one-half the buffer size, whichever is less.

Let's see how we might use this in the example above. When the server receives the initial 360-byte segment from the client and can only process 120 bytes, it does not reduce the window size to 120. It reduces it all the way to 0, closing the window. It sends this back to the client, which will then stop and not send a small segment. Once the server has removed 60 more bytes from the buffer, it will now have 180 bytes free, half the size of the buffer. It now opens the window up to 180 bytes in size and sends the new window size to the client.

It will continue to only advertise either 0 bytes, or 180 or more, not smaller values in between. This seems to slow down the operation of TCP, but it really doesn't. Because the server is overloaded, the limiting factor in overall performance of the connection is the rate at which the server can clear the buffer. We are just exchanging many small segments for a few larger ones.

---

## Sender SWS Avoidance and Nagle's Algorithm

SWS avoidance by the sender is accomplished generally by imposing “restraint” on the part of the transmitting TCP. Instead of trying to immediately send data as soon as we can, we wait to send until we have a segment of a reasonable size. The specific method for doing this is called *Nagle's algorithm*, named for its inventor, John Smith. (Just kidding, it was John Nagle. ☺) Simplified, this algorithm works as follows:

- ☉ As long as there is no unacknowledged data outstanding on the connection, as soon as the application wants, data can be immediately sent. For example, in the case of an interactive application like [Telnet](#), a single keystroke can be “pushed” in a segment.
- ☉ While there *is* unacknowledged data, all subsequent data to be sent is held in the transmit buffer and not transmitted until either all the unacknowledged data is acknowledged, or we have accumulated enough data to send a full-sized (MSS-sized) segment. This applies even if a “push” is requested by the user.

This might seem strange, especially the part about buffering data despite a push request! You might think this would cause applications like Telnet to “break”. In fact, Nagle's algorithm is a very clever method that suits the needs of both low-data-rate interactive applications like Telnet and high-bandwidth file transfer applications.

If you are using something like Telnet where the data is arriving very slowly (humans are very slow compared to computers), the initial data (first keystroke) can be pushed right away. The next keystroke has to wait for an acknowledgment, but this will probably come reasonably soon relative to how long it takes to hit the next key. In contrast, more conventional applications that generate data in large amounts will automatically have the data accumulated into larger segments for efficiency.

Nagle's algorithm is actually far more complex than this description, but this topic is already getting too long. RFC 896 discusses it in (much) more detail.

**Key Concept:** Modern TCP implementations incorporate a set of SWS avoidance algorithms. When receiving, devices are programmed not to advertise very small windows, waiting instead until there is enough room in the buffer for one of a reasonable size. Transmitters use Nagle's algorithm to ensure that small segments are not generated when there are unacknowledged bytes outstanding.

---

## TCP Congestion Handling and Congestion Avoidance Algorithms

By changing the window size that a device advertises to a peer on a TCP connection, the device can increase or decrease the rate at which its peer sends it data. This is how the TCP sliding window system implements flow control between the two connected devices. We've seen how this works in the last few topics, including the changes required to the “basic” mechanism to ensure performance remains high by reducing the number of small segments sent.

---

## Why TCP Must Monitor and Deal With Internetwork Congestion

Flow control is a very important part of regulating the transmission of data between devices, but it is limited in the following respect: it only considers what is going on within each of the devices on the connection, and **not** what is happening in devices between them. In fact, this “self-centeredness” is symptomatic of architectural layering. Since we are dealing with how TCP works between a typical server and client at layer four, we don't worry about how data gets between them; that's the job of the Internet Protocol at layer three.

In practice, what is going on at layer three can be quite important. Considered from an abstract point of view, our server and client may be connected “directly” using TCP, but all the segments we transmit are carried across an internetwork of networks and routers between them. These networks and routers are also carrying data from many other connections and higher-layer protocols. If the internetwork becomes very busy, the speed at which segments are carried between the endpoints of our connection will be reduced, and they could even be dropped. This is called *congestion*.

Again, at the TCP level, there is no way to directly comprehend what is causing congestion or why. It is perceived simply as inefficiencies in moving data from one device to another, through the need for some segments to be retransmitted. However, even though TCP is mostly oblivious of what is happening on the internetwork, it **must** be smart enough to understand how to deal with congestion and not exacerbate it.

Recall that each segment that is transmitted is [placed on the retransmission queue with a retransmission timer](#). Now, suppose congestion dramatically increased on the internetwork, and there were no mechanisms in place to handle congestion. Segments would be delayed or dropped, which would cause them to time out and be retransmitted. This would increase the amount of traffic on the internetwork between our client and server. Furthermore, there might be thousands of other TCP connections behaving similarly. Each would keep retransmitting more and more segments, increasing congestion further, leading to a vicious circle. Performance of the entire internetwork would decrease dramatically, resulting in a condition called *congestion collapse*.

The message is clear: TCP cannot just ignore what is happening on the internetwork between its connection endpoints. To this end, TCP includes several specific algorithms that are designed to respond to congestion, or avoid it in the first place. Many of these techniques can be considered, in a way, to be methods by which a TCP connection is made less “selfish”—that is, it tries to take into account the existence of other users of the internetwork over which it operates. While no single connection by itself can solve congestion of an entire internetwork, having all devices implement these measures collectively reduces congestion due to TCP.

The first issue is that we need to know when congestion is taking place. By definition, congestion means intermediate devices—routers—are overloaded. Routers respond to overloading by dropping datagrams. When these datagrams contain TCP segments, the segments don't reach their destination, and they are therefore left unacknowledged and will eventually expire and be retransmitted. This means that when a device sends TCP segments and does not receive acknowledgments for them, it can be assumed that in most

---

cases, they have been dropped by intermediate devices due to congestion. By detecting the rate at which segments are sent and not acknowledged, a TCP device can infer the level of congestion on the network between itself and its TCP connection peer.

## ***TCP Congestion Handling Mechanisms***

We must then decide what to do with this information. The main TCP standard, RFC 793, includes very little information about TCP congestion handling issues. That is because early versions of TCP based solely on this standard didn't include congestion handling measures—it was problems with these early implementations that lead to the discovery that congestion was an important issue. The measures used in modern devices were developed over the years, and eventually documented in RFC 2001, *TCP Slow Start, Congestion Avoidance, Fast Retransmit, and Fast Recovery Algorithms*.

Here is a simplified description of each of the four techniques that comprise the name of this standard.

### **Slow Start**

In the original implementation of TCP, as soon as a connection was established between two devices, they could each go “hog wild”, sending segments as fast as they liked as long as there was room in the other device's receive window. In a busy internetwork the sudden appearance of a large amount of new traffic could exacerbate any existing congestion.

To alleviate this, modern TCP devices are restrained in the rate at which they initially send segments. Each sender is at first restricted to sending only an amount of data equal to one “full-sized” segment—that is, equal to the [MSS value](#) for the connection. Each time an acknowledgment is received, the amount of data the device can send is increased by the size of another full-sized segment. Thus, the device “starts slow” in terms of how much data it can send, with the amount it sends increasing until either the full window size is reached or congestion is detected on the link. In the latter case, the congestion avoidance feature, described below, is used.

### **Congestion Avoidance**

When potential congestion is detected on a TCP link, a device responds by throttling back the rate at which it sends segments. A special algorithm is used that allows the device to drop the rate at which segments are sent quickly when congestion occurs. The device then uses the *Slow Start* algorithm just above to gradually increase the transmission rate back up again to try to maximize throughput without congestion occurring again.

### **Fast Retransmit**

We've already seen in [our look at TCP segment retransmission](#) that when segments are received by a device out of order (meaning, non-contiguously), the recipient will only acknowledge the ones received contiguously. The Acknowledgment Number will specify the

---

sequence number of the byte it expects to receive next. So, in the example given in that topic, Segment #1 and #2 were acknowledged while #4 was not, because #3 was not received.

It is possible for a TCP device to in fact respond with an acknowledgment when it receives an out-of-order segment, simply “reiterating” that it is stuck waiting for a particular byte number. So, when the client in that example receives Segment #4 and not Segment #3, it could send back an Acknowledgment saying “I am expecting the first byte of Segment #3 next”.

Now, suppose this happens over and over. The server, not realizing that Segment #3 was lost, sends Segment #5, #6 and so on. Each time one is received, the client sends back an acknowledgment specifying the first byte number of Segment #3. Eventually, the server can reasonably conclude that Segment #3 is lost, even if its retransmission timer has not expired.

The *Fast Retransmit* feature dictates that if three or more of these acknowledgments are received, all saying “I want the segment starting with byte #N”, then it's probable that the segment starting with byte #N has been lost, usually because it was dropped due to congestion. In this case, the device will immediately retransmit the missing segment without going through the normal retransmission queue process. This improves performance by eliminating delays that would suspend effective data flow on the link.

### **Fast Recovery**

When *Fast Retransmit* is used to re-send a lost segment, the device using it performs *Congestion Avoidance*, but does not use *Slow Start* to increase the transmission rate back up again. The rationale for this is that since multiple *ACKs* were received by the sender all indicating receipt of out-of-order segments, this indicates that several segments have already been removed from the flow of segments between the two devices. For efficiency reasons, then, the transmission rate can be increased more quickly than when congestion occurs in other ways. This improves performance compared to using the regular *Congestion Avoidance* algorithm after *Fast Retransmit*.

### **Relationship of Congestion Handling Mechanisms**

In practice, these features are all related to each other. *Slow Start* and *Congestion Avoidance* are distinct algorithms but are implemented using a single mechanism, involving the definition of a *Congestion Window* that limits the size of transmissions and whose size is increased or decreased depending on congestion levels. *Fast Retransmit* and *Fast Recovery* are implemented as changes to the mechanism that implements *Slow Start* and *Congestion Avoidance*.

I realize that this is somewhat cryptic; congestion handling is a rather complex process. If you want to learn more, RFC 2001 contains the technical details, showing how each of the algorithms is implemented in each device. I have specifically omitted those details from this topic since I feel my summary descriptions are already complicated enough, and my goal was simply to help you get a feel for how congestion is handled in TCP in general terms.

**Key Concept:** TCP flow control is an essential part of regulating the traffic flow between TCP devices, but takes into account only how busy the two TCP endpoints are. It is also important to take into account the possibility of *congestion* of the networks over which any TCP session is established, which can lead to inefficiency through dropped segments. To deal with congestion and avoid contributing to it unnecessarily, modern TCP implementations include a set of congestion avoidance algorithms that alter the normal operation of the sliding window system to ensure more efficient overall operation.

---

## **Summary Comparison of TCP/IP Transport Layer Protocols (UDP and TCP)**

The [User Datagram Protocol \(UDP\)](#) and [Transmission Control Protocol \(TCP\)](#) are the “siblings” of the transport layer in the TCP/IP protocol suite. They perform the same role, providing an interface between applications and the data-moving capabilities of the Internet Protocol (IP), but they do it in very different ways. The two protocols thus provide choice to higher-layer protocols, allowing each to select the appropriate one depending on its needs.

I have described UDP and TCP in detail in their own sections. However, these sections take some time to read; the UDP section is several pages and the TCP section has many more! For your convenience I have included here [Table 161](#), which helps illustrate the most important basic attributes of both protocols and how they contrast with each other:

**Table 161: Summary Comparison of UDP and TCP**

<b>Characteristic / Description</b>	<b>UDP</b>	<b>TCP</b>
<b>General Description</b>	Simple, high-speed, low-functionality “wrapper” that interfaces applications to the network layer and does little else.	Full-featured protocol that allows applications to send data reliably without worrying about network layer issues.
<b>Protocol Connection Setup</b>	Connectionless; data is sent without setup.	Connection-oriented; connection must be established prior to transmission.
<b>Data Interface To Application</b>	Message-based; data is sent in discrete packages by the application.	Stream-based; data is sent by the application with no particular structure.
<b>Reliability and Acknowledgments</b>	Unreliable, best-effort delivery without acknowledgments.	Reliable delivery of messages; all data is acknowledged.
<b>Retransmissions</b>	Not performed. Application must detect lost data and retransmit if needed.	Delivery of all data is managed, and lost data is retransmitted automatically.
<b>Features Provided to Manage Flow of Data</b>	None	Flow control using sliding windows; window size adjustment heuristics; congestion avoidance algorithms.
<b>Overhead</b>	Very low	Low, but higher than UDP
<b>Transmission Speed</b>	Very high	High, but not as high as UDP
<b>Data Quantity Suitability</b>	Small to moderate amounts of data (up to a few hundred bytes)	Small to very large amounts of data (up to gigabytes)
<b>Types of Applications That Use The Protocol</b>	Applications where data delivery speed matters more than completeness, where small amounts of data are sent; or where multicast/broadcast are used.	Most protocols and applications sending data that must be received reliably, including most file and message transfer protocols.
<b>Well-Known Applications and Protocols</b>	Multimedia applications, DNS, BOOTP, DHCP, TFTP, SNMP, RIP, NFS (early versions)	FTP, Telnet, SMTP, DNS, HTTP, POP, NNTP, IMAP, BGP, IRC, NFS (later versions)

---

# **TCP/IP Application Layer Protocols, Services and Applications (OSI Layers 5, 6 and 7)**

The [OSI Reference Model](#) is used to describe the architecture of networking protocols and technologies and to show how they relate to one another. In the chapter describing the OSI model, I mentioned that [its seven layers could be organized into two layer groupings](#): the lower layers (1 through 4) and the upper layers (5 through 7). While there are certainly other ways to divide the OSI layers, I feel this split best reflects the different roles that the layers play in a network.

The lower layers are concerned primarily with the mechanics of formatting, encoding and sending data over a network; they involve software elements but are often closely associated with networking hardware devices. In contrast, the upper layers are concerned mainly with user interaction and the implementation of software applications, protocols and services that let us actually make use of the network. These elements generally don't need to worry about details, relying on the lower layers to ensure that data gets to where it needs to go reliably.

In this chapter I describe the details of the many protocols and applications that run on the upper layers in modern networks and internetworks. The organization of this chapter is quite different than the previous one. I felt that there was benefit to explaining the technologies in each of the lower layers separately. This is possible because with a few exceptions, the dividing lines between the lower layers are fairly well-established, and this helped show how the layers differ.

The upper layers are much more difficult to separate from each other, because there are many technologies and applications that implement more than one of layers 5 through 7. Furthermore, even differentiating between these layers becomes less important near the top of the networking stack. In fact, the TCP/IP protocol suite uses an architecture that lumps all the higher layers together anyway.

For these reasons, this chapter is divided functionally and not by layer. It contains four different sections that cover distinct higher-layer protocol and application areas. The first discusses naming system, especially the TCP/IP Domain Name System. The second overviews file and resource sharing protocols, with a focus on the Network File System. The third covers network configuration and management protocols, which includes the host configuration protocols BOOTP and DHCP. The last and largest section covers end-user applications and application protocols, including general file transfer, electronic mail, Usenet, the World Wide Web, interactive protocols (such as Telnet) and administration utilities.

---

# **Name Systems and TCP/IP Name Registration and Name Resolution**

Humans and computers first started dealing with each other several decades ago. The relationship between man (and woman!) and machine has been a pretty good one overall, and this is reflected in the fact that while computers were once just the province of techies, they are now *mainstream*. However, there are areas where humans and computers simply don't see eye to eye. One of these is in the way that we deal with information.

Computers work best with numbers, while most people prefer... not to work with numbers. This fundamental disconnect represented a problem for the designers of networking technology. It made sense from a technical standpoint to design addressing schemes for networks and internetworks using simple numeric identifiers, for simplicity and efficiency. Unfortunately, identifying computers using numeric addresses is cumbersome for people, and becomes more so as the number of devices on a network increases.

To solve this problem, the techies went to work, and came up with *name systems* for networks. These mechanisms allow computers to continue to use simple, efficient numeric addresses, while letting humans specify easier-to-remember names that identify them. This way, everyone is happy. Well, almost everyone I guess. These systems mean those of us studying networks have one more thing to learn. ☺

In this section I explain both the theory and practice behind networking name systems. I begin with a section that describes the motivation for name systems and the important concepts and techniques behind how they work. I then have a large section devoted to the name systems used for TCP/IP. This includes both the very important Domain Name System (DNS), as well as the older host table method that preceded it.

---

## **Name System Issues, Concepts and Techniques**

Name systems can be considered in some ways the “diplomats” of the networking protocol stack. Just as a political diplomat is skilled at speaking multiple language and ensuring good communications between those who may view the world in different ways, name systems bridge the gulf between the numeric addresses that computers like to use, and the simpler names that humans prefer.

Before looking at specific name systems, I felt it made sense to discuss them generally. This will help us understand both the reasons why these systems are important, and also the concepts that underlie all name systems regardless of specific implementation. I begin this section with an overview of name systems and a discussion of why they were created. I then discuss the different main functions of a name system: the name space, name registration and name resolution. I then expand upon this functional overview, illustrating how name spaces and architectures work, the issues behind name registration and administration, and finally, name resolution techniques and the practical issues in the resolution process.

Since this is an introductory section, I have attempted to stick to general descriptions and not make too many mentions of specific name systems in the topics here. However, I like to use examples to explain concepts and for this purpose do make reference to the TCP/IP Domain Name System (DNS) at times. However, you do not need to be familiar with DNS to follow this section.

### **Name System Overview and Motivation**

In [the introduction to this section on name systems](#) I mentioned one of several important differences between humans and computers: how we prefer to deal with information. Computers work with numbers, while very few of us humans like to do so. This distinction becomes particularly important when we look at how identifiers or addresses are assigned to network devices.

#### ***Symbolic Names for Addressing***

To a computer, there is no problem with simply assigning a number to each device on the network and using those numbers to move information around. Your computer would be perfectly happy if you assigned a number like 341,481,178,295 to it and all the other machines on your network, and then issued commands such as “send this file to machine 56,712,489,901”. However, most humans don't want to use a network in this manner. These long cryptic numbers don't mean anything to them. They want to tell their machine “send this file to Joe's computer”; “print this on the color laser in the Sales department”, or “check CNN's Web site to see what the latest headlines are”.

It is this disconnect that led to the development of *name systems*. These technologies allow computers on a network to be given both a conventional numeric address and also a more “user-friendly” human-readable name. This name is comprised of letters, numbers and other special symbols, and is sometimes called a *symbolic name*; it can be used as an

---

alternative form of addressing for devices. The name system takes care of the functions necessary to manage this system, including ensuring that names are unique, translating from names to numbers, and managing the list of names and numbers.

### ***A Paradox: Name Systems Are Both Essential and Unnecessary?***

What's interesting about name systems is that they are extremely important to networks... but at the same time, they often aren't strictly necessary for a network to operate. This seeming paradox is due again to the difference between humans and computers. Computers only need the numeric addressing scheme, not the "human names" assigned to them. So the computers and the network can still work—but it will be much harder for us people to use them!

An example of this can most readily be seen when a problem disables the operation of a part of the [Domain Name System \(DNS\)](#) used to provide naming services on the Internet. Technically, DNS isn't needed to use the Internet, because all communications use IP addresses. This means that even though you might normally access CNN's web site at "www.cnn.com", you could instead just use the IP address 64.236.16.20 if DNS wasn't working.

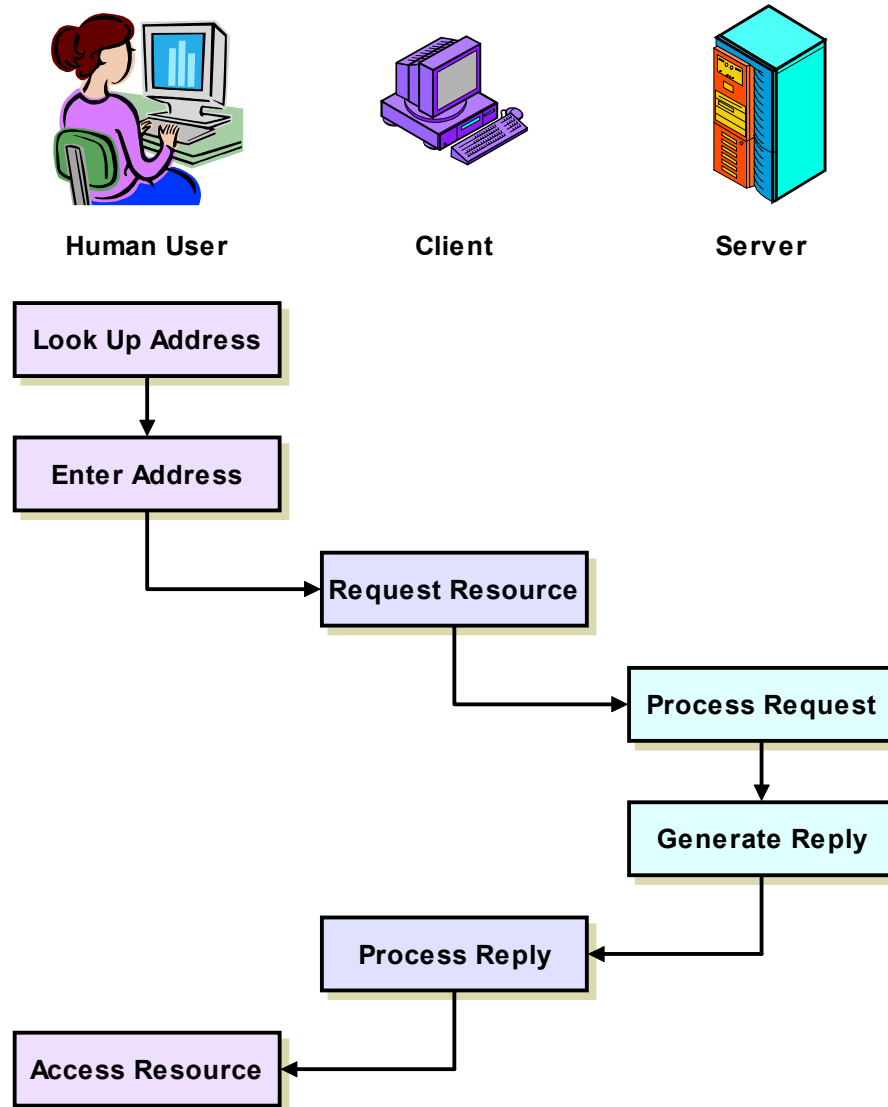

The problem is that prior to reading this, you probably had no idea what the IP address of CNN's Web site was, and that's true of almost everyone else who uses their site as well. Also, you might want to check not just CNN's Web site, but perhaps one, two or twenty other news sites. It would be difficult to remember the numbers for even a small percentage of the thousands of different Web sites on the Internet, so each time you wanted to access a resource you'd have to manually look up its address, as shown in [Figure 229](#).

### ***Factors That Determine the Necessity of a Name System***

It's much easier to remember the names of resources; when a name system is implemented, you just enter the name of a device and the name system converts it to an address, as shown in [Figure 230](#). This is why name systems are so important, even if they aren't needed by the networking technologies themselves. (In fact, the reliance on name systems like DNS is so significant that many people don't even realize they can enter IP addresses into their Web browsers!)

More generally, the importance of a name system depends greatly on the characteristics of the network upon which it is used. The three main issues in determining the need for a name system are:

- ☉ **Network Size:** If you have a really small network with only a handful of computers, having human users remember the numeric addresses for these machines is at least feasible, if not ideal. For example, a small home network with two or three machines doesn't really *need* a name system, in theory. If you have thousands or millions of devices, however, the name system becomes essential.
- ☉ **Address Size and Complexity:** The more complex the numeric addressing scheme, or the larger the numbers used, the more difficult it is for humans to remember the numbers.

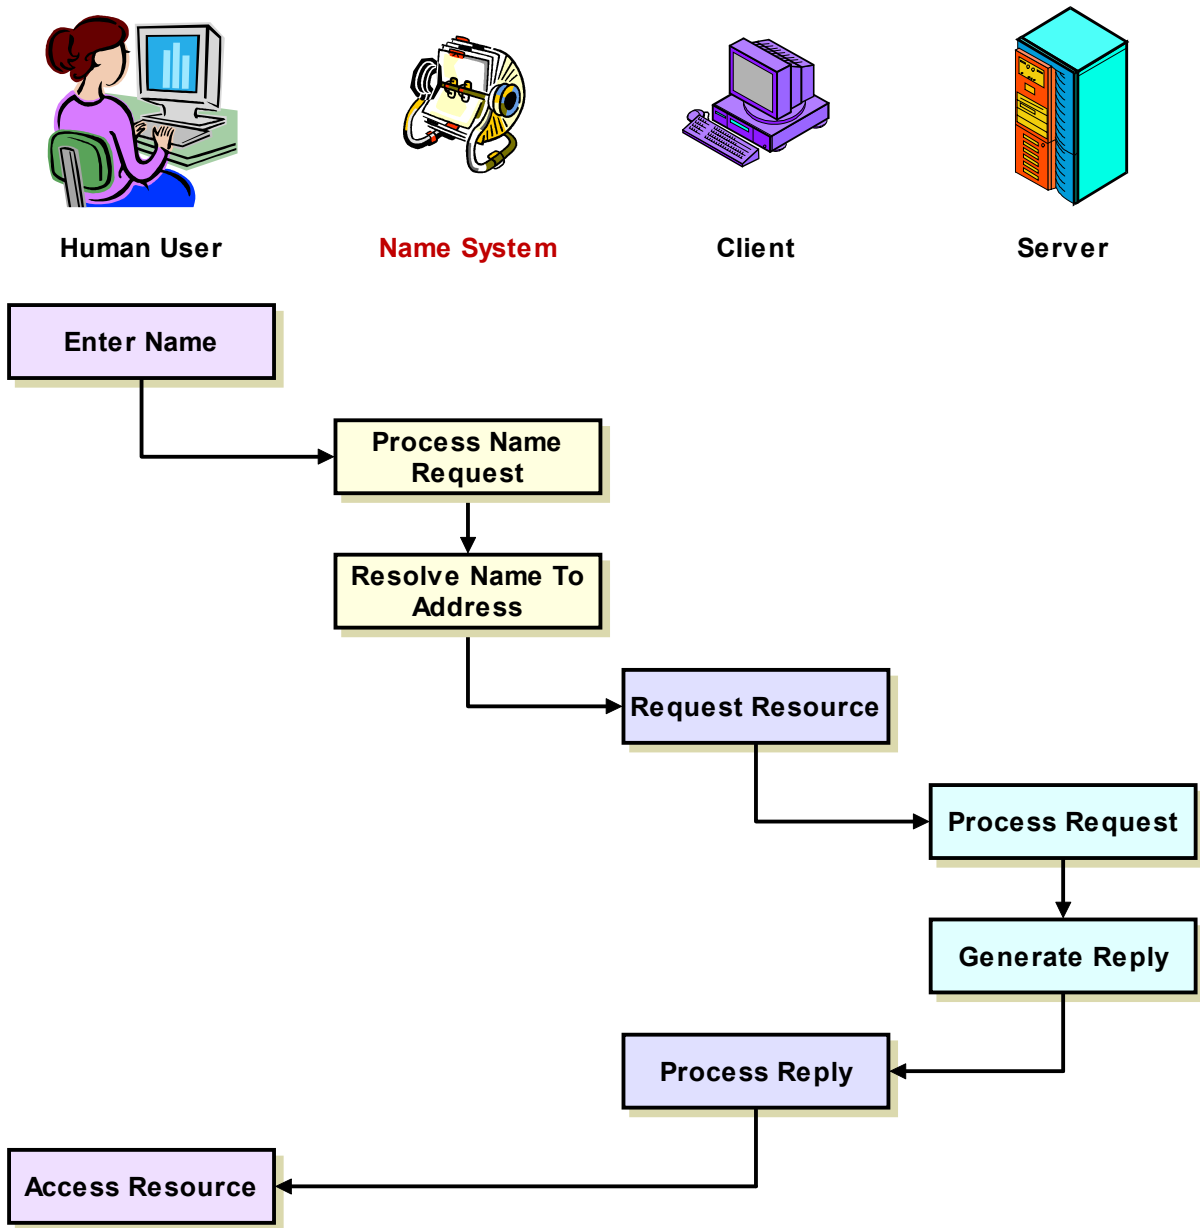

**Figure 229: Internetwork Access Without A Name System**

When there is no name system, a user must know the address of any device he or she wishes to access on the internetwork. Since most of us have limited memories for numbers, this means each access must be preceded by an inefficient, tedious manual address look-up.

- ☉ **User Base Size and Skill:** In the early days of networks, a small number of highly-skilled and well-trained engineers used them, and these people sometimes just memorized the numbers of the machines they worked with every day. In modern networks with thousands or millions of “lay” users, expecting the average person to remember device numbers is not reasonable.

Looking at these issues, we can see that the trends in today’s networks are all in the direction of increasing the importance of name systems. Our networks, both private and public, are growing larger, and we have more people using them, including more people without a technical background. We are also increasingly moving from small addresses to

**Figure 230: Internetwork Access With A Name System**

When an internetwork is equipped with a name system, the user no longer needs to know the address of a device to access it. He or she enters the name and the name system converts it into an address automatically, like a computerized “rolodex”, as I have shown here. ☺ The name system then passes the address to the client software which uses that address to access the requested resource as if the user had entered it directly.

larger ones. The best example of this is [the upcoming change to the Internet Protocol](#). While DNS is important for the 32-bit addresses used in IP version 4, it's even *more* important for dealing with [the enormous 128-bit addresses of IP version 6](#).

**Key Concept:** Networking name systems are important because they allow devices to be assigned efficient numeric addresses, while still enabling humans to access them using names that are easier to remember. Name systems become more important as you increase the size of the network, the address or the user base. They are also more essential when the user base is limited in skill or experience.

---

## **Name System Functions: Name Space, Name Registration and Name Resolution**

While the difference between numeric addresses and symbolic names is very significant to the users of network devices, it's important to remember that both numbers and names really serve the same basic purpose: *device identification*. Even when we use a name system to make devices easier to access, the computers themselves will still normally need to use the underlying numeric identifier. In essence, then, every device will end up with (at least) two identifiers: a number **and** a name.

The fact that devices end up with multiple identifiers is what allows both people and their machines to use the method of identification they prefer. However, it means that there must be ways of managing the assignment of names to devices, and of converting between them. A name system therefore involves more than just slapping names on computers. It must be, in fact, a complete **system** that allows names to be used by the humans while numbers continue to be used by the devices.

### ***Overview of Basic Name System Functions***

At the highest level, I consider a name system's jobs as encompassing these three basic functions:

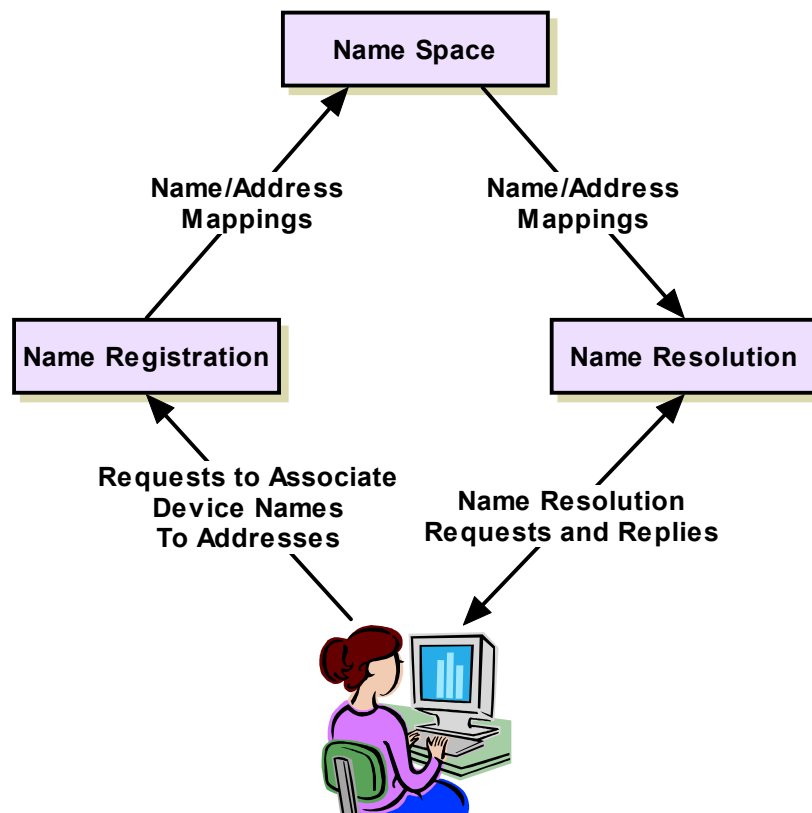

- ☉ **Name Space:** The name system defines a *name space* for the networking system upon which it runs. The name space, also sometimes called a *name architecture*, describes the rules for how names are structured and used. It also defines how the name of one device is related to the names of other devices in the system, and how to ensure that no invalid names are given that would cause problems with the system as a whole.
- ☉ **Name Registration:** To implement the name system, a name must be assigned to each device on the network. Like any addressing system, a name system cannot work properly unless every name on the system is unique; we need some way of managing how the names are assigned so the result is sensible. The process of linking specific names to particular devices is usually called *name registration*.
- ☉ **Name Resolution:** As I mentioned above, even though humans like symbolic names, computers usually have little use for them. It is necessary to define a mechanism by which a device's symbolic name can be translated into its numeric address. This process is usually called *name resolution*.

---

## Relationships Between Name System Functions

The name space is more of a “descriptive” function; it is a definition of how names work in the system. Name registration and resolution are more “active” functions, with each name system including one or more specific procedures for how these jobs are carried out. Name registration and resolution are in some ways complements of each other, so certain registration techniques are most often associated with particular resolution methods. In turn, the types of registration and resolution methods that are possible depends on the name space and in particular its architecture. These relationships are shown in simplified form in [Figure 231](#).

**Figure 231: Name System Functions**

This diagram shows the relationships between the three main functions of a name system. The *name space* defines the structure of the name system and the rules for creating names. The name space is used as the basis for the *name registration* method, which defines the mappings between names and addresses. When a user wants to access a device by name, a name resolution method is used to consult the name space, determine what address is associated with a name, and then convert the name to an address.

The processes of registration and resolution can be either quite plain or fairly complicated, depending on the type of name system used. Simple name systems are largely manual in operation, easy to understand and best used in smaller networks. Larger, more complex networks and internetworks require more sophisticated methods of registration and resolution, which work with less need for administrator intervention and *scale* better as new machines are added to the network.

---

I should also point out that while I consider name registration and name resolution as “functions” at the highest level, they are probably better thought of as **sets** of functions. Name registration is necessarily tied into issues such as name system administration and management, and understanding resolution requires that we look at a number of important implementation issues in the areas of efficiency and reliability. The next few topics expand on this overview by considering each of these three functions in more detail.

---

**Key Concept:** A name system consists of three theoretical high-level functions: the *name space*, which describes how names are created and organized; the *name registration* technique, which is used to set up relationships between names and addresses; and the *name resolution* method, which is responsible for translating names to addresses.

---

## **Name Spaces and Name Architectures (Flat and Hierarchical)**

The main idea of a name system is to provide a way to identify devices using symbolic names. Like any identification mechanism, before we can use the system we must define the way that identification will be performed. Numeric addressing schemes (like IP addresses) have rules for how addresses are created, and assign addresses to each device from their *address space*. In a similar way, devices in a name system are given names from the system's *name space*.

### ***Name Space Functions***

Of the three main functional components of a name system, the name space is the most abstract. It is also the most fundamental part of the system, since it actually describes how the names are created. There are several aspects to what the name space defines in a name system:

- ☉ **Name Size and Maximum Number of Names:** The name space specifies the number of characters (symbols) that comprise names. In so doing, it also defines the maximum number of names that can appear in the system.
- ☉ **Name Rules and Syntax:** The name space specifies what characters or symbols are allowed in a name. This is used to allow legal names to be chosen for all devices while avoiding illegal names.
- ☉ **Name Architecture and Semantics:** Each name space uses a specific *architecture* or *structure*, which describes how names are constructed and interpreted.

### ***Name Architectures***

The concepts of name size and name syntax are relatively straight-forward. The last item, *name architecture*, is probably the most important differentiating characteristic of name systems. For this reason, name spaces are sometimes even **called** name architectures. The architecture of the name space determines whether names are assigned and used as

---

a simple unstructured set of symbols, or whether they have a more complex internal structure. In the latter case, the name space also must define how elements of a particular name are related to each other.

Theoretically, many different name architectures are possible. In practice, most fall into one of two categories: flat and hierarchical architectures.

### Flat Name Architecture (Flat Name Space)

Names are assigned as a sequence of symbols that are interpreted as a single, whole label without any internal structure. There is no clear relationship between any name and any other name.

An example of this sort of architecture would be a name system where computers are given unstructured names like “Engineering Workstation 1” or “Joanne’s PC”, as shown in the example in [Figure 232](#).

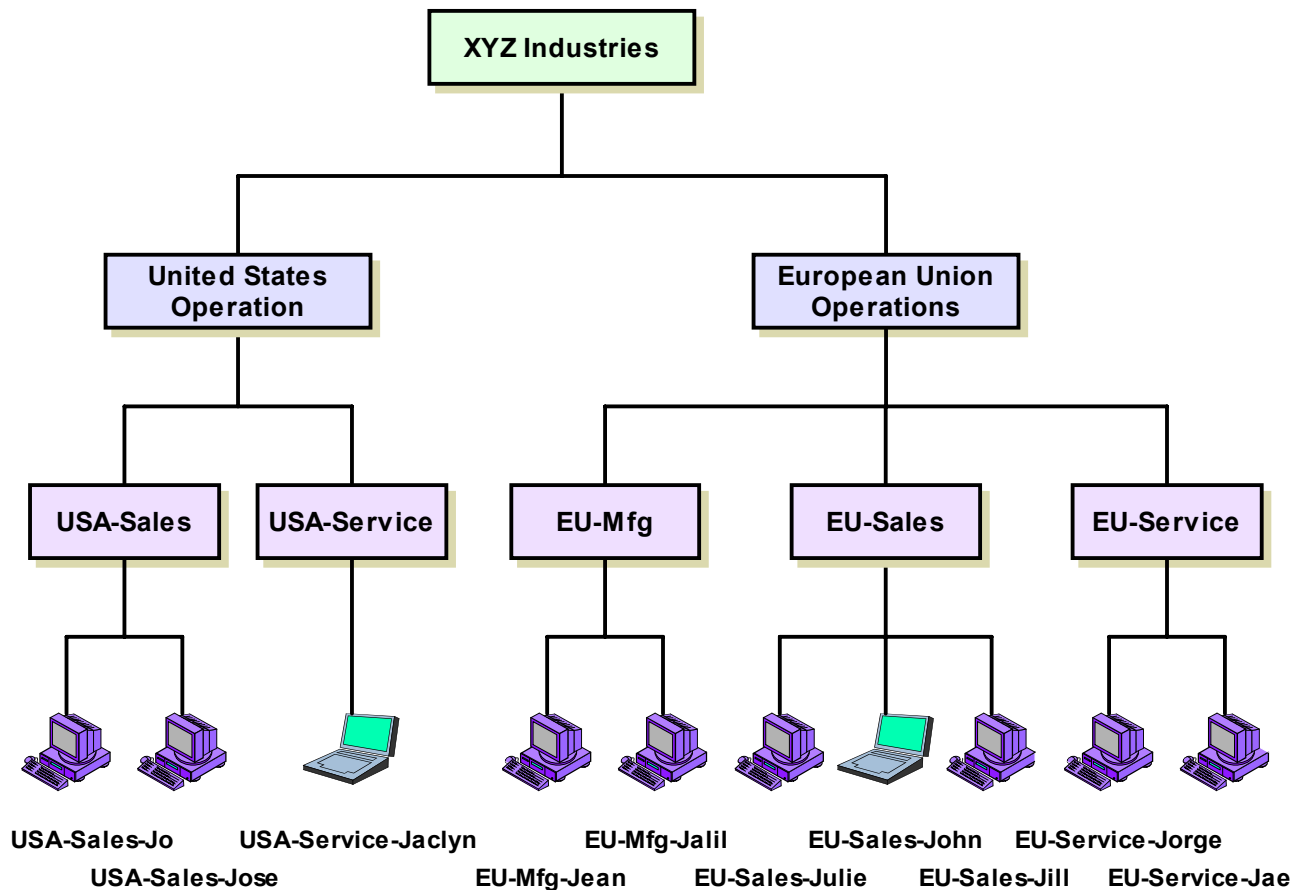

**Figure 232: Flat Name Architecture (Flat Name Space)**

This diagram shows an example of a flat name architecture. There is no structure that organizes the names or dictates how they must be constructed. Logically, each device is a peer of each of the others.

### Hierarchical Name Architecture (Hierarchical or Structured Name Space)

In this architecture, while names consist of a sequence of symbols, these symbols are assigned using a specific and clear structure. The name consists of discrete elements that are related to each other usually using hierarchical “parent/child” semantics. There are many naming architectures in various contexts that use this type of hierarchical structure; for example, consider how a large company might set up an organization chart and name the executives and officers in the organization. One hypothetical example of a hierarchical name architecture is illustrated in [Figure 233](#).

The best-known real world example of a hierarchical name space is the [name space of the TCP/IP Domain Name System](#), which uses text labels separated by periods (“dots”) to form an internal structure. All the names in the system are organized into a structure, and a

**Figure 233: Hierarchical Name Architecture (Structured Name Space)**

This diagram contains the same devices as [Figure 232](#), but they have been arranged using a hierarchical, structured name architecture. In this case, the organization has chosen to structure its device names first by facility location, and then by department. Each name starts with something like “USA-Service-” or “EU-Mfg-”.

This provides immediate benefits by providing local control over device naming without risk of conflicts. If someone named John were hired into the USA sales force, his machine could be named “US-Sales-John” without conflicting with the machine owned by John of the European sales force (“EU-Sales-John”). The structure also makes it easier to know immediately where a device can be found within the organization.

particular device's place in the structure can be determined by looking at its name. For example, “www.tcpipguide.com” refers to the World Wide Web server for The TCP/IP Guide, which is named under the umbrella of “COMmercial” companies.

### ***Comparing Name Architectures***

As we will see in the next two topics, the architecture of the name space is intimately related to how names are registered and managed, and ultimately, how they are resolved as well. A flat name space requires a central authority of some sort to assign names to all devices in the system to ensure uniqueness. A hierarchical name architecture is ideally suited to a more distributed registration scheme that allows many authorities to share in the registration and administrative process.

---

All of this means that the advantages and disadvantages of each of these architectures are not a great mystery. Flat name spaces have the advantage of simplicity and the ability to create short and easily remembered names, as shown in [Figure 232](#). However, they do not scale well to name systems containing hundreds or thousands of machines, due to the difficulties in ensuring each name is unique. For example, what happens if there are four people named John who all try to name their computers “John’s PC”? Another issue is the overhead needed to centrally manage these names.

In contrast, hierarchical name spaces are more sophisticated and flexible, because they allow names to be assigned using a logical structure. We can name our machines using a hierarchy that reflects our organization’s structure, for example, and give authority to different parts of the organization to manage parts of the name space. As long as each department is named uniquely and that unique department name is part of each machine name, we don’t need to worry about each assigned name being unique across the entire organization, only within the department. Thus we can have four different machines named with their department name and “John”, as [Figure 233](#) demonstrates. The price of this flexibility is the need for longer names and more complexity in name registration and resolution.

**Key Concept:** The two most common types of name architecture are the *flat name space* and the *hierarchical name space*. Names in a flat name space are all peers with no relationship; in a hierarchical architecture, a multi-level structure is used to organize names in a specific way. The flat system is simpler and satisfactory for small networks, while the hierarchical name space is more flexible and powerful, and better-suited to larger networks and internetworks.

---

## **Name Registration Methods, Administration and Authorities**

It seems obvious that for our name system to be implemented, we need some method of assigning names to each of the devices that will use the system. Just as a name system has a name space that is comparable to an addressing system's address space, it also must implement a set of rules and procedures for assigning names, just as an addressing system assigns addresses. This is called *name registration*.

### ***Name Registration Functions***

In general, name registration encompasses the following concepts and tasks:

- 🕒 **Name Assignment and Guaranteeing Uniqueness:** The core task of the name registration process is of course assigning names to devices. Like all identification schemes, a key requirement of name registration is ensuring that each name is unique. Duplicated names cause ambiguity and make consistent name resolution impossible.

- 
- ☉ **Central Registration Authority Designation:** Ensuring uniqueness of names requires that there be someone “in charge” of the name assignment process. This *central registration authority* may be a single individual that maintains a file containing names, or an organization that is responsible for the overall name registration process. The authority is also charged with resolving problems and conflicts that may arise in registrations.
  - ☉ **Registration Authority Delegation:** In smaller name systems, the central registration authority may be responsible for the actual registration process for all devices. In larger, hierarchical name systems, having this process centralized is impractical. Instead, the central registration authority will divide the name space and *delegate* authority for registering names in different parts of it to subordinate organizations. This requires a delegation policy to be developed and implemented.
  - ☉ **Defining Hierarchical Structure:** When a hierarchical name space is used, the central authority is responsible for defining how the structure will look. This in turn dictates how names can be registered in different parts of the hierarchy, and of course, also impacts how authority is delegated.

### ***Impact of Name Space Architecture on Name Registration***

The complexity of the name registration process depends to a great extent on the size and complexity of the name system as a whole, and in particular [the architecture of the name space](#). In a simple name system using a flat name space, registration is usually accomplished using a single authority. There is no structure, of course, and usually no delegation of authority, so there isn't much to registration.

For hierarchical name systems, name registration is tied tightly to the hierarchy used for names. The central authority defines the structure of the hierarchy, and decides how the hierarchy is to be *partitioned* into subsets that can be independently administered by other authorities. Those authorities may in turn delegate subsets of their name spaces as well, creating a flexible and extensible system.

This ability to delegate authority for name registration is one of the most powerful benefits of a hierarchical name space. For example, in the [TCP/IP Domain Name System](#), a central authority is responsible for name registration as a whole; it is in charge of deciding what top-level domains, such as “.com”, “.edu”, “.info” and “.uk” are allowed to exist. Authority for managing each of these subsets of the worldwide hierarchy is then delegated to other organizations. These organizations continue the process of dividing the hierarchy as they see fit. Eventually each organization is able to decide how it will name its own internal systems independently; for example, IBM can register names in any way it sees fit within the “ibm.com” name.

### ***Name Registration Methods***

There are several common methods by which the actual process of registration is carried out. Each of these has its strengths and weaknesses, and again, some are better-suited to flat name spaces and some to hierarchical ones.

---

## Table Name Registration

In this technique, name assignments are maintained in a table by an administrator. When names need to be added, deleted or changed the table is edited.

This technique is usually associated with small, flat name space name systems, and has the same benefits and drawbacks as flat architecture in general: it is simple and easy to implement, but doesn't scale well to larger systems. With a dozen machines, having someone edit name registration tables is practical; with thousands of machines it is not. It is also not conducive to a hierarchical system where there are multiple authorities, because the table needs to be kept in one place.

In larger internetworks, tables may be used as an adjunct to one of the more sophisticated techniques below.

## Broadcast Name Registration

This is a “trial and error” technique; a device that wants to use a particular name sends out a message to all other devices on the network asking to see if anyone else is already using it. If so, it chooses a different name. If not, the name is considered registered and can then be used.

This technique is more sophisticated than using tables, but is still limited to use in relatively small systems. It is not practical to attempt to broadcast to thousands of systems, and this method could not be used over the Internet, since there is no way to broadcast to every device on an internetwork.

## Database Registration

A database of name assignments is maintained. To register a name, a request must be made to have the name assignment added to the database. If the authority for the name system is entirely centralized, the database will be centralized and maintained by that authority. If authority for parts of the hierarchy is delegated, then a *distributed database* is used for registration, with each authority maintaining the part of the database describing their section of the hierarchy.

This is the most sophisticated technique, and one normally associated with hierarchical name systems like DNS. It has several benefits, including flexibility, reliability and distribution of maintenance effort; its main drawback is complexity.

**Key Concept:** *Name registration* is the process by which names are linked to addresses in a name system. It encompasses activities such as central registry authority designation and delegation, and name space structure management. The most common methods of name registration, in order of both increasing capability and complexity, are manual table maintenance, broadcast registration and database registration.

---

---

We have just seen that the choice of name space and architecture immediately has an important impact on how name registration is done. [The next topic](#) will show how name resolution is closely related to name registration and architecture as well.

## **Name Resolution Techniques and Functional Elements of A Name Resolution System**

[As we discussed earlier in this section](#), using a name system creates two “parallel” identification systems for computers: the numbers used by machines and the names used by people. The job of the name system is to integrate these two schemes. [Name registration](#) allows humans to specify which machines use which names. This is only half the process, however; we also need a way for machines to take a name given to them by a human and translate it into the “real” address it can actually use for communication. This is called *name resolution*.

Name resolution, also sometimes called *name translation*, *mapping* or *binding*, is the most well-known aspect of name systems, because it is where most of the “heavy lifting” of a name system occurs. The name space is generally set up once, and name registration occurs infrequently: only when names must be created or changed. In contrast, every user of a name system instructs the machines he or she uses to perform name resolution, hundreds or even thousands of times a day.

### ***Name Resolution Methods***

There are several different techniques that can be use for name resolution. How this function is implemented depends a great deal on the other two name system functions, name space and name registration. As you might imagine, a simple name system with a simple name registration method will most often use a simple resolution method as well. Complex hierarchical systems with distributed databases require more sophistication in how names are resolved.

There are three common name resolution methods.

#### **Table Name Resolution**

The table used for table-based name registration is consulted by a device when resolution needs to be performed. The table tells the device how to transform the name of the machine it needs to contact into an address.

This technique obviously corresponds to table name registration; it is the simplest and least capable of the three methods. Table name resolution is suitable for standalone use only in very small name systems, but can be a supplement to other methods as well.

#### **Broadcast Name Resolution**

When a device needs to resolve a name, it broadcasts a query that says something to this effect: “I need to send to the device named 'X', who is that?” The device whose name is 'X' responds back saying “I'm 'X' and my numeric address is 'N'”.

---

This is the complement of broadcast name registration, of course. It too can only be used in simple systems where every device can hear a broadcast. The use of broadcasts also makes it wasteful of network bandwidth.

### **Client/Server Name Resolution**

Servers are programmed with software that allows them to respond to name resolution requests sent by clients. These servers take the name in the request, look up the associated numeric identifier in a database, and send it back in a response.

This technique is, of course, generally used in conjunction with database name registration. It is the most complex of name resolution methods, but is also the most efficient, and the only one that can really work properly on a large, distributed hierarchical name system.

### ***Client/Server Resolution Functional Elements***

The last of these three methods is the one used for most large, modern name systems. The client/server method of request/reply resolution is similar to how many other protocols function. One thing that is unique about name resolution, however, is that name resolution isn't often invoked directly by the client. It's rare, for example, for a human user to say "please resolve the following name". We also certainly wouldn't want a user to have to manually resolve a name to an address each time they wished to contact a device, as this would be cumbersome.

Instead, the system is automated by having software accept machine names input by users. The software resolves the name by passing it to a *name resolver* software component. The resolver acts as the client in the name resolution process. It contacts a *name server*, which responds to the request. The name resolver and name server constitute the two main functional elements in name resolution.

In a distributed database for a hierarchical name system, multiple requests may be required, since name servers will contain only information for certain machines and not others. Resolvers follow a special procedure to "travel" the hierarchy until they find the server that has the information they want. Again, [TCP/IP's Domain Name System \(DNS\) name resolution](#) is the best example of this method.

**Key Concept:** *Name resolution* is arguably the most important of the main functional elements of a name system, because it is the part of the system that actually converts names into addresses. The two main components of name resolution are name resolvers, which act as clients in the resolution process, and name servers. The three main name resolution methods—table-based, broadcast and client/server—correspond closely to the table, broadcast and database methods of name registration.

---

---

## **Efficiency, Reliability and Other Name Resolution Issues and Features**

In [the preceding topic](#) I described the primary function of name resolution: allowing humans to identify devices using names, then converting these names into numbers so that computers can use the numbers instead. This basic task is conceptually quite simple, but it can become quite complex in implementation. The reason for this is the key characteristic that makes name resolution so different from the other tasks performed by a name system: the frequency with which it is done.

Name registration is seldom done, but name resolution is done very often. If you consider a large internetwork with thousands of users running various applications, millions of names must be resolved every day. Now, consider something like the Internet, which must process billions of client/server requests and replies daily! Ensuring that such systems work requires that we do more than just implement a resolution process; we must add facilities to ensure that resolution is done as effectively as possible.

### ***Efficiency Considerations***

The first major concern with name resolution is *efficiency*. Name resolution uses up system resources, especially with resolution techniques that require requests and replies to be sent. This means we want to minimize the number of times resolution is performed, if at all possible. Now, consider that many people will frequently access the same machines over and over again. For example, if you go to a Web site called “www.thisisaside.com” for the first time, your system will need to resolve that name. After the home page for that site loads, if you click a link to another page on that site, the page will also be found at that same name: “www.thisisaside.com”. It would be wasteful to then have to resolve the name a second time.

To avoid this, name systems almost always include some sort of *caching* capability, which allows devices to remember recent name resolutions and retain the mapping from name to address for a period of time. Whenever a name needs to be resolved, the cache is first checked before going through the formal process of resolution. The use of caching eliminates the vast majority of actual name resolution requests that would otherwise be required.

The drawback of caching is that it requires some system resources of its own, and that it adds complexity to the system. One issue is deciding how long to retain data in the cache; if we keep it too short a time, we generate extra unnecessary resolution requests; keep it too long, and we risk having the mapping become “stale” if the name assignment for the machine changes. These are issues that a sophisticated name system must deal with. A typical solution is to allow each name registration to specify how long information about that name-to-address link may be cached.

---

## Reliability Considerations

The main concern with name resolution after efficiency is *reliability*. As I said earlier in the section, having a name system isn't strictly necessary for the computers, but it's very important for the users, especially on a large network like the Internet. While having a single central place that maintains all information about a name system may make administration simpler, it creates a dangerous “single point of failure”. If anything happens to the device storing the information, the entire name system fails.

Modern name systems employ redundancies to prevent having the entire system rely on any particular device for resolution. A typical approach in a client/server system is to have multiple servers in different locations (or attached to different networks) that can respond to name resolution requests.

**Key Concept:** Since name resolution is the part of a name system that is used most often, it is here that we must pay careful attention to implementation issues. The two most important ones are *efficiency* and *reliability*. Efficiency is essential due to the many thousands or millions of resolutions performed every day on a large system; reliability is a consideration because users of the name system quickly come to rely on it and we must make sure it is robust.

---

## Other Considerations

An optional feature in some name resolution systems is *load balancing*. When properly implemented, load balancing allows a single name to map to more than one underlying address. This allows requests sent to a particular “virtual” device to actually be directed to a number of different actual physical devices, spreading the load over multiple machines. A common use of this feature is for very popular, heavily-trafficked Web sites.

Finally, while name resolution is obviously designed to allow names to be mapped into addresses, there are cases where we may wish to go in the other direction: given a numeric address, find the name that goes with it. This process, called *reverse resolution*, is analogous to having a phone number and trying to find the name of the person or company to which it belongs. Just as we can't easily find the name matching a phone number using a conventional phone book (we'd have to scan every page looking for the number), reverse resolution requires special support on the part of the name system. This is especially true if the name system data is distributed over many servers.

---

## **TCP/IP Name Systems: Host Tables and Domain Name System (DNS)**

The TCP/IP protocol suite is the most widely used in networking today. TCP/IP has become sufficiently popular that many people—even non-geeks!—are fairly comfortable working with its numeric identifiers ([IP addresses](#)). Even so, it's a lot easier to work with names than numbers, and it's certainly easier to remember them. We can consider also that name systems become more important when used on larger networks than smaller ones, and that TCP/IP is used to implement the Internet, the world's largest internetwork. Having a good name system is vital to the operation of the Internet, and thus, has become an important element of TCP/IP as a whole.

In this section I describe the name systems used in TCP/IP. I begin with an overview of device naming in TCP/IP, including a discussion of the history of how device naming began. I then describe the two different name systems that have been used in TCP/IP: the simple host table name system, and the modern Domain Name System (DNS). Far more detail is included on the latter than the former, since DNS is both much more complex than host tables, and also more widely used in today's networks.

**Background Information:** This section assumes that you are already familiar with the [general concepts and issues of name systems explained in the preceding section](#). Reference is made to descriptions of name system components and methods where appropriate.

---

---

## **Overview and History of TCP/IP Host Names and Name Systems**

In the section that introduces name systems and describes the concepts behind them, I described an interesting paradox. Even though name systems aren't strictly necessary for the functioning of a networking system, they make using a network so much easier for people that they are considered an essential part of most networks. I think no better evidence of this can be found than the history of name system development in TCP/IP.

### ***Early Use of Host Names on the ARPAnet***

In fact, the history of name systems in the TCP/IP protocol suite actually goes back well before TCP and IP were themselves even created! In the late 1960s and early 1970s, when the predecessor of the Internet (the *ARPAnet*) was being developed, it used older networking protocols that served the same function that TCP and IP do today. The ARPAnet was very small by today's standard, containing at first only a few machines, called *hosts* just as TCP/IP machines often are today. The addressing scheme was also very simple: just the combination of an IMP (computer) number and a port number for each host.

With only a handful of machines names it was easy to memorize addresses, but as the ARPAnet grew to several dozen machines this became untenable. As early as 1971, it was apparent to the engineers designing the ARPAnet that symbolic names were much easier for everyone to work with than numeric addresses. They began to assign simple host names to each of the devices on the network. Each site managed its own *host table* that listed the mappings of names to addresses.

### ***The First ARPAnet Name System: Host Name Lists***

Naturally, the ARPAnet engineers immediately recognized the dangers of having each site maintain a list of possibly inconsistent host names. Since the internetwork was just a small “club” at this point, they used the RFC process itself to document standard host name to address mappings. RFC 226, *Standardization Of Host Mnemonics*, is the first RFC I could find showing how host names were assigned. It was published on September 20, 1971.

This initial name system was about as manual as a system could be. As additions and changes were made to the network, the list of host names was updated in a new RFC, leading to a series of RFCs being published in the 1970s. Each host administrator still maintained his or her own host table, which was updated when a new RFC was published. During this time, the structure of host names was still under discussion and changes were made to just about every aspect of the name system as new ideas were explored and refined.

This worked fine while the ARPAnet was very small, but had many problems. One was that it was extremely slow in responding to network modifications; additions or changes would only be entered into device tables after a new list was published. Even with the centralized list, there were also still potential consistency issues, if a site manager forgot to update a file or made a typographical error. These were in addition to the usual limitations of a host-table-based name system.

---

## ***Storing Host Names in a Host Table File***

The first improvement was to make the list of host name assignments a standard “master” text file that would be centrally managed and could be downloaded using network protocols like FTP. The file was maintained at the Network Information Center (NIC) at Stanford University. The process for defining and using this file was described in RFCs 606 and 608, both entitled *Host Names On-line*, published in December 1973 and January 1974 respectively. These documents also formally specified the syntax for the [TCP/IP host table name system](#).

The use of a centrally-managed host table continued through the 1970s. When TCP/IP was developed the system was maintained, and mappings made between host names and 32-bit IP addresses. RFC 810, *DoD Internet Host Table Specification*, shows how host tables were defined for use with IP addresses. It was published in 1982.

## ***Outgrowing the Host Table Name System and the Transition to DNS***

It was at around this same time that continued growth of the ARPAnet/Internet made it apparent that the simple host table name system would eventually become unmanageable. With at first dozens and then soon hundreds and thousands of new hosts connecting to the internetwork, a single text file maintained in a central location just wasn't up to the task, [for a variety of reasons](#).

The idea of moving to a hierarchical name system based on the concept of *domains* was first introduced in 1981 in RFC 799, *Internet Name Domains*. Considerable discussion and development of this concept occurred in the early 1980s, and by 1983 a plan was put in place to migrate from the flat host table name system to the new *Domain Name System (DNS)*. The detailed history of the development of this name system is continued in [the overview section on DNS](#).

---

## TCP/IP Host Table Name System

The pioneers of the modern Internet made the first name system for the suite when they created simple files containing the names and addresses of the machines in the early ARPAnet. This system was so simple that it originally wasn't even formally specified as a "name system" per se. Since the files contained names for network hosts, the process for relating names to addresses was simply called the "host name" mechanism. Later, these files were called *host tables*, and for this reason I call this technology the TCP/IP *host table name system*.

As a system, it is extremely simple, since it consists of nothing more than a text file maintained on each machine on the network. This file is normally called "/etc/hosts" on a UNIX system, or *HOSTS* on a Windows system (usually residing in the main Windows directory). The file usually begins with some comment lines and then lists pairs of IP addresses and host names. A very simplified example (using the modern table structure, which is slightly different than the original host table format) is shown in [Table 162](#).

**Table 162: Example TCP/IP Host Table**

```
# Host Database
# This file should contain the addresses and aliases
# for local hosts that share this file.
#
# Each line should take the form:
# <address>                <host name>
#
127.0.0.1                  localhost
209.68.14.80               www.pcguide.com
216.92.177.143             www.desktopscenes.com
198.175.98.64              ftp.intel.com
```

### ***Host Table Name Space***

The name space and architecture for this system is theoretically flat, with each name being able to take any form without any real structure. Despite this, certain rules were eventually put in place regarding how names should be created, for consistency. As we will see later in this topic, it's also possible to use host tables to support the implementation of a hierarchical name space, which would obviously mean the names would have to be created using that name space's structural rules.

### ***Host Table Name Resolution***

Name resolution in this system is very simple. Each device reads the host table into memory when it starts up. Users of the system can make reference to the names in that host table in their invocation of various applications, by using a name instead of a numeric IP address. When the software detects a name has been used in this manner, it refers the

---

name to the internal resolver routine in the device, which looks up the name in the host table in memory and returns its address. There is no need for any transmissions or servers to be contacted; resolution is entirely local.

### ***Host Table Name Registration***

Now, here is the part where I am supposed to say that name registration in the host table name system is simple as well, right? Well, yes and no. From a purely technical standpoint it certainly is: a name is “registered” on a particular device when the name and corresponding IP address is entered into the device's host table, and that's it.

However, name registration is much more complicated from an administrative standpoint, and this is in fact where we find the major weakness of using host tables. Each network device maintains its own host table independent of the others, usually stored as a file on its local hard disk. This is in contrast to [database registration systems](#) where the data is centrally stored and managed. This leads to two very important concerns:

- 🕒 **Consistency:** Since every device has its own host table, how do we ensure that information is consistent between all the tables on the different devices?
- 🕒 **Modifications:** How do we ensure that information about new device mappings, or changes to existing ones, is propagated to all devices?

The original mechanism for this was simply [hand-editing](#), with administrators consulting updated published lists of device names. This was a very inefficient method that was prone to error and slow to acknowledge changes to the network. The revised system used a centrally-managed “master” file that was downloaded by all sites on a regular basis. Name registration in this method required that the name/address mapping be submitted to the authority managing the central file, the Network Information Center (NIC).

### ***Weaknesses of the Host Table Name System***

The use of a centralized master file for name registration certainly worked better than using the equivalent of “inter-office memos” to publish host name lists, but was itself only practical in the early days of TCP/IP. As the internetwork grew larger, the weaknesses of the host table system grew:

- 🕒 **Central Administration Overload:** The changes to the central file became more frequent, increasing the administrative load on the individual managing the “master” file to the point where changes were being made many times per day. As the Internet continued to grow, it would eventually have been impossible for a human being to enter the changes as fast as they were being submitted.
- 🕒 **Growth In Size Of the Master File:** Every host needed a line in the master file. When the Internet grew to be thousands and eventually millions of devices, the file size would have become excessive.

- 
- 🕒 **Excessive Bandwidth Use:** Since the file was changing so often, this also meant that all the devices on the network had to keep downloading this master file repeatedly to stay current. At the same time, the file was also growing in size as just mentioned. The combination of many downloads of a large file meant large amounts of network bandwidth were being consumed on something that is, in essence, an overhead activity.
  - 🕒 **Flat Namespace Problems:** The lack of a hierarchical name space led to conflicts when users chose identical names for their devices, and this further increased the workload on the central administrator. These issues were ameliorated in part by using naming conventions, such as using a prefix with a location before each individual machine name, but this was not an ideal solution.

All of these are reasons why the designers of the Internet eventually moved away from using host tables for the entire Internet to the more capable [Domain Name System \(DNS\)](#).

**Key Concept:** The *host table name system* was the original mechanism used for implementing names on the early Internet. It consists simply of a set of tables containing mappings between names and addresses maintained on each machine in the internetwork. When a name needs to be resolved the table is consulted to determine the appropriate address. This system is extremely simple, but not very capable, and not well-suited to a large global Internet, which is why it was eventually abandoned in favor of DNS.

---

### ***Use of the Host Table Name System In Modern Networking***

That said, the host table name system has not gone away entirely. There are two circumstances in which this technique is still of value:

- 🕒 **Small “Island” Networks:** If you are setting up a small local area network using TCP/IP, and you don't need the names of your devices to be accessible by those outside your network, then guess what? You have the equivalent, of sorts, of the early Internet, and the host table system is as applicable to you as it was to the Internet in the 1970s. You can simply set up host tables on each device and manage them manually. As long as the LAN is small enough that editing these files periodically is not a hassle, this is actually a fast and effective name system, because no exchange of messages is needed for resolution. You can even maintain a master file on one machine and copy it to the others when changes are required using a script, to save time.
- 🕒 **Providing Local Name Mappings To Supplement DNS:** Even though modern systems use DNS for most name resolution, they also usually still support the use of host table files. You can manually enter common name mappings into this file, even for devices that are on the global Internet. Your system can then be set up to consult this list before making use of its assigned DNS server.

The use of the HOSTS file in conjunction with DNS allows you to manually specify mappings for commonly-accessed sites, which may provide a slight performance improvement since there is no need to access a server. Since the HOSTS file doesn't

---

enforce any particular structure to names, it is naturally quite possible to put DNS-style hierarchical names into the file, as I showed in [Table 162](#). The file is loaded into memory and used to *override* the normal DNS process for names listed in it.

Of course, you then subject yourself to all the potential maintenance headaches of manually-edited files: you must update these files as host names or addresses are changed in the DNS system. For this reason, this second use of the HOSTS file for Internet sites served by DNS is less popular than the use of the file for local machines.

**Key Concept:** Even though the host table name system is not the primary mechanism used for TCP/IP naming, it still used in two circumstances. The first is to implement a basic name system in a small local TCP/IP internetwork. The second is as an adjunct to DNS, where it allows manual mappings to be created that override the DNS process when needed.

---

---

## TCP/IP Domain Name System (DNS)

The creation of [host tables](#) to map computer names to addresses greatly improved the usability of the early Internet and the TCP/IP protocol suite that implemented it. Unfortunately, while the host table name system worked well when the internetwork was small, it did not scale particularly well as the Internet started to grow in size and complexity. The name system had to stay but the use of host tables had to be dispensed with in favor of a newer, more capable system.

Over the period of several years, many engineers worked to create a system that would meet not just the needs of TCP/IP internetworks of the time, but also of the future. The new name system was based on a hierarchical division of the network into groups and subgroups, with names reflecting this structure. It was designed to store data in a distributed fashion to facilitate decentralized control and efficient operation, and included flexible and extensible mechanisms for name registration and resolution. This new name system for TCP/IP was called the *Domain Name System (DNS)*.

In this section I describe the concepts behind TCP's Domain Name System, as well as its operation. The section is divided into four subsections. The first provides an overview of DNS, including a description of its characteristics and components. The next three subsections describe how DNS implements each of the [three primary name system functions](#): the DNS name space and architecture; the DNS name registration process, including hierarchical authorities and administration; and the DNS name resolution process, focusing on how name servers and resolvers work. Finally, I have a topic that briefly highlights the changes made to DNS to support the new version 6 of the Internet Protocol, and its much longer addresses.

**Background Information:** I assume in this section that you are already familiar with the basics of name systems, and make reference to appropriate topics in the [name system overview](#) as needed. You should also be familiar with how TCP/IP host tables work, [as described in the topic preceding this section](#).

---

**Note:** Now, for a quick terminology note. First, even though the abbreviation “DNS” usually stands for “Domain Name System”, you will also sometimes see the “S” stand for other words, especially “Service” or “Server”. Second, some documents refer to this name system as “the DNS”. Most people just say “DNS” without the definite article, and that’s the convention I follow here as well.

---

---

## **DNS Overview, Functions and Characteristics**

Most of us know that it's a lot easier to be a critic than a creator. It was easy to tell that the host table name system used on the fledgling TCP/IP Internet was not going to serve it going into the future, but finding a solution to this problem was much more difficult. The main reason the host table system was insufficient was that it was too simple, and this meant that its replacement, the *Domain Name System (DNS)*, had to be considerably more sophisticated. Naturally, this made DNS more difficult to design, and also means we have to devote more energy to understanding how it works.

As I like to do with the explanation of most of the complex systems and protocols in this Guide, I begin in this section with background information and an introduction to TCP/IP DNS. I start by providing an overview of DNS's development, history and standards, continuing the history begun in the overall look at TCP/IP name systems. I discuss the design goals and objectives of the creators of DNS, to help you understand better what its designers were trying to do. I then talk about the main components of DNS and the functions it performs, relating these to the basic functions explained in the overview section on name systems.

### **DNS Overview, History and Standards**

The aversion that most people have to trying to remember numeric identifiers led to the very quick adoption of a name system for devices on the predecessors of what we now call the Internet. In the 1960s and early 1970s, names were given to machines, and these names maintained in host tables. The TCP/IP [host table name system](#) worked well for a number of years, with a centrally-maintained master list used by device administrators to ensure a consistent view of the network.

Unfortunately, such a system only works well when the number of devices is small. As the budding Internet grew, numerous weaknesses became apparent in the host table method, as I detailed in the section describing that system. Furthermore, the problems with the system weren't something that could be easily “patched” with small changes; the problems were structural, part of the basic idea of host tables as a whole. A completely new approach was needed for how names would be used on the Internet.

### ***Early DNS Development and the Move to Hierarchical Domains***

The most important “paradigm shift” made by the TCP/IP engineers was the decision to change the name system from one that used a single, centralized list of names to a more decentralized system. The idea was to create a structured topology where names were organized into *domains*. This idea was first introduced in the September 1981 RFC, 799, entitled [\*Internet Name Domains\*](#).

RFC 799 actually describes more the mechanics of delivering electronic mail messages between domains than the domains themselves. Interestingly, the standard assumes a flat structure of domains in its discussion, while mentioning the possibility of creating a hierar-

---

chical structure instead. It was in fact the decision to go to such a [hierarchical name space](#) for domains that led to the creation of the *Domain Name System (DNS)* in the form in which we know it today.

Many different RFC documents were published in the early 1980s, describing the development of different aspects of DNS. The first real milestone in DNS's history was probably the publishing, in November 1983, of a “triplet” of initial documents discussing DNS concepts, shown in [Table 163](#).

**Table 163: Documents Discussing TCP/IP Domain Name System (DNS) Concepts**

RFC Number	Name	Description
881	<u><i>Domain Names Plan and Schedule</i></u>	Discusses the issues involved in implementing the new DNS name system and how to migrate from the older host table system.
882	<u><i>Domain Names: Concepts and Facilities</i></u>	Describes the concepts and functional elements of DNS in fairly extensive detail. Includes a discussion of the name space, resource records, and how name servers and resolvers work.
883	<u><i>Domain names: Implementation Specification</i></u>	Provides the “nitty gritty” details on DNS messaging and operation.

### ***Standardization of DNS and Initial Defining Standards***

The documents above were discussed frequently over the months that followed, and the basic DNS mechanism revised many times. Several subsequent RFCs were published, updating the DNS cut-over plan and schedule. Finally, in November 1987, agreement on the operation of the system was finalized and a “quartet” of new RFCs were published that formalized the DNS system for the first time. These standards are RFCs 1032 through 1035, shown in [Table 164](#).

**Table 164: Initial Standards Defining The TCP/IP Domain Name System (DNS)**

RFC Number	Name	Description
1032	<u><i>Domain Administrators Guide</i></u>	Specifies administrative procedures and policies for those running a domain.
1033	<u><i>Domain Administrators Operations Guide</i></u>	Provides technical details on how to operate a DNS server, including how to maintain portions of the DNS distributed database of names.
1034	<u><i>Domain Names - Concepts and Facilities</i></u>	Replaces RFC 882, providing an introduction and conceptual description of DNS.
1035	<u><i>Domain Names - Implementation and Specification</i></u>	An update to RFC 883, specifying how DNS works in detail, including resource record definitions, message types, master file format, and resolver and name server implementation details.

---

These last two documents, RFCs 1034 and 1035, are considered the definitive original specification for the operation of the Domain Name System. While they are now many years old, they still provide the essential description of how DNS works.

DNS has quickly become a very important part of how both the Internet and TCP/IP work. As the Internet has grown to include thousands and then millions of sites, the importance of DNS has grown as well. Today, most people use DNS almost every time they use TCP/IP to access the Internet. It has gone from an alternative form of addressing for applications to one that is preferred by most users. It is an important building block of the more complete “application layer addressing” scheme developed for TCP/IP: [Uniform Resource Identifiers \(URIs\)](#).

The hierarchical nature of the [DNS name space](#) is the only thing that has allowed the Internet to grow while making the assignment and mapping of names manageable. The [authority structure](#) is also hierarchical, giving local administrators control over the names of devices they manage while ensuring name consistency across the hierarchy as a whole. The [distribution of data using many name servers and a standardized resolution technique](#) following a standard message protocol provides efficiency and reliability. These concepts will become more clear as we explore DNS more completely in later topics.

### ***DNS Evolution and Important Additional Standards***

TCP/IP and the Internet have both changed a lot since 1987, of course, and DNS has also had to change to suit. Many RFCs have been written since the base documents were published in the late 1980s, most of which further clarify the operation of DNS, expand on its capabilities, or define new features for it. You can find all of these by searching for “domain” or “DNS” in a list of RFCs. There are dozens of these, and I see no point in simply listing them all here, but I have highlighted a few of the more interesting ones in [Table 165](#).

**Table 165: Additional DNS Standards (Page 1 of 2)**

RFC Number	Name	Description
1183	<u><i>New DNS RR Definitions</i></u>	Defines several new “experimental” resource record types. Other subsequent RFCs have also defined new RRs.
1794	<u><i>DNS Support For Load Balancing</i></u>	Discusses load balancing for greater performance in DNS servers.
1995	<u><i>Incremental Zone Transfer in DNS</i></u>	Specifies a new feature that allows only part of a zone to be transferred to a secondary name server for efficiency.
1996	<u><i>A Mechanism for Prompt Notification of Zone Changes (DNS NOTIFY)</i></u>	Adds a new message type to DNS to allow primary (authoritative) DNS servers to tell secondary servers that information has changed in the main database.
2136	<u><i>Dynamic Updates in the Domain Name System (DNS UPDATE)</i></u>	Describes a technique for dynamically making resource record changes in the DNS database (also called Dynamic DNS).

---

**Table 165: Additional DNS Standards (Page 2 of 2)**

RFC Number	Name	Description
2181	<u><i>Clarifications to the DNS Specification</i></u>	Discusses several issues with the main DNS standards as defined in RFCs 1034 and 1035 and how to address them.
2308	<u><i>Negative Caching of DNS Queries (DNS NCACHE)</i></u>	Specifies the operation of negative caching, a feature that allows a server to maintain information about names that do not exist more efficiently.

### ***Adapting DNS For IPv6***

[IP version 6](#) was developed starting in the mid-1990s, and brought with it the need to make changes and enhancements to the operation of DNS. (Even though DNS operates at the higher layers, it deals intimately with addresses, and [addresses have changed in IPv6](#).) The modifications required to DNS to support IPv6 were first defined in RFC 1886, *IPv6 DNS Extensions*, which was part of a group of RFCs that laid out the fundamentals of IPv6. Several subsequent standards have been published since that time; these are discussed in [the topic on IPv6 DNS](#).

The three topics following in this section provide a more complete overview of DNS and its development, by discussing the design goals of its creators, and the protocol's key characteristics.

### **DNS Design Goals, Objectives and Assumptions**

[As we just saw in the preceding topic](#), the elapsed time from the first RFC discussing TCP/IP domain names to the publishing of the official standards describing the operation of DNS was over six years. This is a very long time for the development of a system, but it doesn't surprise me. A lot of thought had to go into the creation of DNS, to be certain that it would meet all of the many demands that would be placed upon it.

The first problem was that the creators of DNS had to worry about both how to define the new system and how to migrate from the old one. Considerable time was spent figuring out how all the existing hosts would be moved over to the new DNS name space and how the new protocols for exchanging DNS information would be implemented on them.

The creators of DNS knew they were making the new system because the old one didn't scale very well; they also knew that if migration was a difficult problem with the small number of hosts in existence at that time, it would be much more difficult if they had to go to another new system in the future. This made the key challenge in DNS to create a system that would meet the needs of the Internet not just the day it was introduced, or the following year, but even ten years or more down the road.

---

## DNS Design Goals and Objectives

Back in the 1980s, nobody had any idea how the Internet would grow as it has in the last decade. That DNS still works as well as it does is a testament to the skill of its designers. Much of this success is due to the early groundwork put into the design of the system. DNS engineers documented some of what they considered to be the main design goals in creating it, which can help us understand not just what DNS does but why:

- 🕒 **Creation Of A Global, Scalable, Consistent Name Space:** The name space had to be capable of spanning a large, global internetwork containing millions of machines. It was necessary that it provide a consistent and predictable method for naming devices and resources so they could be easily found. It was also, obviously, essential that name duplication be avoided, even when conflicts could potentially be between devices on different continents.
- 🕒 **Local Control Over Local Resources:** Administrators of networks and small internetworks on the Internet as a whole needed to be able to have control over the naming of their own devices. It would not be acceptable to have to go through a central authority for naming every single object, nor would it be acceptable for every administrator to need to know the names of everyone else's networks and machines.
- 🕒 **Distributed Design To Avoid Bottlenecks:** The designers of DNS knew that they would have to abandon the idea of a centralized database in favor of a distributed approach to data storage, to avoid the bottlenecks that would result in using DNS with many devices.
- 🕒 **Application Universality:** The system had to be general enough that it would support a wide variety of applications. For example, it needed to support host identification, mail delivery and other functions.
- 🕒 **Multiple Underlying Protocol Support:** DNS needed to be inherently able to support different underlying protocols. (Many people don't realize, for example, that DNS can support not just IP addresses but other types of addresses, simply because IP is so dominant in networking today.)
- 🕒 **Hardware Universality:** Both large and small computers needed to be able to use the system.

Keep these objectives in mind as you learn more about DNS, and it will help you understand better why certain design attributes were chosen. For example, if we consider the first two objectives listed above, they seem almost contradictory: how can we have a global name space with unique names if individual administrators were able to assign local names? The answer, as we will see, is that this is where the power of the [DNS hierarchical name space](#) shines through.

## DNS Design Assumptions

The goals above tell us what DNS's creators wanted to make sure the new system addressed. In addition, the engineers that worked on the protocol's implementation details had to make decisions based on certain assumptions of how it would be used. Some of the more significant of these assumptions:

- 
- ☉ **Rapidly Growing Database Size:** By the mid-1980s it was obvious that the DNS database of names would start out rather small but would grow quickly. The system needed to be capable of handling this rapid growth.
  - ☉ **Variable Data Modification Rate:** Most of the data in the name database would change only infrequently, but some would change more often than that. This meant flexibility would be required in how data changes are handled, and how information about those changes was communicated.
  - ☉ **Delegatable Organizational Responsibility:** Responsibility for portions of the name database would be delegated primarily on the basis of organizational boundaries. Many organizations would also run their own hardware and software to implement portions of the overall system.
  - ☉ **Relative Importance of Name Information Access:** It was assumed that the most important thing about DNS was providing reliable name resolution, so the system was created so that it was always possible for a user to access a name and determine its address. A key decision in creating the system was deciding that even if the information is slightly out-of-date it is better than no information at all. If a name server were unable to provide the latest data to fill a request, it would return the best information it had available.
  - ☉ **Handling of Requests For Missing Information:** Since the name data was to be distributed, a particular name server might not have the information requested by a user. In this case, the name server should not just say “I don't know”. It should provide a referral to a more likely source of the information, or take care of finding the data by issuing its own requests. This led to the creation of the several [DNS name resolution techniques](#): local, iterative and recursive.
  - ☉ **Use Of Caching For Performance:** From the start, it was assumed that DNS would make extensive use of [caching](#) to avoid unnecessary queries to servers containing parts of the distributed name database.

Arguably, a lot more assumptions were made in creating this system, like every system. For example, DNS had to make assumptions about how exactly data would be stored, the transport mechanism for sending messages, the role of administrators and so on. We'll learn more about these as we go through our look at the system.

## **DNS Components and General Functions**

To meet the many objectives set for it by its designers, DNS requires a great deal of functionality. It is a true name system with the emphasis on **system**, and as such is considerably more complex than the [host table name system](#) used earlier in TCP/IP. In [the section describing name systems in general](#), I divided the many tasks a fully-featured name system into three categories. DNS includes functions in all of these categories, and so using these categories is a good way to take a high-level look at the way DNS works.

The following are the three basic name system functions, and how DNS implements them (see [Figure 234](#)).

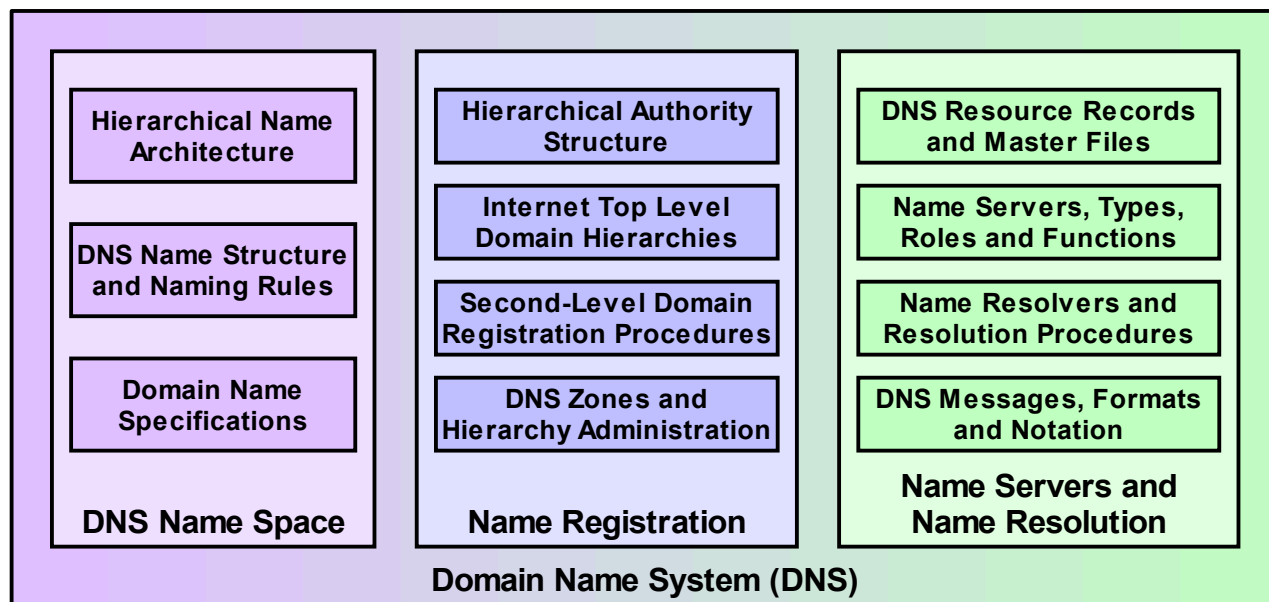

Figure 234: DNS Functions

### ***Name Space***

DNS uses a [hierarchical name space](#) consisting of a single, complex, multi-level structure into which all names in the system fit. The name space is organized starting from a single root into which “containers” (called *domains*) are placed. Each can contain either individual device names or more specific “sub-containers”. The overall structure is somewhat analogous to how a directory system on a computer organizes files from general to specific, using an arbitrary structure that can be optimized to various needs.

A specific syntax is used to define valid names, and special terminology used to describe parts of the structure and identify domain names, from the root down to the device level.

### ***Name Registration (Including Administration and Authorities)***

[DNS name registration](#) is used to enter individual names into the DNS distributed database. DNS uses a hierarchical arrangement of authorities that complements the hierarchical name space. A centralized authority determines the overall shape and structure of the name space, and handles registration of names at the highest level. Authority is then *delegated* to different organizations to manage various parts of the name space. A set of universal policies controls the registration process and deals with problems and conflicts.

### ***Name Resolution***

DNS uses a powerful, distributed, client/server [name resolution mechanism](#). This is probably the area where the most attention had to be put into the design of DNS, to ensure that it could scale to handle millions and eventually billions of name resolution requests each day.

---

The name resolution process is implemented using two basic software elements that play the role of client and server: name servers and name resolvers.

## Name Servers

**DNS name servers** are special programs running on hardware servers that are the heart of DNS. Servers are maintained by organizations that have administrative control over part of the DNS name space, and contain *resource records* that describe names, addresses and other characteristics of those portions of the name space. As such, the servers themselves are arranged into a hierarchy analogous to that of the name space, though not identical in structure.

The main job of name servers is to receive requests for name resolution and either respond with the data requested from the database, or with the name of another name server that will lead to the requested information. Name servers are also responsible for data caching and other administrative tasks to ensure efficient operation of the system as a whole.

## Name Resolvers

**Name resolvers** are the usual clients in the name resolution process. When a user makes reference to a name in a networking application, the name is passed to the resolver, which issues a request to a name server. Depending on the configuration, more than one request may be needed, and several different resolution processes may be combined to find the needed information. Resolvers too may employ caching or implement other features.

**Note:** The division between resolvers and servers is based on role. As we'll see when we look at name resolution, name servers may also function as clients in certain exchanges of data. [See the topic on DNS messaging for an explanation of this apparent paradox.](#)

---

If this seems a lot like the “classic” description of a name system that I gave in the name system concepts section, that's not a coincidence; DNS is considered *the* name system against which most others are usually compared. If you understand these high-level descriptions, then you already know the basics of how DNS works. The next three sections delve into each of these three functional areas in more detail, and will help you really learn how DNS does its thing.

**Key Concept:** As a complete name system, DNS provides numerous capabilities that implement each of the three basic name system functions. The DNS *name space* is hierarchical and its organization using a multi-level structure with particular naming rules. The DNS *name registration system* is based on the idea of a hierarchy of

---

domains and registration authorities responsible for them. DNS *name resolution* is similarly hierarchical, and designed around interaction between *name resolver* and *name server* software components that consult databases of DNS *resource records* and communicate using a special messaging protocol to answer client queries.

---

---

## **DNS Name Space, Architecture and Terminology**

The name space is the most fundamental part of any name system, since it is what defines the ways that the names themselves are created. The name space tells us what form names may take, and provides the rules for how they are created. Most importantly, it specifies the *architecture* of the names—the internal structure of names themselves. This in turn has a critical influence on how name registration and resolution work, making an examination of name space and architecture issues the obvious place to start in learning the details of DNS.

In this section I describe the concepts behind the DNS name space and its structure. I begin with an overview of the DNS name space and description of the hierarchical architecture it uses. I then provide more detail on the name structure, and also explain the terminology often used to refer to parts of the name space. I provide a formal description of DNS labels and the official and unofficial rules for creating domain names. I conclude with a description of domain name specifications, and explain the concept of “qualification” and how fully-qualified and partially-qualified names differ.

### **DNS Domains and the DNS Hierarchical Name Architecture**

The most important element of a name system's name space is its *name architecture*, which describes how names are constructed and interpreted. The architecture of the Domain Name System is, unsurprisingly, based on the concept of an abstraction called a *domain*. This is obviously a good place to start in explaining how DNS works. Unfortunately, it's not the easiest concept to explain from scratch, so as usual, I'll do my best and ask for your patience. ☺

#### ***The Essential Concept in the DNS Name Space: Domains***

Dictionary definitions of the word “domain” generally convey the notion of a *sphere of influence*, or *area of control or rulership*. An essential concept is that in many different contexts, control or authority can be exerted at many different levels. One sphere of influence may contain smaller ones, which can in turn contain smaller ones still. This means that such domains are naturally arranged in a hierarchy.

An obvious example would be geopolitical domains. We have no centralized “world government” on earth, but we do have the United Nations, which deals with world-wide issues. At the next level down, we have individual countries. Some of these countries have divisions such as states and provinces. Still lower levels have counties, municipalities, neighborhoods and individual residences or businesses. The “domains” are inherently hierarchical in organization.

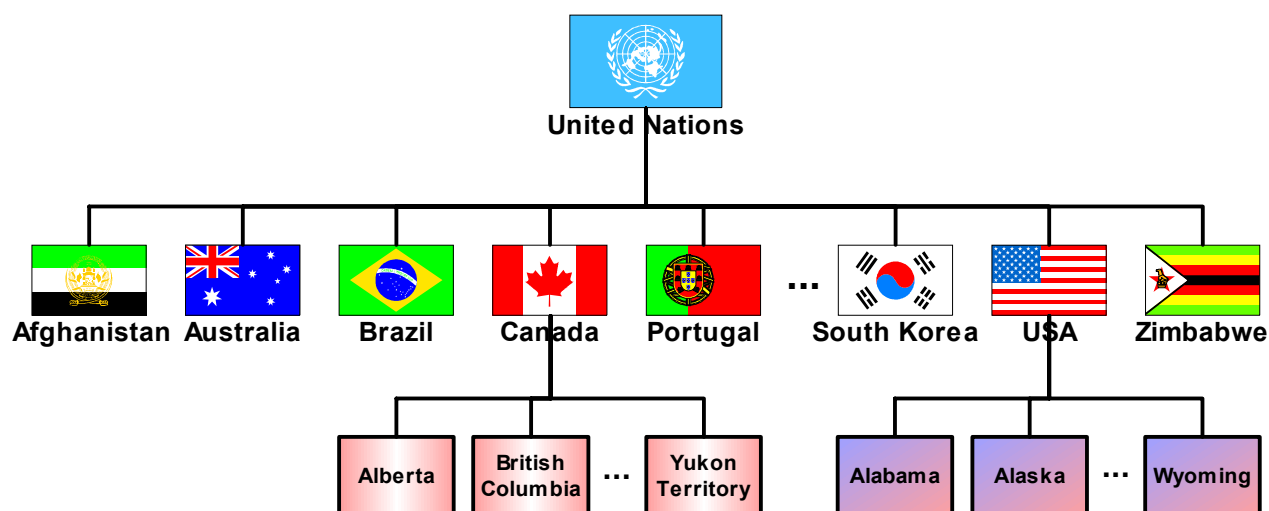

The Domain Name System uses the word *domain* in a manner very similar to this, and employs a hierarchical structure that works in much the same way as the geopolitical example. In DNS, a *domain* is defined as either a single object or a set of objects that have been collected together based on some type of commonality. Usually in DNS that commonality is that they are all administered by the same organization or authority, which makes the name hierarchy tightly linked to the notion of the [DNS hierarchical authority structure](#).

**Note:** The term “domain” is also used in other contexts in the world of networking. The most notable example of this is the use of the term in Microsoft networking, where it too is used to represent the notion of a collection of objects under common authority. However, the two types of domain are completely different and not related beyond this conceptual level.

### The DNS Hierarchical Tree Structure of Names

One could construct a tree diagram with the United Nations on top with lines pointing to each of the countries on earth. Then, within the United States, for example, we could draw lines to each of the states; within each state, lines to each county and so on. The result would be something that looks like an upside-down tree, as we can see in [Figure 235](#). This is called a *tree structure*.

**Figure 235: Example of a Global Hierarchical Domain Architecture**

This diagram shows an example of hierarchical architecture, based on political divisions. The United Nations is an umbrella organization representing (to one extent or another) all of the world’s nations. It is the *root* of the tree; underneath it we find individual nations. Each nation then is further subdivided in a manner it chooses; for example, Canada has provinces and territories, and the USA individual states. These can in turn be further subdivided in any number of ways.

Trees are used all over computing and networking; for example, trees are a type of LAN topology. For our purposes in explaining DNS, the best example of a tree structure is the directory tree used to store files on a computer’s hard disk or other storage devices. The root directory is at the top of the structure and may contain named files and/or named directories. Each directory can itself contain individual files or subdirectories, which can in turn contain their own subdirectories, and so on.

The domain name structure in DNS is conceptually arranged in exactly the same way, only instead of dealing with files, DNS deals with named objects, usually devices like IP hosts. The highest level is still the *root* of the tree. It contains a number of domains, each of which

---

can contain individual objects (names) and/or lower-level domains. Lower-level domains can in turn have still lower-level domains, allowing the tree as a whole to take on an arbitrary structure.

### ***The Benefits of the DNS Hierarchical Name Architecture***

Like a directory structure, the DNS hierarchical name architecture allows names to be organized from most general to most specific. It also has complete flexibility, allowing us to arrange the structure in any way that we want. For example, we could make a name system that is structured exactly paralleling the geopolitical organization chart I described earlier. We could have the root of the name structure represent the “United Nations”, and create a domain for each country. Then for those countries that have states, like the United States, we could create “state domains” within those countries. Smaller countries not needing those domains could have “city domains” directly under the country domain. The hierarchy is flexible, because at each level it can be given a suitable substructure.

**Key Concept:** The DNS name space is arranged into a *hierarchy of domains* shaped like an inverted tree. It is structurally similar to the directory structure of a file system, with a root that contains domains, each of which can contain subdomains and so forth.

---

It's important to remember that every standalone internetwork can have its own name space and unique hierarchical structure. Many times, people conflate the idea of “a DNS name space” with “**the** DNS name space”. The latter refers to the DNS hierarchy used for the global Internet, and it's obvious that this deserves a great deal of attention. But it is just one possible arrangement, if an important one, of an infinite number of possible structures.

In the remaining topics of this section, I continue the generic descriptions of DNS name space and architecture, including a look in the next topic at [DNS names and terminology](#). [The section on name registration and authorities](#) provides more specific information on the Internet's DNS hierarchy. As we'll see there, [geopolitical structures are in fact used](#) in a manner similar to what I described above to assign names to some of the Internet's computers, but other parts of the hierarchy are different.

### **DNS Structural Elements and Terminology: Domains, Subdomains, and Nodes; Roots, Leaves and Branches; Parents, Children and Siblings**

Now that we understand the fundamentals of the Domain Name System's name space, let's look at the DNS structure in more detail. At the same time, we can get a better handle on the many different terms used to refer to parts of the DNS domain name hierarchy.

---

## DNS Tree-Related Terminology

We saw in [the previous topic](#) that the DNS name structure is shaped somewhat like a tree; the comparison between structured elements and trees is a common one in networking. The main difference between technology and biology here is that DNS trees grow from the top down, instead of reaching for the sky. The analogy to a tree naturally leads to the use of several tree-related terms in describing the DNS name structure, some of which are illustrated in [Figure 236](#):

- ☛ **Root:** This is the conceptual top of the DNS name structure. The root domain in DNS contains the entire structure. By definition, it has no name; it is *null*.
- ☛ **Branch:** A branch is any contiguous portion of DNS hierarchy. It consists of a domain and all the domains and objects within it. All branches connect together to the root, just like in a real tree. (Yes, it would be better if the root were called the *trunk*, but computer science majors apparently don't take botany as electives. ☺)
- ☛ **Leaf:** This is an “end object” in the structure, that is, a domain that doesn't have anything underneath it. Again, the analogy to a leaf being at the end of a sequence of branches is apt.

There is no specific term to refer to a domain that is not a leaf. These are sometimes called *interior nodes*, meaning that they are in the middle of the structure. A *node* is the generic computing term for an object in a topology or structure; it is used throughout this Guide. So, in DNS, every node is a domain, and may be either an interior node that contains additional domains and/or objects, or a leaf that is a specific named device. The term *domain* is thus somewhat ambiguous, as it can refer to either a collection of objects which represents a branch of the tree, or a specific leaf.

## DNS Domain-Related Terminology

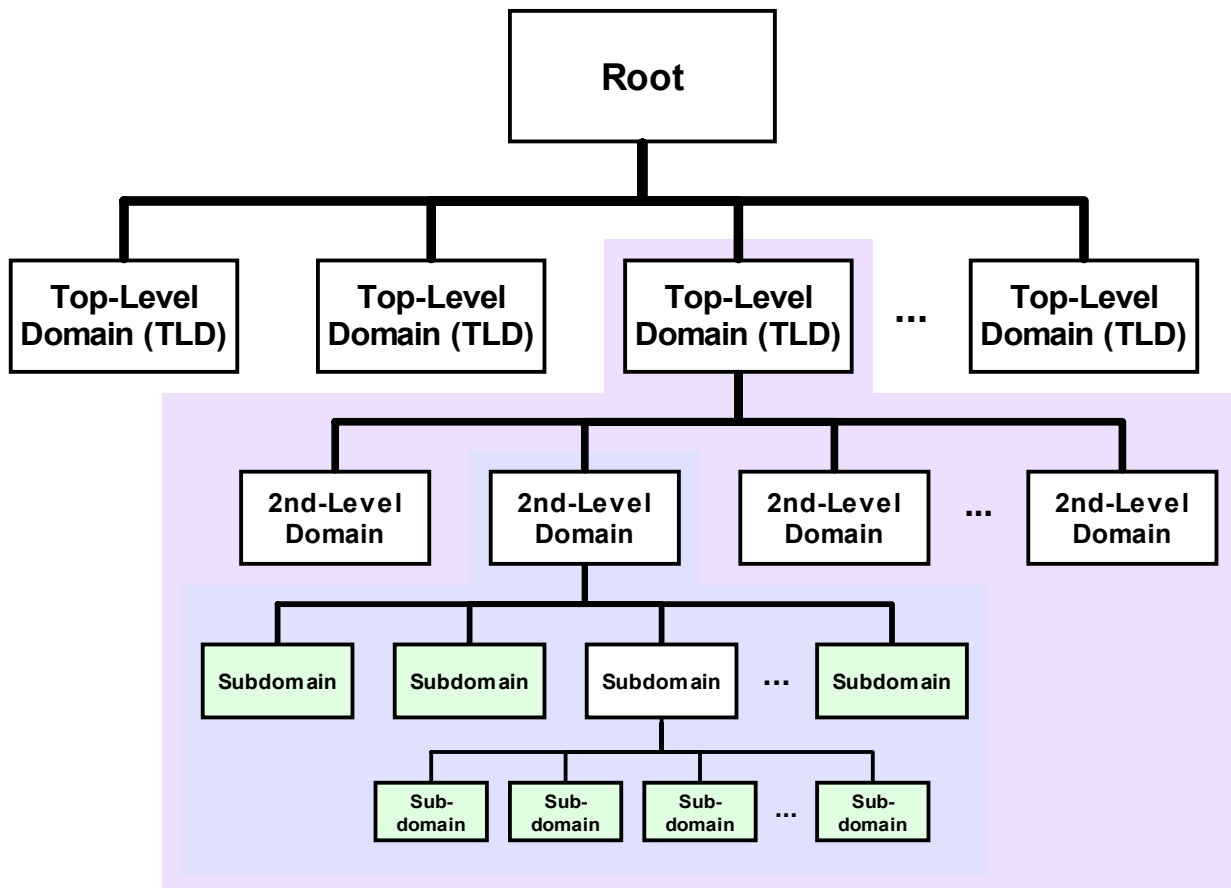

There are also several “domain-like” terms that are often used to refer to domains at different levels of the hierarchy. These terms, shown in [Figure 236](#), include:

- ☛ **Root Domain:** This is the root of the tree, as before.
- ☛ **Top-Level Domains (TLDs):** These are the highest-level domains directly under the root of the tree. They are also sometimes called *first-level domains*.
- ☛ **Second-Level Domains:** Shockingly enough, these are the domains located directly below the top-level domains.
- ☛ **Subdomains:** In some contexts, this term refers only to domains that are located directly below the second-level domains (but see below).

**Key Concept:** The top of the DNS name space is the *root*; under the root come *top-level domains*, and within these are *second-level domains* and then *subdomains*. In theory, any number of levels of subdomains can be created. A *branch* is any contiguous portion of the DNS tree; a *leaf* is a domain with nothing underneath it in the structure, and usually represents a single device.

---

**Figure 236: DNS Name Space Tree and Domain-Related Terminology**

The top of the DNS name space is the root of the tree, and has no name. Under the root comes any number of top-level domains (TLDs); within each of these can be placed second-level domains, then within those subdomains, and so forth.

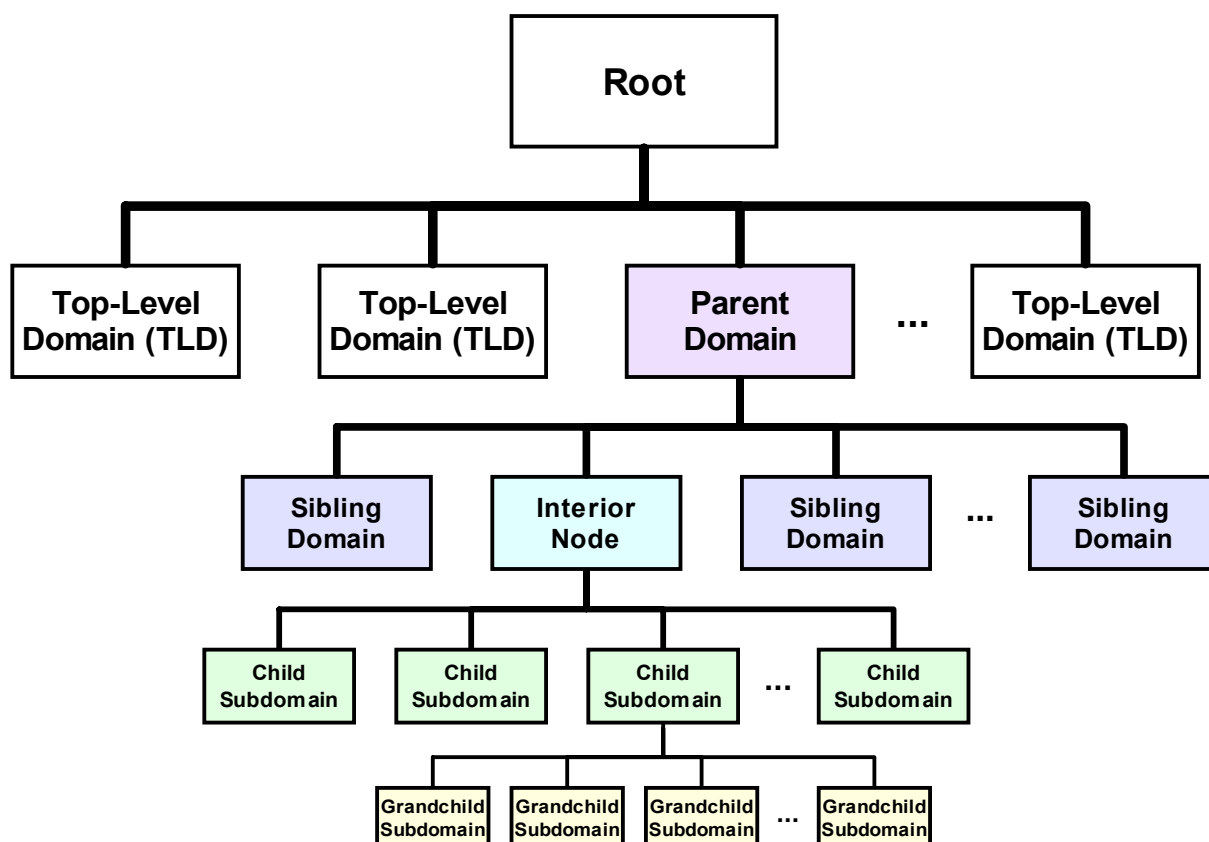

Some of the “tree” terminology used in DNS is also shown here. The portion of the tree with the purple background is one branch; the blue area highlights a smaller “sub-branch” within that branch. The green nodes within that blue area are the leaves of that smaller branch of the tree.

The term “subdomain” can also be used generically, like the word “domain” itself. In that case, it refers simply to the relationship between two domains, with a subdomain being under another domain in the structure. This means, for example, that top-level domains can be said to be subdomains of the root; every second-level domain is a subdomain of a top-level domain, and so on. But again, sometimes “subdomain” means specifically a third-level or lower domain.

### ***DNS Family-Related Terminology***

Another set of terminology you will run into compares the DNS tree structure not to a living tree, but in fact, to another analogy: a family tree. These terms are most often used to describe how a particular domain under discussion relates to the other domains or subdomains around it, so they are relative terms. The ones usually seen are (see [Figure 237](#)):

- ☉ **Parent Domain:** The domain that is above this one in the hierarchy. For example, the root domain is the parent of all top-level domains.
- ☉ **Child:** A domain at the next level down from this one in the hierarchy. Thus, the top-level domains are children of the root.
- ☉ **Sibling:** A peer at the same level as this one in the hierarchy, with the same parent. Thus, all top-level domains are siblings with the root as a parent; all second-level domains within a particular TLD are siblings and so on.

**Figure 237: DNS Name Space “Family Tree”**

This diagram is similar to [Figure 236](#), but I have labeled the nodes differently to show the “family-oriented” terminology sometimes used in DNS. In this case, the names are relative to the interior node shown in cyan. The domain immediately above it is its parent node; other nodes on the same level are siblings, and subdomains within it are children of that node.

**Key Concept:** The domain above a given domain in the DNS name space is called its *parent domain*; domains at the same level within the same parent are *siblings*; and subdomains are called *children* of that domain.

---

## Restrictions on DNS Tree Structure

Note that like a real tree, the DNS name structure must be a **true** tree in its structure. Every domain can have only one parent (except the root), just as every branch of a tree connects to only one limb (except the root/trunk). Also, no “loops” can appear in the structure; you can't have a domain whose child is also its parent, for example.

**Key Concept:** A DNS name space must be arranged as a true topological tree. This means each domain can have only one parent, and no “loops” are permitted in the structure.

---

I also want to point out that even though the name hierarchy represents an arrangement of named devices, it is only a **logical** structure. There is no necessary correspondence to the physical location of devices. A domain with ten children may represent 11 devices in 11 different countries. [We'll explore this more when we look at DNS authority structures.](#)

## DNS Labels, Names and Syntax Rules

We've seen how the DNS name space hierarchy allows us to arrange domains into a virtual tree that reflects the characteristics of how the devices themselves are organized. While using a hierarchical name space is inherently more complex than a flat name space, it yields a powerful result: the ability to specify names that can be locally managed while remaining globally unique. At the same time, the complexity of the tree yields the benefit of relatively simple name construction using domain identifiers.

### DNS Labels and Label Syntax Rules

Naming in DNS begins with giving each domain, or node, in the DNS name space a text *label*. The label identifies the domain within the structure, and must follow these syntax rules:

- ☉ **Length:** Each label can theoretically be from 0 to 63 characters in length. In practice, a length of 1 to about 20 characters is most common, with a special exception for the label assigned to the root of the tree (see below).
- ☉ **Symbols:** Letters, numbers are allowed, as well as the dash symbol (“-”). No other punctuation is permitted, including the underscore (“\_”).
- ☉ **Case:** Labels are not case-sensitive. This means that “Jabberwocky” and “jabberwocky” are both permissible domain name labels, but they are equivalent.

### DNS Label Uniqueness Requirement

Every label must be unique **within its parent domain**. So, for example, if we have a top-level domain (TLD) called “rocks”, we can only have one subdomain within “rocks” called “crystal”. Due to the case insensitivity of labels, we cannot have both “CRYSTAL” and “crystal” within “rocks”, because they are considered the same.

---

It is this concept of “local uniqueness” within a parent domain that ensures the uniqueness of names as a whole, while allowing local control over naming. Whoever is in charge of the “rocks” domain can assign names to as many individual objects or subdomains as he likes as long as they are unique within the domain. Someone else, say, the maintainer of the “glass” domain, can also create a subdomain called “crystal” within “glass”; there is no conflict because the “glass” and “rocks” domains are separate. Of course, since all top-level domains have the same parent (the root), all TLDs must be unique.

---

**Key Concept:** Each node in the DNS name space is identified by a *label*. Each label must be unique within a parent domain, but need not be unique across domains. This enables each domain to have local control over the names of subdomains without causing any conflict in the full domain names created on a global level.

---

### ***Constructing Domain Names From Domain Labels***

Each individual domain within the domain name structure can be uniquely identified using the sequence of labels that starts from the root of the tree and progresses down to that domain. The labels at each level in the hierarchy are listed in sequence, starting with the highest level, from right to left, separated by dots. The result is the formal definition of a *domain name*.

The root of the name space is given a zero-length, “null” name by default. That is, the label for the root exists, it’s just empty. This little bit of geekery is done because the root technically is part of every domain name. This means it must be included in every domain name. If it were something long like “root”, we would have to include that at the end of every domain name. This would simply make every name longer, while not really adding any useful information—we already know every domain name is under the root.

Let’s take the example above again, of a top-level domain called “rocks”, within which is a second-level domain “crystal”. The domain name of “rocks” is “rocks.”, with the dot separating “rocks” and “” (the null root). In practice, the trailing dot is often omitted, so the domain name of the TLD “rocks” can be considered to be just “rocks”. The subdomain “crystal” within “rocks” has the domain name “crystal.rocks”. If we had a named device called “salt” within the “crystal.rocks” domain, it would be called “salt.crystal.rocks”. This is pretty straight-forward, as you can see in the very simple [Figure 238](#).

We can use these names to easily identify subdomains of a particular domain. For example, if we start with “salt.crystal.rocks”, it’s obvious that “crystal.rocks” is its parent domain. It’s also clear that both “crystal.rocks” and “salt.crystal.rocks” are subdomains of “rocks”; one is a single level down from “rocks” and the other is two levels down.

**Figure 238: DNS Labels and Domain Name Construction**

Each node in the DNS name space has a label (except the root, whose label is null). The domain name for a node is constructed simply by placing in order the sequence of labels from the top of the tree down to the individual domain, going from right to left, separating each label with a dot (period).

### ***DNS Name Length Limit***

There is a maximum limit of 255 characters for a complete domain name, for implementation purposes. In practice, most domain names are much shorter than this limit, as it would violate the whole purpose of domain names if we let them get so long that nobody could remember them anyway.

### ***Resource Specification***

In many protocols, it is possible to specify a particular resource within a domain name by providing a directory structure after a name. This is done using the standard TCP/IP uniform resource locator (URL) syntax, where a path is indicated using slashes to separate subdirectories. For example, a specific file at “salt.crystal.rocks” might be located at “salt.crystal.rocks/chem/composition”.

While DNS names are case-insensitive, the labels in a URL path are *not*. So this example would be different from “salt.crystal.rocks/chem/Composition”. [See the topic on URL syntax for more details.](#)

**Key Concept:** A *domain name* is a string of text that uniquely identifies a particular node in the name space. The domain name for a node is constructed by concatenating in right-to-left order all the labels in the branch of the DNS tree starting from the top of the tree down to the particular node, separating each by a dot (period.)

---

## **Absolute (Fully-Qualified) and Relative (Partially-Qualified) Domain Name Specifications**

The [previous topic](#) showed how we can specify the domain name of any node in the DNS name hierarchy. We simply start at the root node and follow the sequence of subdomains down to the node in question, listing each level's labels separated by a dot. When we do this, we get single name that uniquely identifies a particular device.

### ***Fully-Qualified Domain Names (FQDNs)***

Technically, if a top-level domain “A” contains a subdomain “B” that in turn contains subdomain “C”, the full domain name for “C” is “C.B.A.”. This is called the *fully-qualified domain name (FQDN)* for the node. Here, the word “qualified” is synonymous with “specified”. The domain name “C.B.A.” is fully-qualified because it gives the full location of the specific domain that bears its name within the whole DNS name space.

Fully-qualified domain names are also sometimes called *absolute* domain names. This term reflects the fact that one can refer unambiguously to the name of any device using its FQDN from any other portion of the name space. Using the FQDN always instructs the person or software interpreting the name to start at the root and then follow the sequence of domain labels from right to left, going top to bottom within the tree.

### ***Partially-Qualified Domain Names (PQDNs)***

There are also some situations in which we may refer to a device using an incomplete name specification. This is called a *partially-qualified domain name (PQDN)*, which means that the name only partially specifies the location of the device. By definition, a PQDN is ambiguous, because it doesn't give the full path to the domain. Thus, one can only use a PQDN within the context of a particular parent domain, whose absolute domain name is known. We can then find the FQDN of a partially-specified domain name by appending the partial name to the absolute name of the parent domain. For example, if we have the PQDN “Z” within the context of the FQDN “Y.X.”, we know the FQDN for “Z” is “Z.Y.X.”

Why bother with this? The answer is convenience. An administrator for a domain can use relative names as a short-hand to refer to devices or subdomains without having to repeat the entire full name. For example, suppose you are in charge of the computer science department at the University of Widgetopia. The domain name for the department as a whole is “cs.widgetopia.edu.” and the individual hosts you manage are named after fruit.

---

In the DNS files you maintain you could refer to each device by its FQDN every time; for example, “apple.cs.widgetopia.edu.”, “banana.cs.widgetopia.edu.” and so on. But it's easier to tell the software “if you see a name that is not fully qualified, assume it is in the ‘cs.widgetopia.edu’ domain”. Then you can just call the machines “apple”, “banana”, etc. Whenever the DNS software sees a PQDN such as “kiwi” it will treat it as “kiwi.cs.widgetopia.edu”.

**Key Concept:** A *fully-qualified domain name (FQDN)* is a complete domain name that uniquely identifies a node in the DNS name space by giving the full path of labels from the root of the tree down to that node. It defines the *absolute* location of a domain. In contrast, a *partially-qualified domain name (PQDN)* only specifies a portion of a domain name. It is a *relative* name that has meaning only within a particular context; the partial name must be interpreted within that context to fully identify the node.

---

### ***Differentiating FQDNs and PQDNs in DNS***

I mentioned in the prior topic that the trailing dot for the null root domain is usually omitted. This is true in common parlance, and when users specify a domain name in an application; you don't use the trailing dot in your Web browser for instance. However, within DNS itself, the dot is used to clearly distinguish a FQDN from a PQDN within DNS master files. This allows us to use both FQDNs and PQDNs together. In the example above, “apple” would refer to “apple.cs.widgetopia.edu.”, but “apple.com.” would refer to the fully-qualified domain name for Apple Computer, Inc. You have to be careful about watching the dots here, because “apple.com” (no trailing period) would be a PQDN, and would refer to “apple.com.cs.widgetopia.edu.”, and **not** the domain of Apple Computer.

---

## **DNS Name Registration, Public Administration, Zones and Authorities**

The [DNS name space](#) consists of a hierarchy of domains and subdomains. From the root we have a number of top-level domains, then second-level domains below them, and still lower-level domains below that. The obvious questions then become: how do we determine the shape and structure of the name space, and who will manage it? More specifically, who will control the root of the tree and decide what the top-level domains will be called? How will we then subdivide control over the rest of the name space? How do we ensure there are no conflicts in choosing the names of sibling subdomains within a domain?

DNS can be used on private networks controlled by a single organization, and if so, the answer to my questions above is obviously, “that organization”. We'll discuss private naming, but in reality, it's just not that interesting. The vast majority of DNS use occurs on the public Internet. Here, we have a much greater challenge, because we have to construct a name space that spans the globe and covers millions of machines managed by different organizations. For this, we need a very capable *name registration* process and administration methods to support it.

In this section I describe the process of name registration and how authorities are managed within the Domain Name System, focusing on the public Internet. I begin with a description of the DNS hierarchical authority structure and how it relates to the hierarchical name space, and a discussion of the concepts behind the DNS distributed name database. I describe the Internet's organizational and geopolitical top-level domains, and how they are administered by various authorities. I then discuss how authority is delegated to the second-level and lower-level domains, and how public registration of domain names works, including how public registration issues and problems are resolved. I explain how the DNS name space is partitioned into administrative zones of authority, and conclude with a brief discussion of private DNS name registration.

**Related Information:** Most TCP/IP implementations include a special utility called *whois* that can be used to interrogate the DNS distributed name database to obtain registration information about domains. This application can be very useful for troubleshooting; for details, [see the topic discussing whois in the section on TCP/IP administration utilities](#).

---

## **DNS Hierarchical Authority Structure and the Distributed Name Database**

I began [my description of the DNS name space](#) with a dissertation on the central concept of naming in DNS: that of the *domain*. Each domain can be considered [akin to a sphere of influence or control](#). A domain “spreads its wings” over all the objects and subdomains that it contains. Due to this concept of influence, when we consider any DNS name space, we see that it is hierarchical because it reflects a hierarchy of organizations that control domains and the nodes within them. This means that there is in fact a *hierarchical authority structure* that complements the hierarchical name structure in DNS.

---

## ***The DNS Root Domain Central Authority***

The primary reason why the name space hierarchy leads to an authority hierarchy is the requirement that [sibling subdomains be unique within a domain](#). As soon as we have a need for uniqueness, this means we must have some sort of authority or process that ensures that each subdomain or object picks a different name within that domain. This is in fact what name registration is all about.

This concept of a hierarchical authority structure is a bit abstract, but it's easier to understand if we examine a sample DNS name space and discuss the issues involved in assigning names within it. Naturally, we will want to start at the top of the [name hierarchy](#), with the root domain, “null”. To start off the name space we must create top-level domains (TLDs) within the root. Now, each of these must be unique, so one authority must manage the creation of all TLDs. This in turn means that the authority that controls the root domain controls the entire name space.

In the case of the Internet, then, this central authority is ultimately responsible for every name in DNS. The central DNS authority for the Internet, which controls the creation of TLDs, was initially called the *Network Information Center*. It was later the *Internet Assigned Numbers Authority (IANA)*, which is also responsible for protocol numbers, IP addresses and more. These functions are now shared by IANA and the *Internet Corporation for Assigned Names and Numbers (ICANN)*. We'll discuss the specific TLDs of the Internet in the next few topics; IANA/ICANN and related organizations are discussed in [the topic on Internet registration authorities](#).

### ***Top Level Domain Authorities***

At the next level down in the authority hierarchy, we create second-level domains within each of the TLDs. Each TLD must itself be managed using a coordinating authority, however, this is not necessarily the organization that runs the root (IANA). IANA *delegates* authority for some of the TLDs to other organizations. They may delegate control for each TLD to a different authority at this level of the hierarchy. In fact, there can be completely different rules for managing the creation of second-level domains in one TLD than there are in another.

We'll see more of how this works later in the section. We'll also discover that in some TLDs there are in fact **multiple** authorities that work together on name registration.

### ***Lower-Level Authority Delegation***

The process of authority delegation continues as we continue down the name space hierarchy. At each level the name space becomes more specific; if we use an [organizational hierarchy](#), like the “.COM” top-level domain, we generally delegate authority for each second-level domain to the organization whose name it represents. So “IBM.COM” is managed by IBM, and so forth. Since IBM is huge, it may itself subdivide the authority structure further, but smaller organizations probably won't.

---

I want to point out explicitly that the authority hierarchy is **complementary** to the name hierarchy; they are not exactly the same. It is not necessary that there be a different authority for every level of the hierarchy. In many cases a single authority may manage a section of the name space that spans more than one level of the structure. For example, IANA manages the Internet root domain (“null”) and also the “.INT” top-level domain, but other TLDs are managed by other organizations. The name hierarchy is divided into *zones of authority* that reflect [the hierarchy of authorities that manage parts of the name space](#).

It's also worth remembering that authority over a domain doesn't necessarily imply physical control. A domain can contain subdomains that are managed by organizations on different continents, and a single subdomain can contain named devices that are on different continents as well.

### ***The DNS Distributed Name Database***

Of course, with authority comes responsibility, and the main responsibility an authority has for a domain is registering names within the domain. When a name is registered, a set of data is created for it, which can then be used by internetwork devices to resolve the name into an address, or perform other functions. The set of all the data describing all DNS domains constitutes the DNS *name database*. Just as registration authority is distributed and hierarchical, this database too is distributed and hierarchical.

In other words, there is no single place where all DNS name information is stored. Instead, DNS servers carry [resource records](#) that describe the domains for which they have authority. As we'll see, the fact that this database is distributed has major implications on how name resolution is carried out.

**Key Concept:** The name space of the public Internet is managed by a *hierarchy of authorities* that is similar in structure to the hierarchical DNS name space, though not identical. The top of the hierarchy is centrally managed by IANA/ICANN, which delegates authority to other organizations for registering names in various other parts of the hierarchy. The information about name registrations is maintained in resource records stored in various locations, which form a distributed name database on the Internet.

---

### **DNS Organizational (Generic) Top Level Domains and Authorities**

The top of the DNS name hierarchy is managed by a central authority, which controls the entire name space by virtue of deciding what top-level domains (TLDs) are allowed to exist. Obviously, it is very important that a great deal of thought go into how the TLDs are chosen; a poor design at this top level would make the entire hierarchy poorly reflect the actual structure of organizations using the name space.

There are any number of ways that the creators of DNS could have chosen to structure the Internet's name hierarchy. One obvious possibility would be to structure the Internet based on geopolitical boundaries: countries, states and so forth, [as we saw in a topic in the last](#)

---

[section](#). Another sensible idea is to structure the name space based on types of organizations. One could imagine other possible ways to divide up the names of the world's computers as well.

The beauty of the hierarchical name space is that we don't have to choose between different methods of structuring the name space. We can use more than one technique at the same time, and this is exactly what was done when DNS was first implemented. Both of the methods I described above, based on organization type and geography, were used for TLDs. This gives multiple options for name registration for most groups and individuals. I'll begin here by discussing organizational TLDs; geopolitical ones are the subject of [the topic that follows](#).

### **Original Generic TLDs**

The initial deployment of DNS featured a set of seven top-level domains that are in the standard called *generic* TLDs. The idea was that each company or organization could choose a name within one of these TLDs; they were “generic” enough that every organization would find a place that suited them. I prefer to call them *organizational*, because they divide the generic portion of the name space by organization type. The initial TLDs and their original intended organization types were:

- ☉ **.ARPA:** A temporary domain used many years ago for transition to DNS. Its name refers to the ARPAnet, the precursor of the modern Internet (in turn named for the *United States Defense Advanced Research Projects Agency, ARPA*). Today this domain is used for [reverse name resolution](#).
- ☉ **.COM:** Corporations and businesses.
- ☉ **.EDU:** Universities and other educational organizations.
- ☉ **.GOV:** Government agencies.
- ☉ **.MIL:** Military organizations.
- ☉ **.NET:** Organizations that implement, deal with or manage networking technologies and/or the Internet.
- ☉ **.ORG:** Other organizations that don't fit into any of the classifications above.

At first glance this seems like a reasonable way to cover the organizations of the world. However, since the .ARPA domain is “temporary”, this left only six categories for all other organizations. Also, the TLDs weren't all used as was originally foreseen; for example, the .GOV and .MIL domains were not used for all types of government and military organizations, but primarily for the United States federal government and military. .EDU ended up being used only for universities, again in the United States.

This left only three common top-level domains—.COM, .NET and .ORG—for almost all other groups and companies that wanted to use the organizational hierarchy. Since there were only three such TLDs, they quickly became very “crowded”, especially the .COM domain. A new fourth domain, .INT for international organizations, was added fairly soon to the original seven, but it too was only for a small number of organizations, such as interna-

---

tional standards bodies. Despite the handful of organizational TLDs, there is no doubt that they have been much more popular than the geopolitical ones. I explain some of the reasons for this in [the next topic](#).

### ***New Generic TLDs***

There was, of course, no inherent reason why it was necessary to limit the generic domains to only that the few that were originally created. Over the years, many suggestions were made for new generic TLDs that would expand the number of possible second-level domain names and also provide better categorization for different organization types—that is, make the generic TLDs “less generic”. There was some resistance at first to adopting these new names, especially because there were so many different ideas about what new TLDs should be created. As I said before, creating TLDs must be done carefully to ensure that the name hierarchy makes sense.

IANA took input from a lot of people, and followed a complex procedure-that-I'd-rather-not-get-into-here ☺ to determine what new TLDs should be made. In 2001 and 2002, approval was given for the creation of several new top-level domains, and decisions made about authorities for administering them.

Of the new TLDs approved in the last few years, the number that has achieved widespread popularity is, to my knowledge, zero. Humans are creatures of inertia, and most people are still used to names ending in .COM, .NET or .ORG. In time this may change, but it will probably take a few years.

Incidentally, there are some people who actually felt that adding new generic TLDs was a **bad** idea, since it makes organizations potentially more difficult to locate (due to the possibility of a name ending in a variety of different TLDs). This is debatable, however, especially since the exhaustion of address space in the existing TLDs means many companies have had to choose unintuitive domain names anyway.

---

## Summary of Organizational (Generic) TLDs

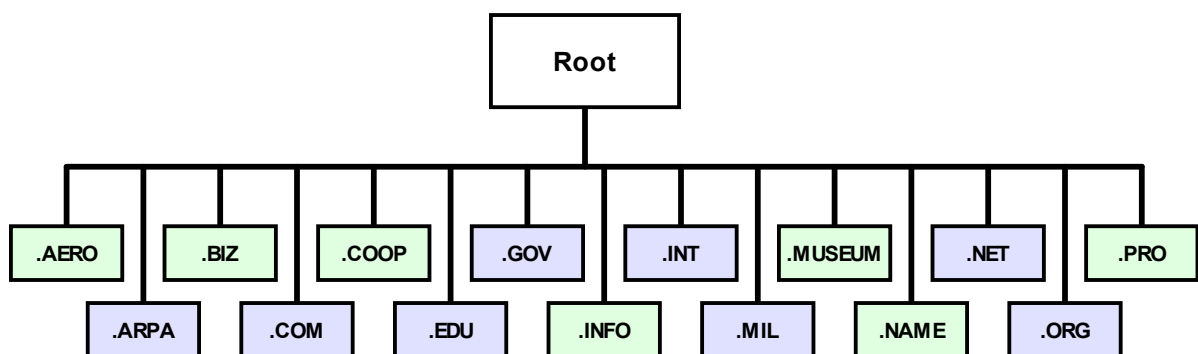

Table 166 shows all the current generic TLDs and describes how they are used, and also lists the current central authority that manages each. The original TLDs are highlighted in italics (I am including .INT as an original TLD since it was created long before the “new” ones earlier this decade). Figure 239 shows the fifteen generic TLDs in graphical form.

**Table 166: Internet DNS Organizational (Generic) Top-Level Domains (Page 1 of 2)**

Generic TLD	Abbreviation For	Authority	Current Use / Description
<b>.AERO</b>	Aerospace	Société Internationale de Télécommunications Aéronautiques (SITA)	Members of the aerospace industry, such as airlines and airports. (Yes, that <i>is</i> French!)
<b>.ARPA</b>	Address and Routing Parameter Area	Internet Assigned Numbers Authority (IANA) / Internet Corporation for Assigned Names and Numbers (ICANN)	First defined as a temporary domain for migration from the older host table system, the “ARPA” of course originally stood for the Advanced Research Projects Agency, creators of the predecessors of the Internet. Today, the .ARPA domain is used for internal Internet management purposes; the abbreviation at left was, I believe, “manufactured” to fit the letters “ARPA”. ☺ The best-known use of this domain is for <a href="#">reverse DNS lookups</a> .
<b>.BIZ</b>	Business	NeuLevel, Inc.	Businesses. Intended as a competitor to .COM.
<b>.COM</b>	Commercial Organizations	VeriSign Global Registry Services	Originally intended for corporations and other commercial interests, .COM is also widely used for other purposes, including small businesses and even individuals who like the popularity of the .COM domain.
<b>.COOP</b>	Cooperative Associations	Dot Cooperation LLC	Cooperative associations.
<b>.EDU</b>	Education	Educause	Originally intended for all types of educational organizations, now used only for degree-granting higher education institutions accredited in the United States. Other educational institutions such as public schools usually use the country code TLDs.
<b>.GOV</b>	Government	US General Services Administration	Reserved for the United States federal government.
<b>.INFO</b>	Information	Afilias Limited	A very generic TLD designed for information resources of various sorts. It is unrestricted, in that anyone can register any sort of organization in .INFO. Also positioned as an alternative to .COM.
<b>.INT</b>	International	IANA .int Domain Registry	Used only for large organizations established by international treaty.

**Table 166: Internet DNS Organizational (Generic) Top-Level Domains (Page 2 of 2)**

Generic TLD	Abbreviation For	Authority	Current Use / Description
<b>.MIL</b>	Military	US DoD Network Information Center	Reserved for the United States military.
<b>.MUSEUM</b>	Museum	Museum Domain Management Association	Take a guess. ☺
<b>.NAME</b>	Names	Global Name Registry	In the original generic hierarchy there was no place set aside for individuals to register names for themselves, so people would instead create domains like "jonesfamily.org". This was non-ideal so .NAME was created as a place for individuals and families to register a domain for their names. .NAME also competes with the country code TLDs.
<b>.NET</b>	Network	VeriSign Global Registry Services	This TLD was supposed to be used only for Internet service providers and other organizations working intimately with the Internet or networking. Due to the exhaustion of name space in .COM and .ORG, many .NET domains are registered to other organizations, however.
<b>.ORG</b>	Organizations	Public Interest Registry	Originally intended for organizations not fitting into the other generic TLDs, .ORG quickly became associated with professional and non-profit organizations. It is possible, however, to have a for-profit company use a .ORG name.
<b>.PRO</b>	Professional	RegistryPro	Reserved for credentialed professionals such as lawyers and doctors.

**Figure 239: Internet DNS Organizational (Generic) Top-Level Domains (TLDs)**

There are fifteen generic TLDs currently defined for the Internet. They have been shown here in alphabetical order, with the original TLDs shown in blue and the new ones added in 2001/2002 in green.

**Key Concept:** One of the two ways in which the Internet's DNS name space is divided is using a set of *generic* top-level domains. These TLDs are intended to provide a place for all companies and organizations to be named based on their organization type. There were originally six such domains, but this has been expanded so that there are now fifteen.

---

## **DNS Geopolitical (Country Code) Top Level Domains and Authorities**

In theory, the [generic top-level domains \(TLDs\)](#) would be sufficient to meet the needs of all the individuals, companies and groups in the world. This is especially true since .ORG by definition is a “catch all” that can include anyone or anything. However, back at the beginning of DNS, its creators recognized that the generic TLDs might not meet the needs of everyone around the world. There are several reasons for this, chief among them:

- ☉ **Americentrism of the Generic Domains:** I don't mean this as a criticism (I'm an American citizen and love my country!) It is indisputable, however, that United States organizations and companies dominate the generic TLDs. This is not surprising, given that the Internet was first developed in the U.S.A., but it still presents a problem for certain groups. For example, if the United States military controls the .MIL domain, where does, say, Britain's military fit into the name space?
- ☉ **Language:** Most of the generic domains are populated by organizations that primarily do business in English. There are hundreds of languages in the world, however, and it's easier for the speakers of those tongues if they can more readily locate resources they can understand.
- ☉ **Local Control:** Countries around the world rarely agree on much, and they certainly differ on how organizations within their nations should have their Internet presence arranged. There was a desire on the parts of many to allow nations to have the ability to set up subsets of the name space for their own use.

## ***Geopolitical (Country Code) Top Level Domains***

For these and other reasons, the Internet's name space was set up with a set of *country-code* top-level domains paralleling the generic ones, sometimes called *ccTLDs*. I call these *geopolitical* TLDs since they are based on geopolitical divisions of the world (similar to [the example I used in my overview of the DNS name space](#)). In this hierarchy, every country of the world is assigned a particular two-letter code as a top-level domain, with a specific authority put in charge of administering the domain. For example, the ccTLD for Great Britain is “.UK”, the one for Canada “.CA” and the one for Japan is “.JP”. The codes often are more meaningful in the local language than in English, incidentally; Germany's is “.DE” and Switzerland's “.CH”.

---

## Designating Countries and Country Code Letters

When I said that countries rarely agree on anything, I wasn't kidding—in fact, they can't even agree on what's a country! Real shooting wars have been fought over whether or not a particular territory was independent or part of another nation, never mind verbal wars, and the creators of DNS wanted no part of this sort of controversy. As the IANA web site says:

“The IANA is not in the business of deciding what is and what is not a country, nor what code letters are appropriate for a particular country.”

To remain neutral, IANA's ccTLD codes are taken directly from the standard country abbreviations maintained by the *International Organization for Standardization (ISO)* in ISO standard 3166-1. When a country is recognized by the ISO and a code assigned to it on this list, IANA creates it as a top-level domain. There are presently over 200 different geopolitical TLDs. No, I am **not** putting them here in a table, I have to draw the line somewhere around here! ☺

**On The Web:** You can find the current list of IANA country code TLDs at: <http://www.iana.org/cctld/cctld-whois.htm>

---

## Country Code TLD Authorities

Each country has the authority to set up its TLD with whatever internal substructure it chooses; again, this is the power of a hierarchical structure. Some countries enforce a further geographical substructure at the lower levels. For example, the .US domain for the United States was originally set up so that all second-level domains were two-letter state abbreviations (this was later changed). Other countries may actually use organizational subdomains within their country code; Great Britain for example has .CO.UK for companies in their country (like .COM but for the UK only; they left off the “M”), and .COM.AU is for corporations in Australia. Other countries may not have any particular substructure at all, especially if they are small.

**Key Concept:** Due to the limitations of the generic TLDs, a set of *country code* top-level domains was created. This *geopolitical* hierarchy allows each nation on earth to set up its own name system based on its own requirements, and to administer it in the manner it sees fit. The IANA determines what is a country based on official decisions made by ISO.

---

## Leasing/Sale of Country Code Domains

Interestingly, some very small countries with recognizable codes, especially to English speakers, have used their codes for very creative purposes, including selling or renting the name space to enterprising companies. A good example is the .TV domain, which techni-

---

cally belongs to the island nation of *Tuvalu*. Of course, to most people, “TV” means something quite different. Some folks thought that domain names ending in “TV” might be popular in the English-speaking world, so they formed a company called “The .TV Corporation” and negotiated with the government of Tuvalu to use the .TV domain. Today, the authority for this TLD is in fact this corporation, headquartered in California! Similar arrangements can be found with the .CC, .NU, .TO and other TLDs.

This serves as a good reminder that the name space is logical and not physical. Obviously, the many computers with “.TV” names are not actually located on a remote island in the South Pacific. Similarly, if a Web site ends with “.CA”, for example, it probably represents a Canadian organization, but that doesn't necessarily mean the Web site itself is actually hosted in Canada.

### **Drawbacks of the Geopolitical TLDs**

The geopolitical domains have been very popular for certain uses; for one thing, national governments and other “official” institutions like to use them, for obvious reasons. Typing “www.gov.XX” or “www.government.XX” where “XX” is a country code is likely to bring you to the national government Web site of most countries. Some companies and organizations use the ccTLDs because they allow them to choose a name already taken in the generic hierarchies, or simply to express national pride.

For many other companies and organizations, however, the generic TLDs have been much more popular than the country codes. I believe there are several reasons for this, but I think the most important one is that organizations are easier to locate using the generic domains.

Here's a good example of what I mean. In the town near where I live, a new grocery store called Aldi recently opened. I like the store and wanted to learn more about them, so I fired up my Web browser and sought out their Web site. Yes, I could have typed it into a search engine, but like most people I am lazy. It was much easier to just enter “www.aldi.com” into my browser, and lo and behold, up popped the web site of Aldi International.

Now, Aldi is actually headquartered in Germany, and they do have a web site at “www.aldi.de” as well. But I had no idea where they were originally from. I found them easily by going to “www.aldi.com”, because I didn't need to know their physical location, and because I know that most large companies have a “.COM” domain. Of course, being “findable” is very important, especially for commercial organizations trying to do business.

Another good example is the United States, which as mentioned above has its own country code, .US, in addition to dominating the generic TLDs. The authority in charge of this domain chose to make it follow a strict geographical hierarchy, so every domain must be of the form “organization.city.state-code.US”. So, to use this part of the name space, a company in Boston must be within the “.boston.ma.us” domain.

---

That's very neat and logical, but it makes names both longer and harder to guess than the generic equivalents. Suppose you wanted to get information on metals giant Alcoa. If you're in the industry you might know they are located in Pittsburgh, but if not, which is easier to find, “www.alcoa.pittsburgh.pa.us”, or “www.alcoa.com”? Anyone here know how to spell Albuquerque? ☺

It is for this reason that the .US domain achieved success in certain segments of society but not in others, especially commercial entities (corporations). The strict hierarchy does have some real advantages, however, such as avoiding [name space conflicts](#). The .US authority eventually abandoned the strict geographical hierarchy due to its non-acceptance.

### **DNS Second-Level and Lower Domains. Delegation of Registration Authority and Public Registration**

The IANA is in charge of deciding what top-level domains (TLDs) exist in the Internet name space, and as such, they are ultimately responsible for all names in the Internet. The entire point of the [authority hierarchy](#), however, is that IANA not be responsible for the whole name space. So, while IANA maintains control over certain TLDs, such as [.INT](#) and [.ARPA](#), control for managing the others is delegated to secondary authorities for each TLD.

Just as IANA had the choice of how to delegate authority to the subdomains of the “root” domain, the organization in charge of each TLD gets to make the same decision about how second-level domains are to be created under the TLD. In many of the TLDs, especially the generic ones, second-level domains are assigned directly to individuals or organizations.

For example, a company named XYZ Industries might want to get the domain “xyzindustries.com”. In other TLDs, second-level domains are set up in a particular structure, like the state codes used in the .US domain. There, you need to go down more levels, but eventually you once again get to the point where companies and people register their own domains; in the .US domain, XYZ Industries might want to register “xyz.phoenix.az.us”, for example, if they were headquartered in Phoenix.

### ***Centralized Public Registration***

This transition point between the authorities granted responsibility for parts of the name space and the “regular” people and groups who want to get names within it is important. A process of *public registration* had to be established to allow such name assignment to occur in a consistent and manageable way. This was not that difficult to accomplish back when the original [generic TLDs](#) and [country code TLDs](#) were first created. The Internet was quite small and it made sense to just have the authority in charge of each TLD perform registrations within that TLD. This ensured that there was no duplication of names within a TLD with a minimum of fuss.

For the very important generic TLDs such as .COM, .NET and .ORG, the authority in charge of registration was the *Internet Network Information Center (the InterNIC)*. The InterNIC was set up as a service administered by the United States government, who later granted

---

the contract to manage it to *Network Solutions Inc. (NSI)*. NSI was eventually purchased by Verisign, then later spun it off as a separate venture. (Things change quickly in the networking world!)

NSI single-handedly performed all registrations within the .COM, .NET and .ORG TLDs for many years. The popularity of the original generic TLDs, however, led to an explosion in demand for name registration in the 1990s in these domains. Having a single company in charge of registration led to this becoming another bottleneck in the Internet's domain name system. There were also many folks who didn't like the lack of accountability and competition that came with having a single "monopoly" in charge of registration; the InterNIC could set its own price and originally charged \$35 per year per domain name, then later \$50 per year.

### ***Deregulation of Public Registration***

In the late 1990s, responsibility for name registration was given to the [Internet Corporation for Assigned Names and Numbers \(ICANN\)](#). The registration process was "deregulated", to borrow a term referring to removal of monopolies from industries like power generation. As of December 1999, there was still a single authority that has overall responsibility for each TLD, including .COM, .NET and .ORG. Today, Network Solutions is still the authority running .COM and .NET. However, they aren't the only ones that register names within these TLDs. They further delegate registration authority to a multitude of other companies, called *accredited registrars*. Any registrar can register names within the TLD(s) for which they are accredited.

Naturally, coordination becomes much more of a concern when you have multiple companies registering names in a TLD compared to just one. A special set of technical and administrative procedures is followed to ensure that there are no problems such as two registrars trying to grab a name at the same time. The system has worked well, and those who wish to use TLDs where competition exists now can choose from a variety of registering companies. The most noticeable result of this was also the most predictable one: the cost of registering a domain name in the deregulated generic TLDs is usually much lower than the fees originally charged by the InterNIC.

Once a company, individual or organization has a registered lower-level domain, he/she/it becomes the authority for that domain. Use of the domain then becomes private, but depending on how the domain is used, further public name registration may be required. [See the topic on private registration for more.](#)

### **DNS Public Registration Disputes (Conflicts, Cybersquatting, "Deceptive Naming", Etc.) and Dispute Resolution**

The Internet started off as a medium for research into networking, evolved into a system for interconnecting scientists and ended up as a global communications tool used by just about everyone. As part of this evolution, the Internet also became a very important part of how business is done in the world. Money started to really come into the Internet picture in the

---

early 1990s, and just a few short years later, its impact on the Internet was so significant that the growth of the stock market to dizzying heights in the late 1990s is now often called “the Internet bubble”.

### ***Public Registration Disputes***

Unfortunately, the increasing importance of the Internet to commercial interests crashed headlong into the non-commercial original design of Internet technology, and nowhere was this more evident than in the Domain Name System. Since there were only a few [generic TLDs](#), since each name within a TLD had to be unique, and since humans are often confrontational creatures, it didn't take a long time before arguments broke out over who should be able to use what name, and why. And of course, from there, it didn't take long before lawsuits and other unpleasanties broke out.

There are a surprising number of significant problems associated with public registration of domain names.

### **Corporate Name Conflicts**

The .COM domain is for corporations, but many corporations have the same name. The ACME Furniture Company, the ACME Restaurant Supply Corporation and ACME Footwear, Inc., probably all would like to have the “acme.com” domain. But there can be only one such domain within .COM. (These are fictional examples; “acme.com” is in fact owned by an organization called *Acme Labs*.)

### **Corporate/Individual/Small-Business Name Conflicts**

There are many corporations that have names similar to or even identical to the names of individuals, leading to potential conflicts. For example, suppose your first name is Wendy and you own a small fabric store called “Wendy's Fabrics”. But you are Internet savvy and decide you want to register “wendys.com” as soon as you hear about the Internet in 1993. Then this big hamburger chain comes along and has a problem with that... ☺

To my knowledge no such issue arose with respect to Wendy's, but there actually was a widely-publicized case that shows just how recently most corporations were “out of the loop” with respect to domain naming. In 1994, a writer for Wired magazine was astonished to find that the “mcdonalds.com” domain name was unregistered! To show just how unregulated the registration process was, he registered it himself, and caused a bit of a stir as a result. The Golden Arch Folks eventually acquired the domain from him in an amicable arrangement where he relinquished the name and they made a donation to charity.

### **“Corporate Warfare”**

A particularly ugly type of conflict is sometimes seen where companies intentionally try to take business from each other by registering names that have nothing to do with their own companies. An example would be if Burger King had tried to register “mcdonalds.com” and use it to advertise Burger King products. (Which they *didn't* do, I might add, so please nobody sue me! ☺)

---

Another example is when companies try to use alternate TLDs, such as registering “burgerking.org” to confuse people trying to find “burgerking.com”. In fact, many companies have taken the step of registering their names in many different TLDs to prevent this sort of thing from happening.

### **“Cybersquatting”**

Some ambitious (to choose a nice term) individuals, recognizing early on the potential value of certain names, registered large volumes of names with the hopes of reselling them. Many people condemned this as exploitative, and the term *cybersquatting* was created to refer to this type of activity. Unfortunately, a lot of money was made this way, and there are many domain names that to this day cannot be used because they have been “reserved” indefinitely by people or individuals who will never use them.

### **Deceptive Naming Practices**

Another type of somewhat-diabolic creativity has been displayed by people who seek to take advantage of the inability of some of us to spell. For example, if you were a competitor of a large company called Superb Transceivers Inc., which registered “superbtransceivers.com”, you might register “superbtranscievers.com” and redirect traffic from there to your own domain. Another example takes advantage of the common mix-up between “O” (the letter) and “0” (the number). For example, a software company once registered “micros0ft.com”, much to the chagrin of the Redmond, Washington software giant.

### ***Dispute Resolution Methods***

So, how do we resolve these situations? As the saying goes, it can be done either the easy way, or the hard way...

### **Domain Name Sharing**

Sometimes the antagonists agree on a productive solution. One particularly constructive idea is to agree to *share* the domain name. For example, the three ACME companies mentioned in my example above could each create their own more-specifically-named domains, such as “acmefurniture.com”, “acmerestaurantsupply.com” and “acmefootwear.com”. Then, they might agree to have the “www.acme.com” registered to nobody, by having one company register it and not use it for anything.

Even better, they could set it up with a simple web page that says the domain is shared, with a link to the three sites above. I have seen this before, but rarely. Unfortunately, it seems grade school children understand the concept of sharing better than most corporate executives do.

---

## Domain Name Purchase

Another option is purchase. If a big company wants a domain name already registered by an individual or small business, they will often just purchase it, as this is the easiest thing to do. During the height of the Internet mania, there were domain names that sold for *millions* of dollars—just for the right to use the name! Again, many cybersquatters and other speculators got rich doing this.

## Litigation

Often the combatants don't play nice, and the usual occurs: threats, intimidation, law suits, and so forth. Sometimes a letter from a lawyer is enough to resolve the issue, especially when some poor individual owning a web site gets threatened with legal action by a large company—this has happened many times.

However, often the disagreeing parties stick to their guns, especially if two companies lock horns and their lawyers refused to back down. Usually the matter then ends up in the courts, and is eventually be resolved one way or the other. This gets into legal issues that I am totally unqualified to even talk about. Usually, claims of trademark infringement would be used by a company challenging a prior domain name registration.

## The Uniform Domain Name Dispute Resolution Policy

Lawsuits are expensive and time consuming, so there was a desire that some other mechanism exist for resolving these conflicts as well. Since the authority for each TLD controls what happens within it, it also has the right to create its own policies for how to deal with these sorts of issues. For the generic TLDs, the original registering authority, the InterNIC, had a dispute resolution policy that allowed someone with a complaint to challenge a domain name registration if they had a trademark interest in that name. The policy was controversial for a number of reasons, not the least of which because it led to some domain names being successfully challenged even if there was no proof of trademark infringement.

The current authority for the generic TLDs, [IANA/ICANN](#), created a new *Uniform Domain Name Dispute Resolution Policy (UDRP)* in 1999, to better handle domain name conflicts. This policy specifies a procedure whereby a company that has a valid trademark can challenge a domain name if it either infringes on the trademark, is confusingly similar to it, or if the name was registered by someone else in bad faith. At the same time, it also lists ways that the original registrant can prove that the registration is valid and should be maintained. This new system eliminates many of the real problems described above, such as deceptive naming, “corporate warfare” and cybersquatting, while not automatically allowing a second-comer to shut down a legitimate domain.

## *Disputes as a Motivation for New Generic TLDs*

Incidentally, it was all this nonsense that led, in part, to the clamor for new generic top level domains. In the interest of fairness, I also want to mention that even though more complicated TLDs like the old strictly hierarchical .US are not very popular, they have a *huge*

---

advantage over the generic domains. Since all registrations there are geographic, there are far fewer conflicts, because a dispute requires that two organizations have the same name and also be in the same state and town.

For example, you could still have three “Joe’s Pizza Parlor”s in Chicago duke it out, but it’s not likely that you’d see big companies on the mat in .US. For example, the ACME Furniture Company might use “acme.seattle.wa.us”, the ACME Restaurant Supply Corporation “acme.mendocino.ca.us” and ACME Footwear, Inc. could go with “acme.anchorage.ak.us”.

## **DNS Name Space Administrative Hierarchy Partitioning: DNS Zones of Authority**

I explained earlier in this topic that the DNS name space is arranged in a hierarchy, and that there is also a [hierarchy of authorities that is related to that hierarchical name structure](#). However, the two hierarchies are **not** exactly the same. The reason is that if they were the same, this would mean we needed a separate authority for every domain at every level of the tree, and that’s something we are very unlikely to want to have everywhere in the structure.

At the very top levels of the DNS tree, it seems reasonable that we might want to designate a separate authority at each level of the structure. Consider the [geopolitical name hierarchy](#); IANA/ICANN manages the “root” domain, but each of the ccTLDs is managed by a distinct national authority

### ***The Need For Authority Hierarchy Partitioning***

However, when you get to the lower levels of the structure, it is often inconvenient or downright impossible to have each level correspond to a separate authority. As an example, let’s suppose you are in charge of the Googleplex University IT department, which runs its own DNS servers for the “googleplex.edu” domain. Suppose there were only two schools at this university, teaching Fine Arts and Computer Science. Suppose also that the name space for the computers were divided into three subdomains: “finearts.googleplex.edu”, “compsci.googleplex.edu”, and “admin.googleplex.edu” (for central administrative functions, including the IT department itself).

Most likely, you don’t want or need the Fine Arts department running its own DNS servers, and they probably don’t want to, either. The same is likely true of the administration machines. However, it’s possible that the Computer Science department **does** want to run its own DNS servers, because they probably have many more computers than the other departments, and they might use running a DNS server as part of their curriculum. In this case, you might want yourself, the administrator for “googleplex.edu”, to maintain authority for the “finearts.googleplex.edu” and “admin.googleplex.edu” subdomains and everything within them, while delegating authority for “compsci.googleplex.edu” to whomever in the Computer Science department is designated for the task.

---

## DNS Zones of Authority

DNS is specifically designed to allow these divisions between the name hierarchy and the authority structure to be created. The complete DNS name structure is divided by making *cuts* (as the standard calls them) between adjacent nodes to create groups of contiguous nodes in the structure. Each group is called a *zone of authority*, or more commonly, just a *zone*. Each zone is usually identified by the domain name of the highest-level node in the zone, that is, the one closest to the root. The zones in DNS are by definition *non-overlapping*—every domain or subdomain is in exactly one zone.

### Methods of Dividing the Name Space Into Zones

The division of the name space into zones can be made in an arbitrary way. At one extreme, we could place a cut between every node, and thereby divide the entire name space so each domain (and subdomain, etc.) was a separate zone. If we did this, the name hierarchy and authority hierarchy would indeed be the same for the entire DNS tree. At the other end of the scale, we could use no cuts at all, defining a single zone encompassing the entire DNS structure. This would mean the root was the authority for the entire tree.

Of course in practice, neither of these is particularly useful, as neither really reflects how the real-world administration of DNS works. Instead, we generally divide the name structure in a variety of places depending on the needs of different parts of the name space. There are many cases where we might want to create a subdomain that is responsible for its own DNS server operation; there are others where we might not want to do that. The significance of a “cut” in the name hierarchy is that making such a cut represents, in essence, a *declaration of DNS independence* by the node below the cut from the one above the cut.

Returning to our example, if googleplex.edu is in charge of its own DNS servers, then there would be a “cut” in the name space between “googleplex.edu” and .EDU at the next higher level. This means that the DNS server for .EDU is no longer in charge of DNS for the “googleplex.edu” domain; instead, either the University itself or someone they hire as a third party must provide DNS for it. In this case, we are assuming Googleplex U. themselves run their own DNS. Without making any other cuts, the “googleplex.edu” domain would be a single zone containing everything below that name, including both “finearts.googleplex.edu” and “compsci.googleplex.edu”.

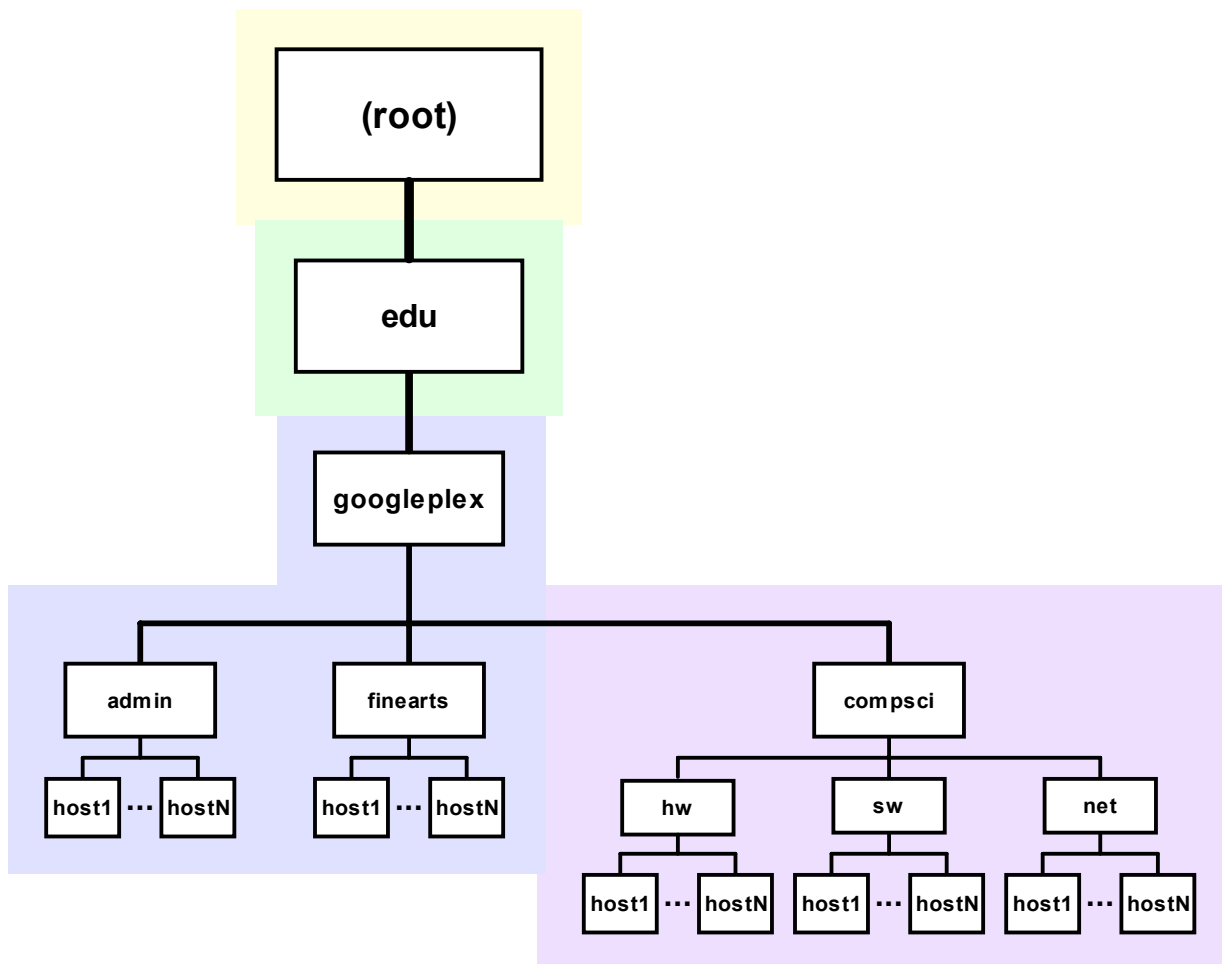

In our example, however, we would make another “cut”, between “googleplex.edu” and “compsci.googleplex.edu”. This in effect *liberates* “compsci.googleplex.edu”, allowing its administrators to be in charge of their own DNS server. In so doing, we end up with two distinct zones: one encompassing “googleplex.edu”, “finearts.googleplex.edu” and “admin.googleplex.edu” (and everything underneath them) and another for “compsci.googleplex.edu” (and everything below it). This is illustrated in [Figure 240](#).

**Key Concept:** The DNS name registration hierarchy is divided into regions called *zones of authority*. Each zone represents an area that is administered independently, and consists of a contiguous segment of the DNS name tree.

---

**Figure 240: DNS Zones Of Authority**

This example shows how *cuts* can be made between nodes in the DNS name tree to create an arbitrary hierarchy of name authorities. In this example I have shown the DNS tree branch for “googleplex.edu”, with each zone indicated using a different background color. IANA/ICANN is responsible for the root domain (yellow), and a separate authority named *Educause* takes care of “.EDU” (green). The blue zone covers much of “googleplex.edu”, except that a cut has been made between “googleplex” and “compsci” to create an independent zone of authority for “compsci.googleplex.edu”, shown in purple.

### ***The Impact of Zones on Name Resolution: Authoritative Servers***

The concept of zones is critical to understanding how DNS name servers work, and therefore, how name resolution is performed. All of the information about the subdomains and individual devices in the zone is represented using a set of resource records stored on a DNS name server. Usually, this name server is associated with the highest-level domain name in the zone. A name server that contains the definitive information for the zone is said to be *authoritative* for the zone. An authoritative server for a zone is one that maintains the official information about the zone, and the one that is ultimately responsible for providing name resolution information about it. We'll see more about this in [the section on DNS servers and name resolution](#).

---

Every DNS zone has a set of authoritative servers, which are usually a pair called the *primary* (or *master*) and *secondary* (or *slave*) servers. However, it is also possible for a single DNS name server to be authoritative for more than one zone. As mentioned above, it is not always necessary for the actual owner of a domain to provide DNS services for it. Very often, especially for the domains owned by small businesses or individuals, DNS services are provided by a third party, often an Internet Service Provider.

For example, I have had “pcguide.com” registered as a domain since 1997, but my long-time Web hosting provider, pair Networks, has provided DNS services for me since the beginning. This means that pair's DNS servers in the “pair.com” hierarchy are responsible for “pcguide.com”. They are also responsible for many other domains for their customers.

## **DNS Private Name Registration**

We have now seen [the hierarchical nature of the DNS name space](#), and [the authority structure](#) that administers it. Name registration begins with the [generic](#) and [country code](#) top-level domains (TLDs) within the root of the name hierarchy, proceeds to [second-level domains](#) within the TLDs, and then lower-level subdomains below those. As we progress down the name tree, we move from the most general, public authority (IANA/ICANN, which runs all of DNS), through the high-level TLD authorities, and eventually down to the level of individual organizations, corporations and individuals.

### ***Private Domain Name Ownership***

This “dividing line” between public authorities and private authorities occurs in many different places in the name structure. Wherever it does occur, below that line, responsibility for the domain becomes that of the organization that registered it. It can further subdivide the name space, granting parts of it to other organizations or even reselling it if they wish. Alternately, they may decide to use the name space to create a purely internal structure. I call this *private name registration*, in contrast to the *public name registration* we discussed earlier in this section.

For example, if a company called XYZ Industries registers “xyzindustries.com”, they become the owner of not just that domain name, but any subdomain structure or named items within it that they may choose to create. This is, of course, the beauty and power of authority delegation and the hierarchical structure. The company has an important decision that they must make however: they must choose whether they want to create names that are part of the global DNS name structure, or if they want to use names within the structure purely privately.

### ***Using Publicly-Accessible Private Names***

If a company wants names within its domain to be part of the global DNS name structure, it is required to perform the work necessary to properly set up and manage these names so they fit into the Domain Name System. The most common example, of course, is creating a public World Wide Web server. Most companies name such servers beginning with “www”, so XYZ Industries would probably wish to have the name “www.xyzindustries.com” for its WWW server address.

---

Obviously, they want and need anyone on the Internet to be able to locate this server. Thus, even though XYZ has private control of the “xyzindustries.com” domain, and thus owns the name “www.xyzindustries.com”, they must follow proper procedures for ensuring that DNS resource records are set up for their “www” subdomain so everyone on the Internet can find it. They may do this themselves, if they run their own DNS servers, or may have an ISP or other third party do it for them, as described in the [previous topic](#).

### ***Using Private Names For Internal Use***

The alternative is to create “purely private” names for use only within the organization. For example, it is likely that even if XYZ wants a public Web server, it may wish to name many other machines that are to be accessed only within the company itself. In this case, they don't need to set these machines up so they are publicly recognizable. They can create private machine names and manage them internally within their own network.

One common way in which this is done is to make use of the older host table name system. This system is now archaic for large internetworks, but is often still used in smaller companies due to its simplicity. A name is “registered” by being added to the host tables on each of the computers within the organization, and “resolved” when the operating system on a host checks this file prior to using standard DNS resolution methods. The host table supplements DNS in this case (it is not really a part of DNS.) The two systems are complements and can work together, as I explained at the end of [the topic describing host tables](#).

**Key Concept:** Once an organization registers a particular domain name, it becomes the owner of that name and can decide whether and how to create a substructure within that domain. If it wants objects in the domain to be accessible on the public Internet, it must structure its domain to be consistent with Internet DNS standards. Alternately, it can create a purely private domain using any structure and rules it prefers.

---

### ***Using Private Names On Networks Not Connected to the Internet***

If you are running a “purely private” network not connected to the Internet at all, you can actually set up your own entirely private name hierarchy and run DNS yourself. In this case, you become “the boss” in charge of the DNS root and can use any naming system you like. This is sometimes considered attractive, because one can then use very simple machine names on small networks, without having to perform any public registration or even use names that correspond to the global hierarchy. Instead of the accounting computer in XYZ Industries being named “accounting.xyzindustries.com”, internally it could be named just “accounting”. You can mix these with real DNS names too when accessing resources, so Joe's machine could be called just “joe”, while the Web site of UPS would of course still be “www.ups.com”.

---

The most common example of this mixing of private and public names is the definition of the private local name for the loopback address of a computers. Most Windows and UNIX machines define the name “localhost” to be the address 127.0.0.1, which means “this computer” on any TCP/IP machine.

---

## DNS Name Servers and Name Resolution

The preceding two sections describe the Domain Name System's hierarchical name space, and the authorities that manage it and are responsible for name registration. These two elements, the name space and name registration, are the more “intangible” parts of the name system, which define how it is created and managed. The “tangible” aspect of the name system is the set of software and hardware that enables its primary “active function”: *name resolution*. This is the specific task that allows a name system to replace cumbersome numeric addresses with easy-to-use text names.

Name resolution is the part of DNS that generally gets the most attention, because it is the portion of the system that most people work with on a daily basis. DNS uses a very capable client/server name resolution method that makes use of a distributed database of name information. The most commonly used implementation of the DNS name resolution process is, of course, the one used for the Internet itself, which resolves many billions of name requests every day.

In this section I explain in detail the concepts and operation of the DNS name resolution function. The section is broken into three subsections. The first two cover each of the two key software elements that work together to implement the DNS client/server name resolution function. The first describes DNS name servers, and how they represent, manage and provide data when resolution is invoked. The second describes DNS clients, called *resolvers*, how they initiate resolution, and the steps involved in the resolution process. After these I have a third subsection that ties together the information about name servers and resolvers by providing a look at message exchange between these units, and describing the formats of messages, resource records and DNS master files.

**Background Information:** The material in this section assumes that you are already familiar with the topics in the preceding two sections, and references those sections where appropriate. If you have not already read the sections on the [DNS name space](#) and [name registration](#), you should at least review the [overview of DNS components and general functions](#).

---

**Related Information:** A set of related TCP/IP utilities called *nslookup*, *host* and *dig* can be used by an administrator to query DNS name servers for information. They are useful for a variety of purposes, including manually determining the IP address of a host, checking for specific resource records maintained for a DNS name, and verifying the name resolution function. [See the topic discussing these programs in the section on TCP/IP administration utilities.](#)

---

---

## **DNS Name Server Concepts and Operation**

Of all the components and functional elements that combine to form the Domain Name System, DNS *name servers* are arguably the most important. These servers, which may be either dedicated devices or software processes running on machines that also perform other tasks, are the workhorses of DNS. They store and manage information about domains, and respond to resolution requests for clients—in some cases millions of times each day. Understanding how they perform both this most basic task and the many support jobs for which they are also responsible is crucial to understanding DNS as a whole.

In this section I describe the concepts related to DNS name servers, and explain how they operate. I begin with an overview of DNS name server functions and general operation. I describe the way that DNS name server data is stored in resource records and the role of classes. I discuss the different roles of name servers in DNS, and explain the all-important root name servers. I discuss how DNS zones are managed, the notions of domain contacts and zone transfers, and how caching and load balancing are used to improve efficiency in DNS. I conclude with a brief outline of two enhancements to basic DNS server operation, using the new *Notify* and *Update* message types, as well as incremental zone transfers.

**Related Information:** The information in this section should be considered complementary to that in [the following section on DNS resolvers](#).

---

## **DNS Name Server Functions, Name Server Architecture and General Operation**

The [three major functions of a name system](#) are creating a name space, performing name registration and providing name resolution services. We've seen earlier in this larger section on the Domain Name System that DNS uses a [hierarchical tree structure for its name space](#), and also a [hierarchical tree for name authorities and registration](#). I'm sure that, given this, you will have to struggle to contain your surprise when I tell you that name resolution is also oriented around the notion of a hierarchical structure.

The devices that are primarily charged with performing the functions required to enable name resolution are *name servers*. They are arranged in a hierarchy that is closely related to the authority structure of the name system. Just as the authority structure **complements** the name structure but is not exactly the same as it, the name server architecture complements both the authority structure and the name structure, but may be different in its actual composition from both.

## ***DNS Name Server Architecture and the Storage of the Distributed Name Database***

In a large DNS implementation, information about domains is not centralized in a single database run by one authority. Instead, it is *distributed* across many different authorities that manage particular top-level domains (TLDs), second-level domains or lower-level subdo-

---

mains. In the case of the global Internet, literally millions of different “authorities”, many of them responsible only for their own local domain space, participate cooperatively in running the DNS system.

With authority for registration distributed in this manner, this means that the information about domains is similarly spread amongst many entities, resulting in a *distributed database*. A key concept in DNS name resolution is that each entity that maintains responsibility for a part of the name space must also arrange to have that information stored on a DNS server. This is required so that the server can provide the information about that part of the name space when resolution is performed. As you can see, then, the existence of a structured hierarchy of authorities directly implies the need for a hierarchy of servers that store that hierarchical name information.

Each DNS [zone of authority](#) is required to have one or more DNS servers that are “in charge” of managing information about that zone. These servers are said to be *authoritative* for the zone. Storing information about the domains, subdomains and objects in the zone is done by recording the data in special [resource records that are read from DNS master lists](#) maintained by administrators. Servers then respond to requests for this information.

Since information in DNS is stored in a distributed form, there is no single server that has information about every domain in the system. As we'll see in [the section on name resolvers](#), the process of resolution instead relies on the hierarchy of name servers described just above. At the top of the DNS hierarchy is the *root* domain, and so we also see there the [root name servers](#). These are the most important servers, because they maintain information about the top-level domains within the root. They also have knowledge of the servers that can be used to resolve domains one level below them. Those servers in turn are responsible for the TLDs and can reference servers that are responsible for second-level domains. Thus, a DNS resolution may require that requests be sent to more than one server.

**Key Concept:** DNS public name information is stored in a *distributed database* of DNS *name servers* that are structured in a hierarchy comparable to the hierarchy of authorities. Each zone has one or more DNS name servers in charge of the zone's information, called *authoritative* name servers.

---

## **DNS Server Support Functions**

The storing and serving of name data (through responses to requests from DNS resolvers) is the main function of a DNS server. However, other support jobs are also typically required of a DNS server, including the following:

- 🔊 **Interacting With Other Servers:** As mentioned above, the DNS resolution process often requires that multiple servers be involved. Servers must thus maintain not just name information, but information about the existence of other servers. Depending on the type of DNS request, servers [may themselves become clients and generate requests to other servers](#).

- 
- ☛ **Zone Management and Transfers:** The server must provide a way for [DNS information within the zone to be managed](#). A facility also exists to allow a *zone transfer* to be performed between the master (primary) server for a zone and slave (secondary) servers.
  - ☛ **Performance Enhancement Functions:** Due to the large number of requests servers handle, they employ numerous techniques to reduce the time required to respond to queries. The most important of these is [caching of name information](#). A variation of regular caching called *negative caching* may also be used to improve performance, and [load balancing](#) is a feature that can be used to improve efficiency of busy devices registered within the DNS system.
  - ☛ **Administration:** Various other administrative details are required of name servers, such as storing information about the different types of “[contacts](#)” ([humans](#)) [who are responsible for certain tasks related to management of a domain or zone](#).

As we'll see later in this section, not all name servers perform all of the tasks described above in this topic; some perform only a subset.

### ***The DNS Name Server Hierarchy is Logical, Not Physical***

Like the other hierarchies, the name server hierarchy is **logical** in nature. I already mentioned that it often is not exactly the same as the authority hierarchy. For one thing, it is common for a single DNS name server to be the authoritative server for a number of domains. Even if a particular group has authority for a subdomain of a particular domain, it's possible they will “share” the DNS servers with the authority of their parent domain for efficiency reasons. For example, a university might delegate control over parts of its domain space to different groups (as in [our example in the topic on DNS zones](#)) but still manage all subdomains on the same server. In practice, the lower the level the subdomain in the DNS name hierarchy, the less likely that subdomain has its own DNS server.

Another important aspect of the logical nature of the name server hierarchy is that there is no necessary relationship between the structure of the name servers and their location. In fact, in many cases name servers are specifically put in different places for reliability reasons. The best example of this is the set of root name servers—despite all being at the “top” of the DNS server architecture, they are spread around the globe to prevent a single problem from taking all of them out. Also remember not to be fooled by the structure of a name in the [geopolitical DNS name hierarchy](#)—a name server called “ns1.blahblah.ca” might be in Canada, but it very well might not.

**Key Concept:** The DNS name server hierarchy is logical in nature and not exactly the same as the DNS name server tree. One server may be responsible for many domains and subdomains. Also, the structure of the DNS name server hierarchy doesn't necessarily indicate the physical locations of name servers.

---

---

## **DNS Name Server Data Storage: Resource Records and Classes**

One of the most important jobs performed by name servers is the storage of name data. Since the authority for registering names is distributed across the internetwork using DNS, the database of name information is likewise distributed. An *authoritative* server is responsible for storing and managing all the information for the zones of authority it is assigned.

Each DNS server is, in essence, a type of database server. The database contains many kinds of information about the subdomains and individual devices within the domain or zone for which the server is responsible. In DNS, the database entries that contain this name information are called *resource records (RRs)*. A specific set of RRs is associated with each node within the zone.

### ***Binary and Text Representations of Resource Records***

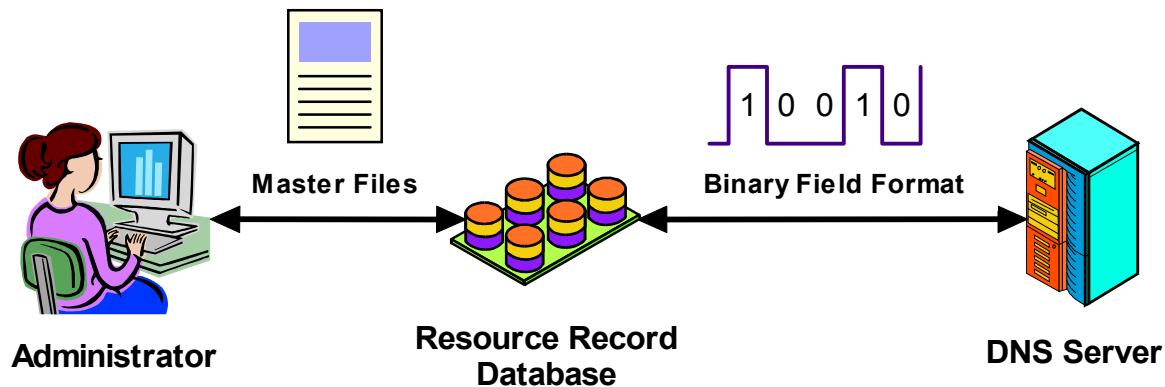

The entire point of DNS is to allow humans to work with names and computers to work with numbers, and we see this principle further reflected in the two very different representations that exist for the DNS resource records themselves:

- ☉ **Resource Record Field Format (Binary) Representation:** Name servers are required to respond to queries for name information by sending resource records within DNS messages. Obviously, we want to do this in as efficient a way as possible, so each resource record is internally stored using a special field format that is similar to the many field formats we have seen used for messages in other protocols. All resource records use a general field format for some of their fields, and then have a unique portion that is specific to the resource record type.
- ☉ **Master File (Text) Representation:** Computers are happy to exchange binary-encoded field formats and have no problem remembering that, for example, resource record type 15 corresponds to a mail exchange (MX) record. However, human administrators want to be able to quickly and easily maintain DNS information without having to remember cryptic codes or work with binary values. For this reason, DNS uses a *master file* format for its user-machine interface, which allows resource records to be specified in text form for easier maintenance.

### ***Use of Resource Records and Master Files***

Each node may have a variable number of records, depending on the node type and what information is being kept for it. The resource records are added, changed or deleted when DNS information changes, by administrators who make modifications to the text master files on the server computer. These files are then read into memory by the DNS server software, parsed (interpreted) and converted into binary form. They are then ready for use in [resolving DNS name requests and other queries](#). This is illustrated in [Figure 241](#).

I describe both the binary RR field formats and master file format in [the section on DNS messaging and formats](#).

**Figure 241: DNS Resource Record Master File and Binary Field Formats**

To meet the needs of humans and computers, DNS uses two representations for the data stored in resource records. Administrators enter and maintain information in textual DNS master files. These are read by DNS server software and internally stored in binary format for answering DNS requests.

**Key Concept:** DNS name servers store DNS information in the form of *resource records (RRs)*. Each RR contains a particular type of information about a node in the DNS tree. There are two representations for resource records: conventional binary field formats are used for communication between DNS name servers and resolvers, while text *master files* are edited by administrators to manage DNS zones.

### ***Common Resource Records Types***

The main DNS standards, RFC 1034 and 1035, defined a number of resource record types. Over time, the list has changed, with new RR types being created in subsequent standards and the use of others changed. Like other Internet parameters, the list of DNS RR types is maintained in a file at [IANA](http://www.iana.org). Also like other Internet parameters, there are in fact several dozen defined RRs in DNS, but only a few are commonly used; others are now obsolete, used for special purposes or “experimental” in nature.

**On The Web:** The current list of DNS resource records is maintained in a file that can be found at: <http://www.iana.org/assignments/dns-parameters>

[Table 167](#) summarizes the most important resource record types. For each, I have shown the numeric *Type* value for the record, which is used to identify the resource record type in message exchanges, and also the text code used for the RR in master files. I have also provided a brief description of each.

**Table 167: Summary Of Common DNS Resource Records**

RR Type Value	RR Text Code	RR Type	Description
1	A	Address	Contains a 32-bit IP address. This is the “meat and potatoes” of DNS, since it is where the address of a node is stored for name resolution purposes.
2	NS	Name Server	Specifies the name of a DNS name server that is authoritative for the zone. Each zone must have at least one NS record that points to its primary name server, and that name must also have a valid <i>A (Address)</i> record.
5	CNAME	Canonical Name	This resource record is used to allow aliases to be defined that point to the real name of a node. The <i>CNAME</i> record provides a mapping between this alias and the “canonical” (real) name of the node. The <i>CNAME</i> resource record is commonly used to hide changes in the internal DNS structure from outside users, by letting them use an unchanging alias while the internal names are modified based on the needs of the organization. <a href="#">See the topic on name resolution for an example.</a>
6	SOA	Start Of Authority	The SOA resource record is used to mark the start of a <a href="#">DNS zone</a> and provide important information about it. Every zone must have exactly one SOA record, which contains details such as the name of the zone, its primary (master) authoritative server name, and technical details such as the e-mail address of its administrator and parameters for how often slave (secondary) name servers are updated.
12	PTR	Pointer	Provides a pointer to another location in the name space. These records are best known for their use in <a href="#">reverse resolution through the IN-ADDR.ARPA domain</a> .
15	MX	Mail Exchange	Specifies the location (device name) that is responsible for <a href="#">handling e-mail sent to the domain</a> .
16	TXT	Text String	Allows arbitrary additional text associated with the domain to be stored.

All of these resource records are used in different ways to define zones and devices within them, and then permit name resolution and other functions to take place. We'll see how they are used in more detail in [the section on name resolution](#). You can also find a more lengthy description of some of them in [the topic devoted to resource record field formats](#).

**Related Information:** See [the topic on IPv6 DNS support](#) for IPv6-specific resource record types.

---

## **Resource Record Classes**

Finally, a historical note that needs to be mentioned. When DNS was first created, its inventors wanted it to be as generic as possible. To that end, they designed it so that a DNS server could, theoretically, provide name service for more than one type of underlying protocol. That is, DNS could support TCP/IP as well as other protocols simultaneously.

Of course, protocols have different addressing schemes and also varying needs for name resolution. Therefore, DNS was defined so that each protocol could have a distinct set of resource record types. Each set of resource record types was called a *class*. Technically, a resource record must be identified using both a class identifier and a resource record type. Like the resource record types, classes have a numeric code number and a text abbreviation. The class for TCP/IP uses the number 1, with the text code “IN” (for “Internet”).

In practice, this notion of multiple classes of resource records never took off; DNS is today, to my knowledge, only used for TCP/IP. (There may be some obscure exceptions.) Several other classes have been defined by RFC 1035 and are in the IANA DNS parameters list, but they are for relatively obscure, experimental or obsolete network types, with names such as CSNET, CHAOS and Hesiod. You'll still see this concept of “class” in the specification of DNS message and resource record formats, but there really is only class today: “IN” for TCP/IP. For this reason, in most cases, the class name can be omitted in DNS-related commands and data entries, and “IN” will be assumed by default.

**Key Concept:** The DNS standards were originally created to allow them to work with multiple protocols, by specifying the class of each resource record. Today the only class commonly used is that for TCP/IP, which is called “IN” (for “Internet”).

---

## **DNS Name Server Types and Roles: Primary/Master, Secondary/Slave and Caching-Only Servers**

In the first two topics in this section, we have looked at the functions of DNS servers, with a particular eye to the important job of storing name server information. There are many thousands of DNS servers on the Internet, and not all are used in the same way. Each DNS server has a particular *role* in the overall operation of the name system. The different kinds of servers also interact with each other in a variety of ways that we need to understand.

Every zone needs to have at least one DNS name server that is responsible for it. These DNS name servers are called *authoritative* servers for the zone, because they contain the full set of resource records that describe the zone. When any device on the Internet wants to know something about a zone, it consults one of its authoritative servers.

---

From a strictly theoretical perspective, having one name server for each zone or domain is “sufficient” to provide name resolution services for the entire DNS name structure. From an implementation standpoint, however, having only one name server for each part of the name space is not a wise idea. Instead, each zone usually has associated with it at least two name servers: one *primary* or *master* name server, and one *secondary* or *slave* name servers. Some zones may have more than one secondary name server.

**Note:** The terms “primary” and “secondary” are used often in the DNS standards to refer to the roles of the two authoritative servers for a zone. However, “master” and “slave” are now the preferred terms, because “primary” and “secondary” are somewhat ambiguous and used in other contexts. You should be prepared to see both terms used.

---

### ***Reasons for Using Slave Name Servers***

The master name server is obviously the most essential server. It is on this name server that the [master files](#) for the zone's resource records are maintained, so the master name server is the “final word” for information on the zone. However, there are several reasons why slave servers are also important:

- ☉ **Redundancy:** We've already discussed how important DNS is, especially on the Internet; with only one name server, if it ever failed nobody would be able to resolve names such as “www.xyzindustries.com” into IP addresses, which would be a Bad Thing [tm]. ☺ Slave name servers act as a backup for the masters they support.
- ☉ **Maintenance:** With more than one server, we can easily take the primary server down for maintenance when needed without name resolution service being disrupted.
- ☉ **Load Handling:** Busy zones can use multiple servers to spread the load of name resolution requests to improve performance.
- ☉ **Efficiency:** There are many cases where there is an advantage to positioning a name server in a particular geographical location for the sake of efficiency. For example, a company may have an office in a distant location connected using a low-speed WAN link. To reduce name resolution traffic across that link, it makes sense to have that zone's information available in a name server on both sides of the connection, so one would require two physical servers.

Redundancy is the most important consideration in setting up master and slave name servers. Sticking two machines side by side in a server room, plugged into the same electrical service, both connected to the Internet with the same Internet Service Provider, and making one your master DNS server and the other your slave is not a smart move. Ideally, the primary and secondary servers should be as independent as possible; they should be physically distant and have separate connections to the Internet.

---

## Propagating Information From the Master Server to Slaves

Just as the names “master” and “slave” suggest, the secondary name servers are not the original source of information about a zone. They normally obtain their resource records not from human-edited master files, but from updates obtained from the master server. This is accomplished using a process called a [zone transfer](#). These transfers are performed on a regular basis to ensure that the slave servers are kept up to date. The slaves can then respond to name resolution requests with current information. Both the master and the slave are considered authoritative for the zone.

### Name Server Roles

The “master” and “slave” roles for a zone are logical and do not always correspond to individual physical hardware devices. A single physical name server can play multiple roles in the following cases:

- ☉ It can be the master name server for more than one zone. Each zone in this case has a distinct set of resource records maintained in separate master files.
- ☉ It can be a slave name server for more than one zone.
- ☉ It can be a slave name server for certain zones as well as a primary for others.

Note however that a single physical name server cannot be a primary and a secondary server for the **same** zone, since... well, what would be the point?

**Key Concept:** The *master* DNS server for a zone is its *primary* server, which maintains the master copy of DNS information. Most DNS zones also have at least one *slave* or *secondary* DNS server. These are important because they serve as backups for the primary server, and they can also help share the load of responding to requests in busy zones. Secondary name servers get their information from primary servers on a routine basis. Both master and slave servers are considered authoritative for the zones whose data they maintain.

---

### Caching-Only Name Servers

We'll see later in this section that for efficiency reasons, all DNS servers perform [caching of DNS information](#) so it can be used again if requested in the near future. This includes both master and slave name servers. The importance of caching is so significant that there are some servers that are set up only to cache information from other DNS servers. Unsurprisingly, these are called *caching-only* name servers.

These name servers are not authoritative for any zone or domain, and don't maintain any resource records of their own. They can only answer name resolution requests by contacting other name servers that *are* authoritative and then relaying the information. They then store the information for future requests. Why bother? The reason is performance. Through strategic placement, a caching-only server can increase DNS resolution performance substantially in some networks by cutting down on requests to authoritative servers.

**Key Concept:** There are DNS servers that do not maintain DNS resource records of their own but solely hold recently-used information from other zones. These are called *caching-only* name servers and are not authoritative for any zone.

---

## **DNS Zone Management, Contacts and Zone Transfers**

The authority for a particular **DNS zone** is responsible for performing a variety of tasks to manage it. *Zone management* encompasses the entire gamut of jobs related to a zone: deciding on the name hierarchy within the zone, specifying procedures for name registration, technical work related to keeping DNS servers running and other “administrative overhead” of all sorts. This job can be either very small or incredibly large, depending on the type of organization. A small domain owned by an individual doesn’t require much work to manage, while one for a huge company might require a dedicated staff to maintain.

### ***Domain Contacts***

It is important that it be possible for anyone on an internetwork to be able to determine who the owner of a domain is, so that person can be reached for whatever reason. On the Internet, each DNS domain has associated with it a set of three *contacts* that are responsible for different facets of managing a domain. These are the:

- ☉ **Administrative Contact:** The “main” contact, responsible for the domain as a whole. This individual or organization is considered the overall owner of the domain.
- ☉ **Billing Contact:** A contact responsible for handling payment for domain services and other accounting matters.
- ☉ **Technical Contact:** A contact who handles the technical details of setting up DNS for the domain and making sure it works.

For smaller domains, there usually is no separate billing contact; it is the same as the administrative contact. In contrast, the technical contact is often different from the administrative contact in both large and small domains. Large organizations will make the technical contact someone in their information technology department. Small organizations often let their Internet Service Provider (ISP) provide DNS services, and in that case, the technical contact would be someone at that ISP.

**Key Concept:** Each DNS domain has associated with it a set of three contact names that indicate who is responsible for managing it. The administrative contact is the person with overall responsibility for the domain. The billing contact is responsible for payment issues; this may be the same as the administrative contact. The technical contact is in charge of technical matters for the domain, and is often a different person than the administrative contact, especially when DNS services are out-sourced.

---

---

## Zone Transfers

The ultimate purpose of zone management is to ensure that information about the zone is kept current on the zone's master and slave name servers, so it can be efficiently provided to [name resolvers](#). Thus, the management of a zone begins with decision-making and administrative actions that result in changes to the resource records for the zone. These are reflected in changes made to the DNS master files on the master (primary) DNS server for the zone.

In contrast, each zone's secondary DNS server(s) act as "slaves" to the "master" primary server. They carry information about the zone, but do not load it from local master files that are locally edited. Instead, they obtain their information from the master name server on a regular basis. The procedure responsible for this is called a *zone transfer*.

The resource records on the master name server can be updated at any time; as soon as the master name server's records have been changed, the information at the slave name servers becomes partially out of date. This is not generally a big deal, because most of the data will still be accurate, and the secondary server will continue to respond to resolution requests using the most current information it has. However, it is obviously important that we update the slave servers on a regular basis; if this is not done, eventually their data will become "stale" and unreliable.

### Controlling When Zone Transfers Occur Using DNS *Start of Authority* Fields

To this end, it is necessary that zone transfers be performed on a regular basis. This requires implementation of a communication process between the servers that consists of two basic parts. First, we need a mechanism to allow slave servers to regularly check for changes to the data on the master. Second, we must have a mechanism for copying the resource records for the zone from the primary name server to the secondary when needed.

Both mechanisms make use of standard DNS query/response facilities, and special fields in the resource records for the zone. Of particular importance is the *Start Of Authority* (SOA) record for the zone, which contains several parameters that control zone status checking and zone transfers. The formal description of these parameters can be found in [the topic on resource record formats](#), I'll discuss how they are used here.

When a slave name server starts up, it either has no information about the zone at all, or it may have a copy of the zone's resource records stored on its local storage, from the last time it was running. In the former case, it must immediately perform a full zone transfer, since it has no information. In the latter case, it will read its "last known" copy of the zone from local storage; it may immediately perform a *poll* on the master server to see if the data has changed, depending on configuration. A poll is done by requesting the *Start Of Authority* resource record for the zone.

The *Serial* field in the SOA record contains a serial number (which may be arbitrary or may be encoded so it has a particular meaning) that acts as the "version number" of the master server's zone database. Each time the master file for the zone is modified (either manually

---

by editing or automatically through another means) this serial number is increased. Therefore, a slave server can detect when changes have been made on the master by seeing if the *Serial* field in the most recent SOA record is greater than the one the slave stored the last time it polled the master. If the serial number has changed, the slave begins a zone transfer.

Three other fields in the SOA record control the timing that slave name servers use for polling and updating their information:

- ☉ **Refresh:** This field specifies how many seconds a slave server waits between attempts to check for an update on the master. Assuming the slave can make contact, this is the longest period of time that data on a slave will become “stale” when the master changes.
- ☉ **Retry:** This field controls how long the slave must wait before trying again to check in with the master if its last attempt failed. This is used to prevent “rapid fire” attempts to contact a master that may clog the network.
- ☉ **Expire:** If, for whatever reason, the slave name server is not able to make contact with the master for a number of seconds given by this field value, it must assume that the information it has is stale and stop using it. This means that it will stop acting as an authoritative name server for the zone until it receives an update.

The fact that these parameters are part of the SOA record for the zone gives the administrator of the zone complete control over how often master name servers are updated. In a small zone where changes are rare, the interval between checks made by the slave servers can be increased; for larger zones or ones that are changed often, the *Refresh* interval can be decreased.

## Zone Transfer Mechanism

When a zone transfer is required, it is accomplished using a DNS query sent to the master server using the regular DNS query/response messaging method used for name resolution (discussed in the next section). A special DNS question type, called *AXFR* (*address transfer*) is used to initiate the zone transfer. The server will then transfer the resource records for the zone using a series of DNS response messages (assuming that the server that requested the transfer is authorized to do so). Since it's important that zone transfers be received reliably, and since the amount of data to be sent is large and needs to be managed, a TCP session must first be established and used for zone transfers. This is in contrast to the simpler UDP transport used for regular DNS messages. This is discussed in [the topic discussing the use of UDP and TCP for DNS](#).

Once the zone transfer is complete, the slave name server will update its database and return to regular operation. It will continue to perform regular polls of the master server every *Refresh* seconds. If it has a problem with a regular poll, it will try again after *Retry* seconds. Finally, if an amount of time equal to *Expires* seconds elapses, the master name server will stop serving data from the zone until it re-establishes contact with the primary name server.

**Key Concept:** Slave name servers do not have their DNS information managed directly by an administrator. Instead, they obtain information from their master name server on a periodic basis through a process called a *zone transfer*. Several fields in the *Start Of Authority* DNS resource record control the zone transfer process, including specifying how often transfers are done and how slave name servers handle problem conditions such as an inability to contact the master server.

---

Note that the DNS *Notify* feature is an enhancement to the basic zone status check / zone transfer model. It allows the master server to notify a slave server when the master's database has changed. Another new feature allows only part of a zone to be transferred instead of the entire zone. [See the topic on DNS name server enhancements for more.](#)

## **DNS Root Name Servers**

The domain name system is strongly oriented around the notion of hierarchical structure: the name space, registration authorities and name servers are all arranged in a tree structure. Like these structures, the name resolution process is also hierarchical. As described in gory detail in [the section on name resolution](#), a [fully-qualified domain name](#) is resolved by starting with the least-specific domain name element (label) and working towards the most-specific one.

Naturally, the least-specific portion of every name is the [root node](#) under which the entire DNS structure exists. This means that, absent caching and other performance enhancements, all name resolution begins with the root of the name tree. We find here a set of name servers that are responsible for name server functions for the DNS root: the DNS *root name servers*.

Like all name servers, they store information about, and provide name resolution services for, all the nodes within the “root zone”. This includes certain specific top-level domains and subdomains. Most top-level domains (TLDs), however, are in their own zones. The root name servers are used as the “go to” spot to obtain the names and addresses of the authoritative servers for each of these TLDs. For example, if we want to resolve the name “www.xyzindustries.co.uk”, the root name servers are where a resolver would find the identity of the name server that is responsible for “uk”.

## ***Ensuring Access to the Root Name Servers***

Clearly, the root name servers are extremely important to the functioning of the DNS system as a whole. If anything were to ever happen to cause the root name servers to stop operating, the entire DNS system would essentially shut down. For this reason, there obviously isn't just one root server, nor are there two or three; there are (at present) thirteen different root name servers.

---

In fact, there are actually far more than thirteen physical servers. Most of the thirteen name servers are implemented as clusters of several independent physical hardware servers. Some are in fact distributed collections of servers that are in different physical locations. The best example is the “F” root server, which has been implemented as a set of over a dozen *mirrors* in various places around the world, to provide better service.

The principles of redundancy that I mentioned are a good idea for choosing a secondary name server for a regular domain, obviously apply that much more to the root. This is why the various physical devices that comprise the thirteen root servers are all located in different places all around the globe. Many of them are in the United States, but even these are in many locations throughout the country (albeit concentrated in a couple of “hot spots” in California and near Washington, DC) and are set up to use different networks to connect to the Internet.

The root name servers are of course rather powerful; despite there being several dozen pieces of hardware to spread the load, they must each handle large amounts of data, 24 hours a day. They are run by networking professionals who ensure that they function efficiently. An Internet standard, RFC 2870 (*Root Name Server Operational Requirements*), spells out the basic rules and practices for the operation of these name servers. It specifies extensive procedures for ensuring the security of the servers, and for avoiding performance problems due to their pivotal role.

Despite all the efforts taken to ensure that the root servers are widely distributed and secure, they still collectively represent a point of weakness in the global Internet. Millions and millions of people depend on these servers. There have been incidents in the past where rogue elements on the Internet have attempted to disrupt DNS by attacking the root name servers. One widely-publicized incident was a denial of service (DoS) attack against the root servers on October 21, 2002. The attack failed, but it significantly raised awareness of the importance of these servers and how essential DNS security is.

**Key Concept:** Information about the DNS root and its top-level domains is managed by a set of *root name servers*. These servers are essential to the operation of DNS; they are arranged into thirteen groups and physically distributed around the world.

---

### **Current Root Name Servers**

Originally, the root name servers were given domain names reflecting the organizations that ran them. In these historical names we can see a veritable “who's who” of the big players in the development of the Internet: ISI, NASA, the United States military and others. Several of the servers are still run by government agencies or the US military, where added security can be put into place to protect them. For convenience, however, all the root name servers are now given alphabetical “letter names” in the special domain “root-servers.net”.

Table 168 shows the most current information about the DNS root name servers as of the date of publishing of this Guide. For your interest and amusement I have also mapped the locations of these servers in Figure 242.

**Table 168: Internet DNS Root Name Servers**

Root Server Name	IP Address	Historical Name	Location(s)
a.root-servers.net	198.41.0.4	ns.internic.net	Dulles, VA, USA
b.root-servers.net	128.9.0.107	ns1.isi.edu	Marina Del Rey, CA, USA
c.root-servers.net	192.33.4.12	c.psi.net	Herndon, VA and Los Angeles, CA, USA
d.root-servers.net	128.8.10.90	terp.umd.edu	College Park, MD, USA
e.root-servers.net	192.203.230.10	ns.nasa.gov	Mountain View, CA, USA
f.root-servers.net	192.5.5.241	ns.isc.org	Auckland, New Zealand; Sao Paulo, Brazil; Hong Kong, China; Johannesburg, South Africa; Los Angeles, CA, USA; New York, NY, USA; Madrid, Spain; Palo Alto, CA, USA; Rome, Italy; Seoul, Korea; San Francisco, CA, USA; San Jose, CA, USA; Ottawa, ON, Canada
g.root-servers.net	192.112.36.4	ns.nic.ddn.mil	Vienna, VA, USA
h.root-servers.net	128.63.2.53	aos.arl.army.mil	Aberdeen, MD, USA
i.root-servers.net	192.36.148.17	nic.nordu.net	Stockholm, Sweden; Helsinki, Finland
j.root-servers.net	192.58.128.30	—	Dulles, VA, USA; Mountain View, CA, USA; Sterling, VA, USA; Seattle, WA, USA; Atlanta, GA, USA; Los Angeles, CA, USA; Amsterdam, The Netherlands
k.root-servers.net	193.0.14.129	—	London, UK; Amsterdam, The Netherlands
l.root-servers.net	198.32.64.12	—	Los Angeles, CA, USA
m.root-servers.net	202.12.27.33	—	Tokyo, Japan

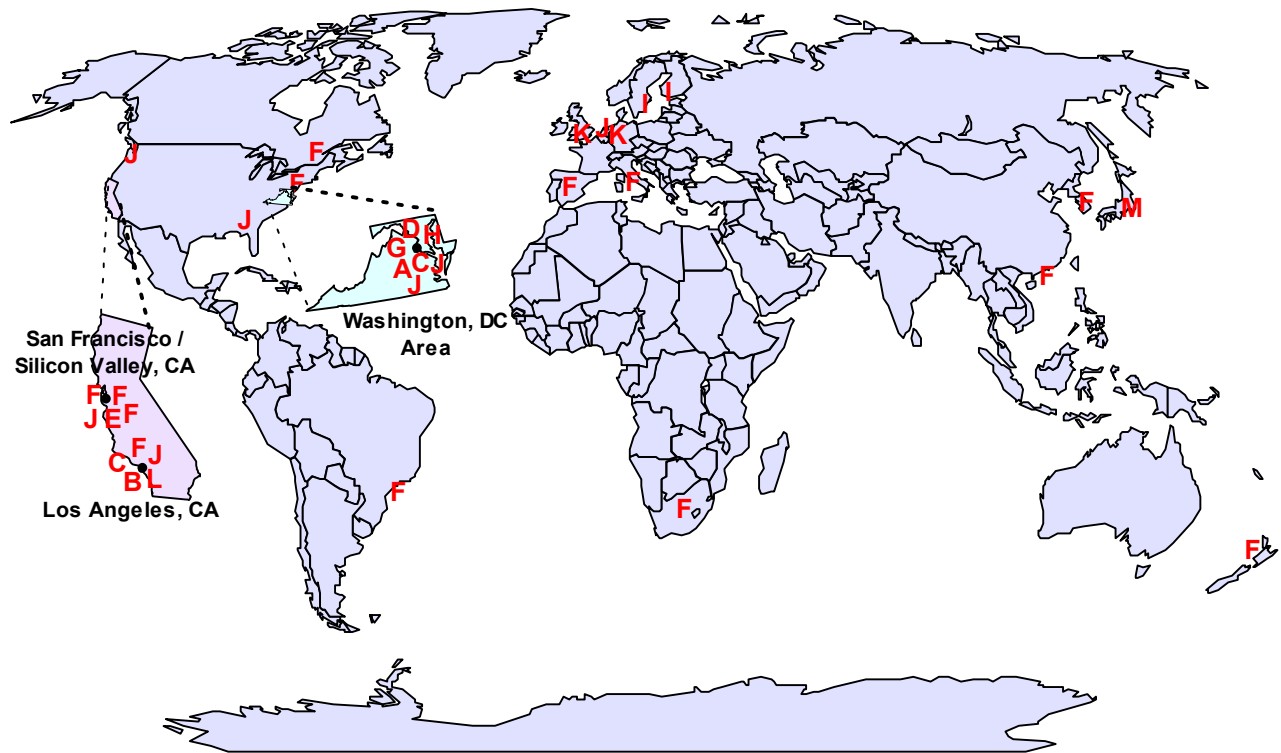

**On The Web:** The current list of root name servers can be found in the file <ftp://ftp.rs.internic.net/domain/named.root>. You can also find the information in a more user-friendly format at <http://www.root-servers.org>.

## **DNS Name Server Caching, Negative Caching and Data Persistence**

Most of the “grunt work” done by name servers is responding to [name resolution requests](#). Busy servers, like the root name servers, the ones that carry zone information for the top-level domains, and ones that serve very busy zones, have to handle hundreds or even

**Figure 242: Geographic Locations of Internet DNS Root Name Servers**

thousands of name resolution requests each *second*. Each of these requests takes time and resources to resolve; it also takes internetwork bandwidth away from the business of transferring data. It is essential, therefore, that DNS server implementations employ mechanisms to improve their efficiency and cut down on unnecessary name resolution requests. One of the most important of these is *caching*.

### **Name Server Caching**

The word *cache* refers to a store, or a place where something is kept. In the computer world, the term usually refers to an area of memory set aside for storing information that has been recently obtained so it can be used again. In the case of DNS, caching is used by DNS name servers to store the results of recent name resolution and other requests, so that if the request occurs again it can be satisfied from the cache without requiring another complete run of the name resolution process. Due to how most people use computers, a particular request is often followed by another request for the same name, so caching can significantly reduce the number of requests that result in complete name resolution procedures.

An example is the best way to illustrate this. Suppose you are using a host on your company's local network. This host is probably configured to use your company's DNS name server to handle resolution requests. You type "www.xyzindustries.com" into your Web browser, which causes a resolution attempt to be made for that address. Most likely,

---

your local DNS server doesn't know that name, so it will follow the complete [name resolution process](#) to get its address. After doing this, your local DNS server will *cache* the name “www.xyzindustries.com” and the address associated with it.

If you click on a link for a page at that Web site, that new page will also probably be somewhere at the “www.xyzindustries.com” site. This will result in another DNS resolution request being sent off to your local DNS server again. However, this time, the local server will not have to perform a resolution; it remembers that this name is in its cache and returns the saved address for the name immediately. Voila! You get your answer faster, and unnecessary Internet traffic is avoided.

**Key Concept:** *Caching* is an essential efficiency feature that reduces DNS message traffic by eliminating unnecessary requests for recently-resolved names. Whenever a name is resolved the resulting DNS information is cached so it can be used for subsequent requests that occur shortly thereafter.

---

### ***Caching Data Persistence and the Time To Live Interval***

Of course, things aren't entirely this simple. One very important issue that comes up with every caching system, including the one used in DNS, is the matter of the *freshness* of the cache. Suppose our local DNS server resolves the name “www.xyzindustries.com” and then caches its address. In the example above where we click a link a few seconds after the XYZ Industries home page loads, we aren't likely too concerned about how fresh the DNS data is. But how about if we shut down our computer to go on vacation for 2 weeks and then come back to work and type the name again into our browser. If our local server still has the name in its cache, how do we know the IP address of “www.xyzindustries.com” hasn't changed during that two-week period?

Two different mechanisms are used to address this issue. The first is that when data is cached, the caching server also makes a note of the authoritative server from which it came. When a resolver (client) asks for a name resolution and the address is drawn from the cache, the server marks the answer as *non-authoritative* to clearly tell the client that the name came from the cache. The server also supplies the name of the authoritative server that originally supplied the data.

The client then has a choice: it can either use the non-authoritative answer, or issue a request for a fresh name resolution from the authoritative server. This is a trade-off between performance (using the cached data) and currency (asking for a fresh resolution each time). Usually, the cached data can be used safely, because DNS information doesn't change very often.

The second technique for ensuring that caching data doesn't get too old is a procedure for limiting the *persistence* of DNS cached data. Each resource record has associated with it a time interval, called the *Time To Live (TTL)*. Whenever a resource record is read from a server, the *TTL* for the record is also read. Any server caching the record is supposed to discard the record after that time interval expires.

---

Each zone also has associated with it a default value for the *TTL* field to be applied to all records in the zone. This allows an administrator to select a *TTL* value for all records in a zone without having to enter *TTL* numbers for each record individually. At the same time, the administrator can assign an “override” *TTL* value to any records that need a number different from the default. This default *TTL* was originally found in the special *Start Of Authority* resource record for each zone, but is now done using a special directive in the zone’s [master file](#).

**Note:** This *Time To Live* field is not related to [the one used in Internet Protocol datagrams](#). Obviously IP and DNS are totally different protocols; more than that, despite having the same name, the *TTL* fields in IP and DNS don't have the same meaning at all.

---

It's worth emphasizing that DNS gives control over caching to the **owner of the record**, not whoever is running the DNS server doing the caching. While it is possible for a particular caching server to “override” the *TTL* and specify how long data will be held in its own cache, DNS is not supposed to work that way. The ability to specify a *TTL* on a record-by-record basis allows the persistence of cache data to be tailored to the needs of the individual data elements. Data that changes often can be given a small *TTL* value, while infrequently-modified records can be given a higher *TTL*. Selecting the *TTL* value must be done carefully; this is another trade-off between performance (which is optimized with higher *TTL* values, reducing the number of queries made for cached data) and “freshness” of the data (which increases as *TTL* is lowered).

**Key Concept:** Cached information can become stale over time, and result in incorrect responses sent to queries. Each resource record can have associated with it a time interval, called the *Time To Live (TTL)*, that specifies how long the record may be held in a cache. The value of this field is controlled by the owner of the resource record, who can tailor it to the specific needs of each resource record type.

---

## Negative Caching

Classical DNS caching stores only the results of successful name resolutions. It is also possible for DNS servers to cache the results of **unsuccessful** name resolution attempts; this is called *negative caching*. To extend the example above, suppose you mistakenly thought the name of the company's web site was “www.xyz-industries.com” and typed that into your browser. Your local DNS server would be unable to resolve the name, and would mark that name as “unresolvable” in its cache; a negative cache entry.

Suppose you typed the name in incorrectly because someone mis-typed it on an internal memo. If a colleague later tried the same name, the DNS server would say “I already know this is a bogus name” and not try again to resolve it. Since there is no resource record for an invalid name the server itself must decide how long to cache this negative information.

---

Negative caching improves performance because resolving a name that doesn't exist takes resources, just as resolving an existent one does. Note that “regular” caching is sometimes called “positive caching” to contrast it to “negative caching”.

The value to be used for negative caching in a zone is now specified by the *Minimum* field in the *Start Of Authority* resource record for each zone. As mentioned above, this was formerly used to specify the default *TTL* for a zone.

### **DNS Name Server Load Balancing**

The *Address (A)* resource record is the most fundamental one in DNS, since it records an actual mapping between a domain name and an IP address. Let's consider for a moment one of the words in that sentence in more detail. No, not “address” or “resource record” or “mapping”. The word “an”. ☺ The *Address* record only mentions a **single** address for each domain name. This means that, as we have described DNS so far, each domain name maps to only a single physical hardware device.

When the number of requests that a particular server or other device needs to handle is relatively small, this is not a problem—the function can usually be implemented using a single physical hardware device. If the server gets busier, the usual solution is to throw more hardware at the problem—get a bigger machine. However, some hosts on a large internetwork, especially the Internet, feature servers that must handle tremendous amounts of traffic from many clients. There simply is no single hardware device that can readily handle the traffic of a site like “www.cnn.com” or “www.microsoft.com” for example, without becoming unwieldy.

### ***Using Multiple Address Records to Spread Out Requests to a Domain***

Sites like CNN's must use a technique called *load balancing* to spread requests across multiple hardware servers. One simple way to do this would be to have multiple machine names; for example, CNN could create several different Web sites called “www1.cnn.com”, “www2.cnn.com” and so on, each of which points to a different hardware device. DNS certainly supports this type of solution. The problem with this solution is that it is cumbersome; it requires users to remember multiple server names.

It would be better if we could balance the load automatically. DNS supports this by providing a simple way to implement load balancing. Instead of specifying a single *Address* resource record for a name, we can create several such records, thereby associating more than one IP address with a particular DNS name. When we do this, each time the authoritative name server for the zone in which that name exists resolves that name, it sends all the addresses on the list back to the requester. The server changes the order of the addresses supplied in the response, choosing the order randomly or in a sequential “round robin” fashion. The client will usually use the first address in the list returned by the server, so by changing the list, the server ensures that requests for that device's name are resolved to multiple hardware units.

---

As Internet traffic increases, load balancing is becoming more popular. In early 2003 I saw a survey that indicated approximately 10% of Internet names at that time used load balancing—a fairly significant number. Most employed either two or three addresses, but some used as many as 60! Incidentally, at last check, “www.cnn.com” was associated with eight different IP addresses. (Incidentally, you can check the number of addresses associated with a name using the [“host” command](#).)

**Key Concept:** Rather than creating a single *Address* resource record for a DNS domain name, it is possible to create multiple. This associates several IP addresses with one name, which can be used to spread a large number of access to one domain name over many physical IP devices. This allows DNS to implement load balancing for busy Internet servers.

---

### ***Using Multiple DNS Servers to Spread Out DNS Requests***

“DNS load balancing” also has a completely different meaning from what I described above. In my discussion of DNS server roles, I talked about how each zone should have at least one secondary DNS server in addition to the primary. The usually-stated main reason for this is redundancy, in case something happens to cause the master server to fail. However, having a slave server can also allow the load of DNS resolution requests to be balanced between multiple servers. In fact, some busy domains have more than two servers specifically for this reason.

Thus, “DNS load balancing” can refer to either using DNS to spread the load of requests (such as Web page requests) to a device that is named using DNS, or to spreading the load of DNS requests themselves.

### **DNS Name Server Enhancements: DNS Notify, Incremental Zone Transfers, and DNS Update (Dynamic DNS)**

The fundamentals of operation of Domain Name System servers, as explained in the preceding topics in this section, are specified in the main DNS standards, RFC 1034 and 1035. These documents are pretty old by computer industry standards; they were published in 1987. To the credit of the designers of DNS, most of what they originally put into the DNS protocol is still valid and in use today. The creators of DNS knew that it had to be able to “scale” to a large size, and the system has in fact successfully handled the expansion of the Internet to a degree far beyond what anyone could have imagined 15 or so years ago.

As originally defined, the Domain Name System requires that DNS information be updated manually by editing master files on the primary server for a zone. The zone is then copied in its entirety to slave servers using a [polling/zone-transfer mechanism](#). This method is satisfactory when the internetwork is relatively small, and changes to a zone are made infrequently.

---

However, in the modern Internet, large zones may require nearly-constant changes to their resource records. Hand-editing and constantly copying master files can be impractical, especially when they grow large, and having slave servers get out of date between zone transfers may lead to reliability and performance concerns. For these reasons, several enhancements to the operation of DNS servers have been proposed over the years. I'm going to take a closer look at three of them here.

### ***Automating Zone Transfers: DNS Notify***

The first problem that many DNS administrators wanted to tackle was the reliance on polling for updating slave name servers. Imagine that you placed an order for a new music CD at your favorite online music store, but it was out of stock—backordered. Which makes more sense: having you call them every 6 hours to ask if it has arrived yet until it gets there, or having the store simply call you when it shows up?

The answer is so obvious that the question seems ridiculous. Yet DNS uses the first model: slave name servers must constantly “call up” their zone masters and ask them “has anything changed yet?” This both generates unnecessary traffic, and results in the slave name server being out of date from the time the master **does** change until the next poll is performed. Tweaking the *Refresh* time for the zone only allows one to choose between more polls or more staleness when changes happen; neither is really “good”.

To improve upon this situation, a new technique was developed; it was formalized in RFC 1996, published in 1996 (weird coincidence!) This standard, *A Mechanism for Prompt Notification of Zone Changes (DNS NOTIFY)*, defines a new DNS message type called *Notify*, and describes a protocol for its use. The *Notify* message is a variation on the [standard DNS message type](#), with some of the fields redefined to support this new feature.

When both the master and slave name servers support this feature, when a modification is made to a resource record, the master server will automatically send a *Notify* message to its slave server(s), saying “your CD has arrived!” er... “the database has changed”. ☺ The slave then acts as if its *Refresh* timer has just expired. Enabling this feature allows the *Refresh* interval to be dramatically increased, since slave servers don't need to constantly poll the master for changes.

**Key Concept:** The optional DNS *Notify* feature allows a master name server to inform slave name servers when changes are made to a zone. This has two advantages: it cuts down on unnecessary polling by the slave servers to find out if changes have occurred to DNS information, and it also reduces the amount of time that slave name servers have out-of-date records.

---

---

## Improving Zone Transfer Efficiency: Incremental Transfers

The second issue with regular DNS is the need to transfer the entire zone whenever a change to any part of it is made. There are many zones on the Internet that have truly enormous master files that change constantly. Consider the master files for the “.COM” zone for example; having to copy the entire thing to slave name servers every time there is a change to even one record is beyond “inefficient”—it's downright insane!

RFC 1995, *Incremental Zone Transfer in DNS*, specifies a new type of zone transfer called an *incremental zone transfer*. When this feature is implemented on master and slave name servers in a zone, the master server keeps track of the most recent changes made to the database. Each time a slave server determines that a change has occurred and the secondary's database needs to be updated, it sends an *IXFR (incremental transfer)* query to the master, which contains the *Serial* number of the slave's current copy of the database. The master then looks to see what resource records have changed since that *Serial* number was the current one, and sends only the updated resource records to the secondary server.

To conserve storage, the master server obviously doesn't keep all the changes made to its database forever. It will generally track the last few modifications to the database, with the *Serial* number associated with each. If the slave sends an *IXFR* request that contains a *Serial* number for which recent change information is still on the primary server, only the changes are sent in reply. If the request has a *Serial* number so old that the master server no longer has information about some of the changes since that version of the database, a complete zone transfer is performed instead of an incremental one.

**Key Concept:** The DNS *incremental zone transfer* enhancement uses a special message type that allows a slave name server to determine what changes have occurred since it last synchronized with the master server. By transferring only the changes, the amount of time and bandwidth used for zone transfers can be significantly reduced.

---

## Dealing With Dynamic IP Addresses: DNS Update / Dynamic DNS

The third problem with “classical” DNS is that it assumes changes are made infrequently to zones, so they can be handled by hand-editing master files. Some zones are so large that hand-editing of the master files would be nearly continuous. However, the problem goes beyond just inconvenience. Regular DNS assumes that the IP address for a host is relatively static. Modern networks, however, make use of host technologies such as the [Dynamic Host Configuration Protocol \(DHCP\)](#) to assign IP addresses dynamically to devices. When DHCP is used, the IP address of *each* host in a zone could change on a weekly, daily or even hourly basis! Clearly, there would be no hope of keeping up with this rate of change using a human being and a text editor.

---

In April 1997, RFC 2136 was published, entitled *Dynamic Updates in the Domain Name System (DNS UPDATE)*. This standard describes an enhancement to basic DNS operation that allows DNS information to be dynamically updated. When this feature is implemented, the resulting system is sometimes *called Dynamic DNS (DDNS)*.

RFC 2136 defines a new DNS message type: the *Update* message. Like the *Notify* message, the *Update* message is designed around the structure of regular DNS messages, but with changes to the meanings of several of the fields. As its name implies, *Update* messages allow resource records to be selectively changed within the master name server for a zone. Using a special message syntax, it is possible to add, delete or modify resource records.

Obviously, care must be taken in how this feature is used; we don't want just anyone to be making changes “willy-nilly” to our master records. The standard specifies a detailed process for verifying *Update* messages, and security procedures that must be put into place so the server only accepts such messages from certain individuals or systems.

Dynamic DNS allows changes to be made much more easily for an administrator, but its true power only becomes evident when it is used to integrate DNS with other address-related protocols and services. Dynamic DNS solves a major weakness with traditional DNS: the inability to easily associated a host name with an address assigned using a protocol like DHCP.

With DNS servers supporting this feature, DNS and DHCP can be integrated, allowing automatic address and name assignment, and automatic update of DNS records when a host's IP address changes. One common application of dynamic DNS is to allow the use of DNS names by those who access the Internet using a service provider that dynamically assigns IP addresses. Dynamic DNS is similarly used by certain directory services, notably Microsoft's Active Directory, to associate addresses with device names.

**Key Concept:** An enhancement to DNS, commonly called *dynamic DNS*, allows DNS information in a server's database to be updated automatically, rather than always requiring hand-editing of master files. This can not only save time and energy on the part of administrators, it allows DNS to better handle dynamic address assignment, such as the type performed by host configuration protocols such as DHCP.

---

---

## DNS Resolution Concepts and Resolver Operations

In the preceding three sections, I have described the Domain Name System's [name space](#), [authority and registration mechanism](#), and [name servers](#). These elements can all be considered part of the *infrastructure* of DNS; they are the parts of the system that must be established first to enable it to be used. Once we have these components in place, we can actually get down to the business at hand: name resolution. This is accomplished using a specific set of procedures carried out by DNS clients called *resolvers*.

In this section I describe DNS name resolvers and the process of name resolution itself. I begin with an overview of the functions performed by DNS resolvers and how they work in general terms. I then describe the two fundamental methods of name resolution used in DNS: iterative and recursive resolution. I discuss the way that resolvers improve efficiency through local resolution and caching. I describe the steps in the actual name resolution algorithm. I then cover two special cases of name resolution: reverse name resolution using the special IN-ADDR.ARPA domain, and the way that DNS provides mail support using *Mail Exchange* resource records.

**Related Information:** The information in this section complements that in [the previous section on DNS name servers](#). I assume in the topics here that you have at least basic familiarity with DNS servers.

---

### DNS Resolver Functions and General Operation

The DNS name servers we explored in [the preceding section](#) are arguably the most important part of the system as a whole. After all, they store all the data on the system and actually provide the addresses we need when names are given to them; without these servers, there would be no DNS at all. Of course, what use is a server if nobody is asking for service? The clients in the system, called *resolvers*, are also important, because they initiate the process of name resolution; resolvers are where the “rubber meets the road”, so to speak.

The operation of DNS resolvers is explained in the two main DNS standards. RFC 1034 describes the functions performed by resolvers, and how they work in general terms. This includes a discussion of the algorithm used to conduct name resolution. RFC 1035 deals more with the implementation details of resolvers, and the fine points of **how** they do their jobs. Several subsequent standards have of course modified these base standards, changing some of the ways that resolvers work in different ways.

---

## **Name Resolution Services**

Just as the main job of a DNS server is to store DNS name data and “serve” it when it receives requests, the main job of a DNS resolver is to, well, **resolve**. ☺ While most people only think of name resolution as the process of transforming a DNS name into an IP address, this is but one of several types of resolution services performed by DNS. A few of the most typical types of DNS resolution are:

- ☛ **Standard Name Resolution:** Taking a DNS name as input and determining its corresponding IP address.
- ☛ **Reverse Name Resolution:** Taking an IP address and determining what name is associated with it.
- ☛ **Electronic Mail Resolution:** Determining where to send electronic mail (e-mail) messages based on the e-mail address used in a message.

There are other types of resolution activities as well, though again, most name resolution requests are of the “standard” variety, making it the primary focus in our discussion.

### **Resolution Functions Performed By Name Resolvers**

To accomplish its resolution duties, name resolvers perform a number of related functions:

- ☛ **Providing The User Interface:** In order for DNS to be of maximum value to TCP/IP users, it must be possible for names to be used interchangeably with addresses. This is usually done automatically by the resolver, which provides an interface to the user to allow names to be entered and used like addresses.
- ☛ **Forming and Sending Queries:** Given a name to resolve, the DNS resolver must create an appropriate query using the DNS messaging system, determine what type of resolution to perform, and send the query to the appropriate name server.
- ☛ **Processing Responses:** The resolver must accept back responses from the DNS server to which it sent its query, and decide what to do with the information within the reply. As we'll see, it may be necessary for more than one server to be contacted for a particular name resolution.

This seems fairly simple, and it is in some ways, but implementation can become rather complicated. Bear in mind that the resolver may need to “juggle” several outstanding name resolutions simultaneously. It has to keep track of the different requests, queries and responses and make sure everything is kept straight.

The user interface is a very important part of a name resolver's job. We want users to be able to just use a name and have their software automatically treat it like an address. For this reason, normal name resolution usually doesn't involve explicitly running a piece of “resolver software”. Consider again your Web browser. You don't have to say “please find the IP address for `www.xyzindustries.com`” and then say “please connect to this IP address for XYZ Industries”. You just type in “`www.xyzindustries.com`” and the name resolution happens “magically”.

---

There is no magic, of course. The resolver is just called *implicitly* instead of explicitly. The Web browser recognizes that a name has been entered instead of an IP address and feeds it to the resolver, saying “I need you to resolve this name, please”. (Hey, it never hurts to be polite.) The resolver then takes care of resolution and provides the IP address back to the Web browser, which connects to the site. Thus, the resolver is the interface between the user (both the human user and the software user, the browser) and the DNS system.

**Key Concept:** The primary clients in DNS are software modules called DNS *name resolvers*. They are responsible for accepting names from client software, generating resolution requests to DNS servers, and processing and returning responses.

---

### ***Other Functions Performed By Name Resolvers***

Name resolvers don't have to perform nearly as many administrative jobs as name servers do; clients are usually simpler than servers in this regard. One important support function that many name resolvers *do* perform, however, is [caching](#). Like name servers, name resolvers can cache the results of the name resolutions they perform to save time if the same resolution is required again (not all resolvers perform caching, however.)

I should point out that even though resolvers are the DNS components that are most associated with name resolution, name servers can also act as clients in certain types of name resolution. In fact, it is possible to set up a network so that the resolvers on each of the client machines do nothing more than hand resolution requests to a local DNS server and let the server take care of it. In this case, the client resolver becomes little more than a shell, sometimes called a *stub resolver*. This has the advantage of centralizing name resolution for the network, but a potential disadvantage of performance reduction.

### **DNS Basic Name Resolution Techniques: Iterative and Recursive Resolution**

Conventional name resolution transforms a DNS name into an IP address. At the highest level, this process can be considered to have two phases. In the first phase, we locate a DNS name server that has the information we need: the address that goes with a particular name. In the second phase, we send that server a request containing the name we want to resolve, and it sends back the address required.

### ***The Difficult Part of Name Resolution: Finding The Correct Server***

Somewhat ironically, the second phase (the actual mapping of the name into an address) is fairly simple. It is the first phase—finding the right server—that is potentially difficult, and comprises most of the work in DNS name resolution. While perhaps surprising, this is a predictable result of how DNS is structured. Name information in DNS is not centralized, but rather distributed throughout a [hierarchy of servers](#), each of which is responsible for one zone in the DNS name space. This means we have to follow a special sequence of steps to let us find the server that has the information we need.

---

The formal process of name resolution parallels the tree-like hierarchy of the DNS name space, authorities and servers. Resolution of a particular DNS name starts with the most general part of the name, and proceeds from it to the most specific part. Naturally, the most general part of every name is the *root* of the DNS tree, represented in a name as a trailing “dot”, sometimes omitted. The next most-specific part is the top-level domain, then the second-level domain and so forth. The DNS name servers are “linked” in that the DNS server at one level knows the name of the servers that are responsible for subdomains in zones below it at the next level.

Suppose we start with the fully-qualified domain name (FQDN) “C.B.A.”. Formally, every name resolution begins with the root of the tree—this is why the root name servers are so important. It’s possible that the root name servers are authoritative for this name, but probably not; that’s not what the root name servers are usually used for. What the root name server **does** know is the name of the server responsible for the top-level domain, “A.”.

The name server for “A.” in turn may have the information to resolve “C.B.A.” It’s still fairly high-level, though, so “C.B.A” is probably not directly within its zone. In that case, it will not know the address we seek, but it will know the name of the server responsible for “B.A.”. In turn, that name server may be authoritative for “C.B.A.”, or it may just know the address of the server for “C.B.A.”, which will have the information we need. As you can see, it is very possible that several different servers may be needed in a name resolution.

**Key Concept:** Since DNS name information is stored as a distributed database spread across many servers, name resolution cannot usually be performed using a single request/response communication. It is first necessary to find the correct server that has the information that the resolver requires. This usually requires a sequence of message exchanges, starting from a root name server and proceeding down to the specific server containing the resource records that the client requires.

---

## ***DNS Name Resolution Techniques***

The DNS standards actually define two distinct ways of following this hierarchy of servers to discover the correct one. They both eventually lead to the right device, but they differ in how they assign responsibility for resolution when it requires multiple steps.

### **Iterative Resolution**

When a client sends an iterative request to a name server, the server responds back with either the answer to the request (for a regular resolution, the IP address we want) **or** the name of another server that has the information or is closer to it. The original client must then *iterate* by sending a new request to this referred server, which again may either answer it or provide another server name. The process continues until the right server is found; the method is illustrated in [Figure 243](#).

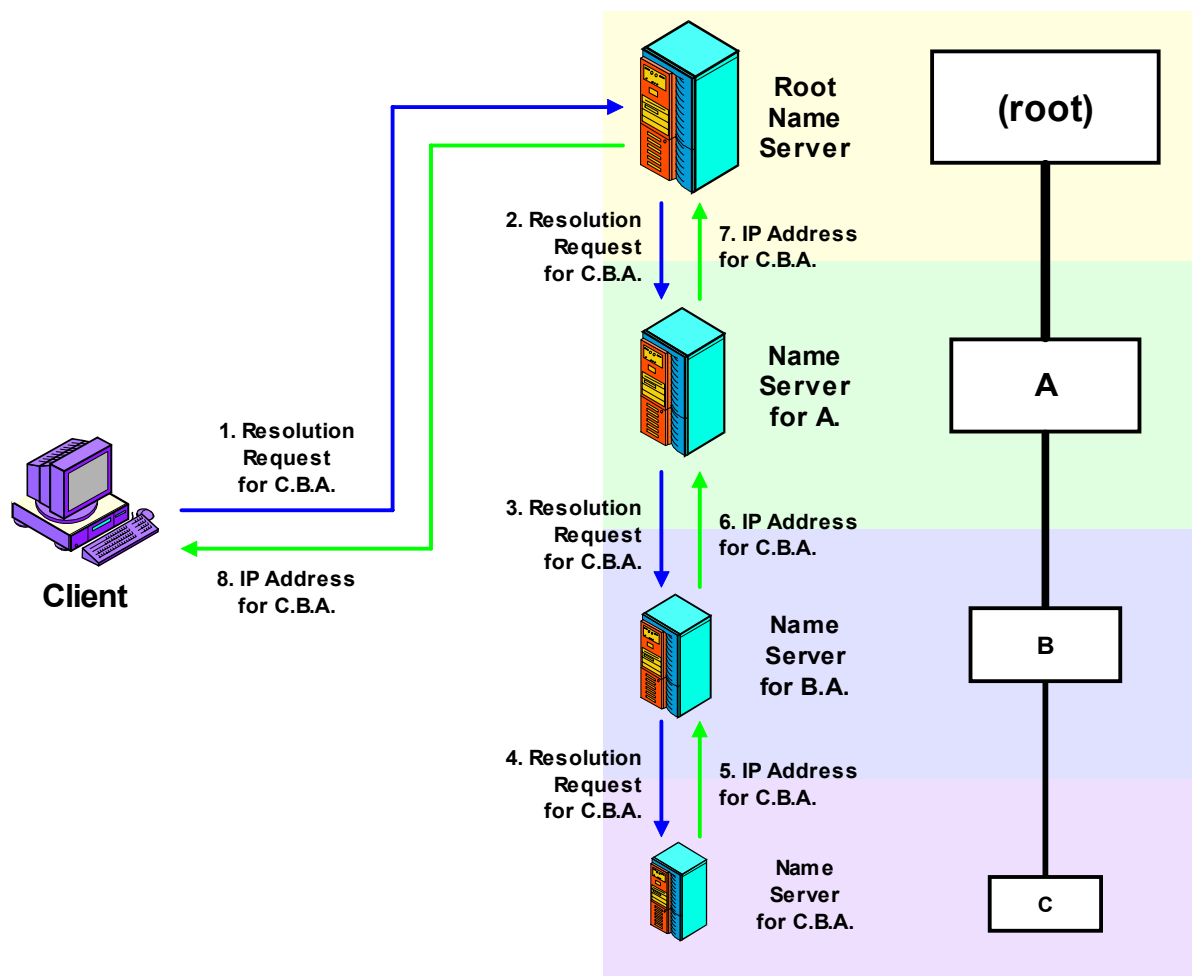

**Figure 243: Iterative DNS Name Resolution**

In this example, the client is performing a name resolution for "C.B.A." using strictly iterative resolution. It is thus responsible for forming all DNS requests and processing all replies. It starts by sending a request to the root name server for this mythical hierarchy. That server doesn't have the address of "C.B.A.", so it instead returns the address of the name server for "A.". The client then sends its query to that name server, which points the client to the server for "B.A.". That name server refers the client to the name server that actually has the address for "C.B.A.", which returns it to the client. Contrast to [Figure 244](#).

### Recursive Resolution

When a client sends a recursive request to a name server, the server responds back with the answer if it has the information sought. If it doesn't, the server takes responsibility for finding the answer by becoming a client on behalf of the original client and sending new requests to other servers. The original client only sends one request, and eventually gets the information it wants (or an error message if it is not available). This technique is shown in [Figure 244](#).

**Figure 244: Recursive DNS Name Resolution**

This is the same theoretical DNS resolution that I showed in [Figure 243](#), but this time, the client asks for the name servers to perform recursive resolution and they agree to do so. As in the iterative case, the client sends its initial request to the root name server. That server doesn't have the address of "C.B.A.", but instead of merely returning to the client the address of the name server for "A.", it sends a request to that server itself.

That name server sends a request to the server for "B.A.", which in turn sends a request to the server for "C.B.A.". The address of "C.B.A." is then carried back up the chain of requests, from the server of "C.B.A." to that of "B.A.", then "A.", then the root, and then finally, back to the client.

### ***Contrasting Iterative and Recursive Resolution***

To help explain the difference between these methods, let's take a side-trip to a real-world case. Suppose you are trying to find the phone number of your old friend Carol, with whom you haven't spoken in years. You call your friend Joe; he doesn't have Carol's number, but he gives you John's number, suggesting you call him. So you dial up John; he doesn't have the information but he knows the number of Carol's best friend, Debbie, and gives that to you. You call Debbie and she gives you Carol's information. This is an example of an iterative process. In contrast, suppose you called Joe and Joe said "I don't know, but I think I know how to find out ". He called John and then Debbie and called you back with the phone number. That would be like recursive resolution.

---

So in essence, iteration is doing the job yourself, while recursion is “passing the buck”. You might think that everyone would always want to use recursion since it makes “the other guy” do the work. This is true, but “passing the buck” is not considered good form if it is not done with permission. Not all name servers support recursion, especially servers near the top of the hierarchy. Obviously, we don’t want to bog down the root name servers and the ones that handle “.COM” and other critical TLDs with doing recursion. It is for this reason that clients must *request* that name servers perform recursion for them.

One place where recursion *is* often used is with the local name server on a network. Rather than making client machine resolvers perform iterative resolution, it is common for the resolver to generate a recursive request to the local DNS server, which then generates iterative requests to other servers as needed. As you can see, recursive and iterative requests can be combined in a single resolution, providing significant flexibility to the process as a whole. This is demonstrated in a more realistic example in [the topic detailing the DNS name resolution process](#).

Again, remember that for the purpose of understanding resolution, a DNS server can in fact act as a client. As soon as a DNS server accepts a recursive request for resolution on a name it cannot resolve itself, it becomes a client in the process. I should also point out that it is common for resolvers to know the names of not one but two local DNS servers, so if a problem occurs reaching the first they can try the second.

**Key Concept:** The two methods of name resolution in DNS are *iterative resolution* and *recursive resolution*. In iterative resolution, if a client sends a request to a name server that does not have the information the client needs, the server returns a pointer to a different name server and the client sends a new request to that server. In recursive resolution, if a client sends a request to a server that doesn’t have the requested information, that server takes on the responsibility for sending requests to other servers to find the necessary records, then returns them to the client. A server doing this takes on the role of client for its requests to other servers.

---

### **DNS Name Resolution Efficiency Improvements: Caching and Local Resolution**

The basic resolution techniques—[iterative and recursive](#)—can be considered “complete” from an algorithmic standpoint. By starting at the top (root) and working our way down, we are “guaranteed” to always eventually arrive at the server that has the information we need. I put “guaranteed” in quotes only because as always, there are no real “guarantees” in networking—we might have asked for a non-existent name, or a server might have bad data for example. But in the absence of such atypical problems, the process leads to the information eventually.

---

The problem is that last word: “eventually”. Both iterative and recursive resolution will get us to the right server, but they take a long time to do it, especially if the name we are trying to resolve is in a “deep” part of the DNS hierarchy (for example, “F.E.D.C.B.A.”). Since resolution is done so often, it is helpful to define changes to the basic resolution process that improve efficiency as much as possible.

### ***The Motivation for Caching: Locality of Reference***

A computer science principle called *locality of reference* describes two common phenomena related to how computers (and networks) are used. The first, sometimes called *spatial locality of reference*, observes that a resource is more likely to be referenced if it is near another resource that was recently referenced. The second, *temporal locality of reference*, says a resource is more likely to be accessed if it was recently accessed.

We can observe both of these phenomenon by using the example of browsing the Web. To observe spatial locality of reference, notice what happens when you visit a site such as <http://www.tcpipguide.com>. The initial request asks the server for the main index document of The TCP/IP Guide. However, that document contains links to several images and other items, all of which are **also** located at the domain “tcpipguide.com”. When your browser asks for the main document, it will shortly thereafter also ask for a number of graphics. Of course, as you navigate the site, you will click links to go to other Web pages. Again here, most of these will also be at the same domain, “tcpipguide.com”.

What this means is that if we resolve a particular domain name, it is likely that we will need to resolve it again very soon in the future. It would be silly to have to interrogate the same domain server dozens of times, each asking it to resolve the same name.

The second phenomenon, *temporal locality of reference*, is one you have probably noticed yourself. You are far more likely to access a resource you have used recently than one you have not looked at in a year. This means that maintaining information about recently-used resources can be inherently advantageous.

### ***Name Resolver Caching***

These two phenomena are the rationale for caching in the computer world in general, and as we have seen, in DNS servers in particular. The same advantages applies to resolvers, and so many of them perform caching also, in a way rather similar to [how it is done in servers](#). On a particular client computer, once a particular name is resolved, it is cached and remains ready for the next time it is needed. Again, this eliminates traffic and load on DNS servers. (Note however that not all resolvers perform caching.)

You might be wondering why we bother having caching on both resolvers and servers. This is not “redundant”, as it may appear. Or rather, it's redundant, but in a good way. To understand why, we much recognize that a fundamental trade-off in caching is that a cache provides better performance the **closer** it is the requestor of the data, but better coverage the **further** it is from the user.

---

If resolvers didn't cache results but our local server did, we could get the information from the server's cache, but it would require waiting for the exchange of a query and response. The resolver's cache is “closer” to the user and so more efficient. At the same time, this doesn't obviate the need for caching at our network's local DNS server. The server is further away from the user than the resolver, but its cache is shared by many machines. They can all benefit from its cache, so that if I look up a particular name and then someone else does a few minutes later, they can use my cached resolution even though they are typing it for the first time.

Caching by name resolvers follows the same general principles and rules as caching by name servers. The amount of time a resource record is specified by its *Time To Live* figure. Also, resolvers will not cache the results of certain queries, such as reverse lookups, and may also not cache a resolution if they suspect that for whatever reason the data returned is unreliable or corrupted.

**Key Concept:** In addition to the caching performed by DNS name servers, many (but not all) DNS resolvers also cache the results of recent resolution requests. This cache is checked prior to beginning a name resolution, to save time when multiple requests are made for the same name.

---

## **Local Resolution**

One other area where resolution efficiency can be improved is the special case where we are trying to resolve the names of computers in our own organizations. Suppose that I, an employee at XYZ Industries, want to get some sales information using FTP from “sales.xyzindustries.com”. My FTP client will invoke my local resolver to resolve that name, by sending it to our local DNS server. Now, would it be smart for that server, which is here inside the company, to start the resolution process up at the root name server? Not really.

The local DNS server that accepts local resolution requests from resolvers on the network may in fact **be** the authoritative name server for “sales.xyzindustries.com”. In other cases, it may know how to answer certain resolution requests directly. Obviously, it makes sense for the server to check to see if it can answer a resolver's query before heading up to the root server, since this provides a faster answer to the client and saves internetwork traffic. This is called *local resolution*.

Most DNS servers will perform this check to see if they have the information needed for a request before commencing the “formal” top-down resolution process. The exception is DNS servers that do not maintain information about any zones: *caching-only servers*. In some cases, DNS resolvers on client machines may also have access to certain local zone information, in which case they can use it instead of sending a resolution query at all.

---

There's one more thing I also want to point out: most operating systems also support the use of the old [host table mechanism](#), which can be useful for local machines on a network. If a host has a host table, the resolver will check the host table to see if it can find a mapping for a name before it will bother with the more time-consuming DNS resolution process. This is not technically part of DNS, but is often used in conjunction with it.

## **DNS Name Resolution Process**

In the previous topics I have described [what name resolvers do](#), explained [the basic top-down resolution process using iterative and recursive resolution](#), and discussed how [local resolution and caching](#) are used to improve resolution performance. Now I would like to tie all this background material together and finally show you how the name resolution process works as a whole!

As usual, the best way to do this is by example. Here, I will actually combine two examples I have used earlier: the fictitious company “XYZ Industries” and the non-existent college, Googleplex University. Let's say that XYZ Industries runs its own DNS servers for the “xyzindustries.com” zone. The master name server is called “ns1.xyzindustries.com”, and the slave is, ta-da, “ns2.xyzindustries.com”. These are also used as local DNS servers for resolvers on client machines. We'll assume for this example that as is often the case, our DNS servers will accept recursive requests from machines within our company, but will *not* assume other machines will accept such requests. Let's also assume that both the server and resolver perform caching, and that the caches are empty.

Let's say that Googleplex University runs its own DNS servers for the “googleplex.edu” domain, as I gave in the example in [the topic describing DNS zones](#). There are three subdomains: finearts.googleplex.edu, compsci.googleplex.edu, and admin.googleplex.edu. Of these, compsci.googleplex.edu is in a separate zone with dedicated servers, while the other subdomains are in the “googleplex.edu” zone (this is shown in [Figure 240](#).)

## ***Resolution Process Steps***

Now, suppose you are an employee within XYZ Industries and one of your clients is in charge of the networking department at Googleplex U. You type into your Web browser the address of this department's Web server, “www.net.compsci.googleplex.edu”. In simplified terms, the procedure would involve the following set of steps ([Figure 245](#) shows the process graphically):

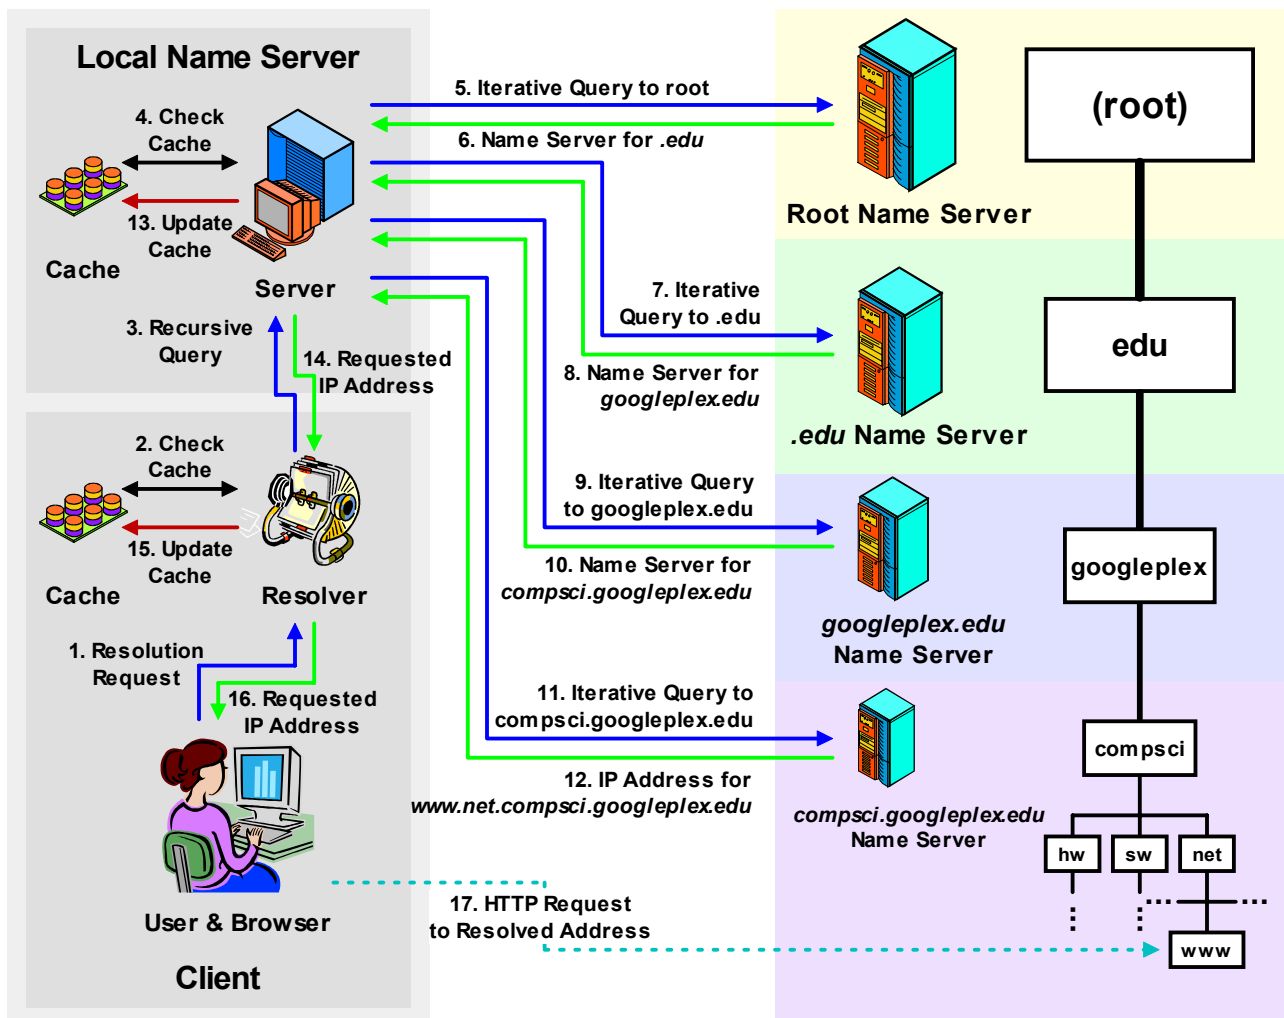

1. Your Web browser recognizes the request for a name and invokes your local resolver, passing to it the name “www.net.compsci.googleplex.edu”.
2. The resolver checks its cache to see if it already has the address for this name. If it does, it returns it immediately to the Web browser, but in this case we are assuming that it does not. The resolver also checks to see if it has a local [host table file](#). If so, it scans the file to see if this name has a static mapping. If so, it resolves the name using this information immediately. Again, let's assume it does not, since that would be boring.
3. The resolver generates a recursive query and sends it to “ns1.xyzindustries.com” (using that server's IP address, of course, which the resolver knows).

- 
4. The local DNS server receives the request and checks *its* cache. Again, let's assume it doesn't have the information needed. If it did, it would return the information, marked "non-authoritative", to the resolver. The server also checks to see if it has in its zone resource records that can resolve "www.net.compsci.googleplex.edu". Of course it does not, in this case, since they are in totally different domains.
  5. "ns1.xyzindustries.com" generates an iterative request for the name and sends it to a root name server.
  6. The root name server does not resolve the name. It returns the name and address of the name server for the ".edu" domain.
  7. "ns1.xyzindustries.com" generates an iterative request and sends it to the name server for ".edu".
  8. The name server for ".edu" returns the name and address of the name server for the "googleplex.edu" domain.
  9. "ns1.xyzindustries.com" generates an iterative request and sends it to the name server for "googleplex.edu".
  10. The name server for "googleplex.edu" consults its resource records. It sees, however, that this name is in the "compsci.googleplex.edu" subdomain, which is in a separate zone. It returns the name server for that zone.
  11. "ns1.xyzindustries.com" generates an iterative request and sends it to the name server for "compsci.googleplex.edu".
  12. The name server for "compsci.googleplex.edu" is authoritative for "www.net.compsci.googleplex.edu". It returns the IP address for that host to "ns1.xyzindustries.com".
  13. "ns1.xyzindustries.com" caches this resolution. (Note that it will probably also cache some of the other name server resolutions that it received in steps #6, #8 and #10; I have not shown these explicitly.)
  14. The local name server returns the resolution to the resolver on your local machine.
  15. Your local resolver also caches the information.
  16. The local resolver gives the address to your browser.
  17. Your browser commences an HTTP request to the Googleplex machine's IP address.

Seems rather complicated and slow. Of course, computers work faster than you can read (or I can type, for that matter.) Even given that, the benefits of caching are obvious—if the name was in the cache of the resolver or the local DNS server, most of these steps would be avoided.

### ***Changes to Resolution to Handle Special Cases***

This example is highly simplified, and also only shows one possible way that servers might be set up. For one thing, it is possible that even though "compsci.googleplex.edu" is in a separate zone from "googleplex.edu", they might use the same server. In that case, one iteration in the process would be skipped. The example also above doesn't show what happens if an error occurs in the process.

**Figure 245: Example Of The DNS Name Resolution Process**

This fairly complex example illustrates a typical DNS name resolution using both iterative and recursive resolution. The user types in a DNS name ("`www.net.compsci.googleplex.edu`") into a Web browser, which causes a DNS resolution request to be made from her client machine's resolver to a local DNS name server. That name server agrees to resolve the name recursively on behalf of the resolver, but uses iterative requests to accomplish it. These requests are sent to a DNS root name server, followed in turn by the name servers for ".edu", "googleplex.edu" and "compsci.googleplex.edu". The IP address is then passed to the local name server and then back to the user's resolver and finally, her Web browser software.

If the domain name entered was an alias, indicated by a *CNAME* record, this would change the processing as well. *CNAME* records are used to allow a "constant" name for a device to be presented to the outside world while allowing the actual device that corresponds to the name to vary inside the organization. When a *CNAME* is used, it changes the name resolution process by adding an extra step: first we resolve the alias to the canonical name and then resolve the canonical name.

For example, Web servers are almost always named starting with "www.", so at XYZ Industries we want people to be able to find our Web site at "`www.xyzindustries.com`". However, the Web server may in fact be shared with other services on "`bigserver.xyzindustries.com`".

---

We can set up a *CNAME* record to point “www.xyzindustries.com” to “bigserver.xyzindustries.com”. Resolution of “www” will result in a *CNAME* pointing to “bigserver”, which is then itself resolved. If in the future our business grows and we decide to upgrade our Web service to run on “bigserver.xyzindustries.com”, we just change the *CNAME* record and users are unaffected.

## **DNS Reverse Name Resolution Using the IN-ADDR.ARPA Domain**

If most people had to boil down the core job of the Domain Name System to one function, they would probably say it was converting the names of objects into the numeric IP addresses associated with them. Well, they would if they knew much about DNS. For this reason, DNS is sometimes compared to a telephone book, or to telephone “411” service. There are certain problems with this analogy, but at the highest level it is valid. In both cases we take a name, consult a database (of one type or another), and produce from it a number that matches that name.

### ***The Need for Reverse Name Resolution***

In the real world, there are sometimes situations where you don't want to find the phone number that goes with a name, but rather, you have a phone number and want to know what person it belongs to. For example, this might happen if your telephone records the number of incoming calls but you don't have Caller ID to display the name associated with a number. You might also find a phone number on a piece of paper and not remember whose number it is.

Similarly, in the networking world, there are many situations where we have an IP address and want to know what name goes with it. For example, a World Wide Web server records the IP address of each device that connects to it in its server logs, but these numbers are generally meaningless to humans, who prefer to see the names that go with them.

A more serious example might be a hacker trying to break into your computer; by converting the IP address into a name you might be able to find out what part of the world he is from, what ISP he is using, and so forth. There are also many reasons why a network administrator might want to find out the name that goes with an address, for setup or troubleshooting purposes.

### ***The Original Method: Inverse Querying***

DNS originally included a feature called *inverse querying* that would allow this type of “opposite” resolution. A resolver could send a query which, instead of having a name filled in and a space for the server to fill in the IP address, had the IP address and a space for the name. The server would check its resource records and return the name to the resolver.

This works fine in theory, and even in practice if the internetwork is very small. However, remember that due to the distributed nature of DNS information, the biggest part of the job of resolution is in fact finding the right server. Now, in the case of regular resolution, we can easily find the right server by traversing the hierarchy of servers. This is possible because the servers are connected together following a hierarchy of names.

---

DNS servers are *not*, however, arranged based on IP address. This means that to use inverse queries, we have to use the right name server for the IP address we want to resolve into a name, with no easy way to find out what it is. Sure, we could try sending the inverse query to the authoritative DNS server for **every** zone in the hierarchy. If you tried, it would probably take you longer than it took to write this Guide. So let's not go there. The end result of all of this is that inverse queries were never popular except for local server troubleshooting. They were formally removed from DNS in November 2002 through the publishing of RFC 3425.

### ***The IN-ADDR.ARPA Name Structure for Reverse Resolution***

The problem here is that the servers are arranged by name and not by IP address. The solution, therefore, is as simple as it sounds: arrange the servers by IP address. This doesn't mean we remove the name hierarchy, or duplicate all the servers, or anything silly like that. Instead, we create an additional, numerical hierarchy that coexists with the name hierarchy. We then use this to find names from numbers, using a process commonly called *reverse name resolution*.

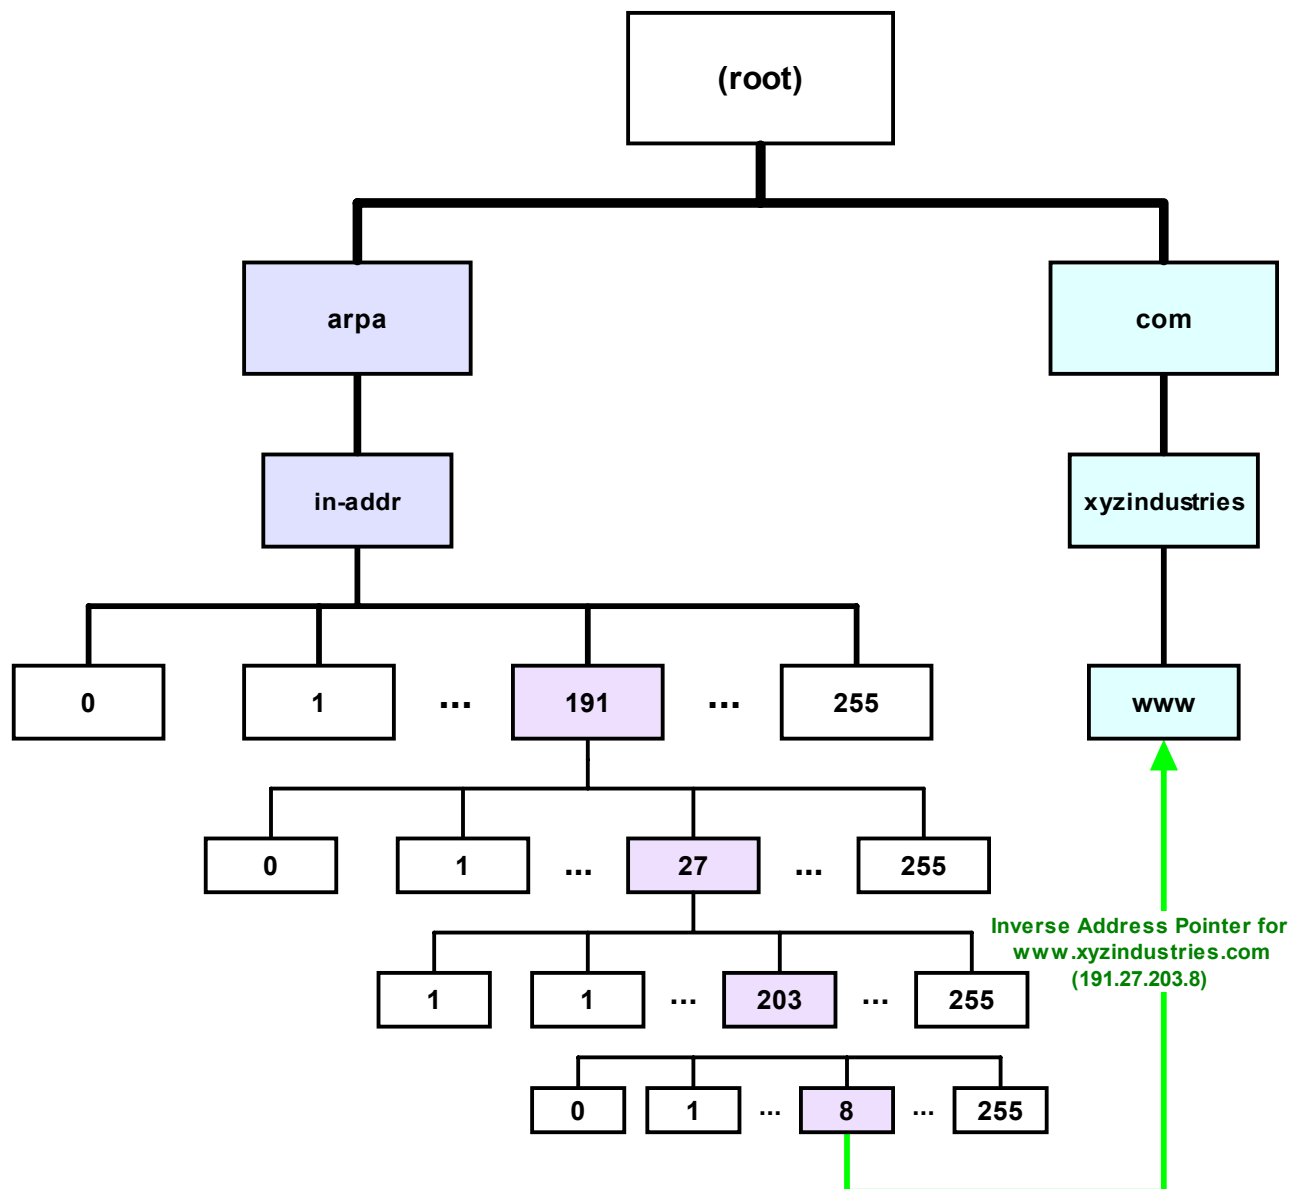

The name hierarchy for the Internet is implemented using a special domain called "IN-ADDR.ARPA", located within the reserved [".ARPA" top-level domain](#) ("IN-ADDR" stands for "INternet ADDRess". Recall that ".ARPA" was originally used to transition old Internet hosts to DNS, and is now used by the folks that run the Internet for various purposes.

A special numerical hierarchy is created within "IN-ADDR.ARPA" that covers the entire IP address space:

- ☉ At the first level within "IN-ADDR.ARPA" there are 256 subdomains called "0", "1", "2" and so on, up to "255". For example, "191.IN-ADDR.ARPA". (Actually there may not be all 256 of these since some IP addresses are reserved, but let's ignore that for now).
- ☉ Within each of the subdomains above, there are 256 further subdomains at the second level, numbered the same way. So for example, one of these would be "27.191.IN-ADDR.ARPA".
- ☉ Again, there are 256 subdomains at the third level within each of the above, such as "203.27.191.IN-ADDR.ARPA".
- ☉ Finally, there are 256 subdomains at the fourth level within each of the third-level subdomains, such as "8.203.27.191.IN-ADDR.ARPA".

This structure is illustrated in [Figure 246](#). As you can see, within "IN-ADDR.ARPA" we have created a name space that parallels the address space of the Internet Protocol. (Yes, this means there are several **billion** nodes and branches in this part of the Internet DNS name space!)

**Figure 246: The DNS *IN-ADDR.ARPA* Reverse Name Resolution Hierarchy**

The special “IN-ADDR.ARPA” hierarchy was created to allow easy reverse lookups of DNS names. “IN-ADDR.ARPA” contains 256 subdomains numbered 0 to 255, each of which has 256 subdomains numbered 0 to 255, and so forth, down four levels. Thus, each IP address is represented in the hierarchy. In this diagram I have shown as an example the DNS domain name “www.xyzindustries.com”. It would have a conventional resource record pointing to its IP address, 191.27.203.8, as well as a reverse resolution record at 8.203.27.191.IN-ADDR.ARPA, pointing to the domain name “www.xyzindustries.com”.

---

## **Resource Record Setup for Reverse Resolution**

With the IN-ADDR.ARPA structure in place, we can now associate one entry in this name space with each entry in the “real” DNS name space. We do this using the “PTR” (pointer) resource record type. For example, if “www.xyzindustries.com” has the IP address 191.27.203.8, then the DNS server for its zone will have an address resource record indicating this. In master file text format, it will say something like this:

```
www.xyzindustries.com.  A  191.27.203.8
```

However, there will also be the following entry for it within the IN-ADDR.ARPA domain:

```
8.203.27.191.IN-ADDR.ARPA  PTR  www.xyzindustries.com
```

(Remember that DNS names are case-insensitive, so the “IN-ADDR.ARPA” could also be given as “in-addr.arpa”).

Once this is done, reverse name resolution can be easily performed by doing a name resolution on “8.203.27.191.in-addr.arpa”. If we do this, a server for the “IN-ADDR.ARPA” domain will return to us the name “www.xyzindustries.com”. This is also shown in [Figure 246](#).

### ***Why The IN-ADDR.ARPA Structure Is the Opposite of Normal IP Addresses***

I’m sure you’ve noticed that the numbers are “backwards” in the IN-ADDR.ARPA domain. We’ve already seen the reason for this: name resolution proceeds from the least-specific to the most-specific element, going from right to left. In contrast, IP addresses have the least specific octet on the left, and the most specific on the right. Thus, we reverse them to maintain consistency with the DNS name space.

This immediately yields us one extra benefit. Just as we can delegate authority for portions of the regular name space, for example, letting “XYZ Industries” be in charge of everything in “xyzindustries.com”, we can also delegate authority for parts of the IN-ADDR.ARPA name space. For example, since MIT owns all IP addresses with a first octet of 18—at least I think they still do—it is possible that if MIT wanted to, they could control the “18.IN-ADDR.ARPA” domain as well for reverse queries. This would not be possible without reversing the octets as we have done.

Note that for this system to work reliably, it is essential that the data in the “regular” name space and the reverse name space remain consistent. Whenever a new DNS name is registered, an appropriate entry must be made within IN-ADDR.ARPA as well. Special procedures have been put into place to allow these pointer entries to be created automatically.

**Related Information:** A similar scheme using a different reverse domain is used for [DNS under IPv6](#).

---

**Key Concept:** Most name resolutions require that we transform a DNS domain name into an IP address. However, there are cases where we want to perform a *reverse name resolution*, by starting with an IP address and finding out what domain name matches it. This is difficult to do using the conventional DNS distributed name hierarchy, because there is no easy way to find the DNS server containing the entries for a particular IP address using the regular DNS name hierarchy. To this end, a special hierarchy called *IN-ADDR.ARPA* was set up for reverse name lookups. This hierarchy contains four levels of numerical subdomains structured so that each IP address has its own node. The node for an IP address contains an entry that points to the DNS domain name associated with that address.

---

## **DNS Electronic Mail Support and Mail Exchange (MX) Resource Records**

Most savvy users of the Internet know that the Domain Name System exists, and usually associate it with the most common Internet applications. Of these applications, the “big kahuna” is of course the [World Wide Web](#). It's probably the case that the majority of DNS name resolution requests are spawned as a result of Web server domain names being typed into browsers billions of times a day, as well as requests for named pages generated by both user mouse clicks and Web-based applications.

Of course, DNS is not tied specifically to any one application. We can specify names in any place where an IP address would go. For example, you can use a DNS name instead of an address for an [FTP](#) client, or even for a troubleshooting utility like [traceroute](#) or [ping](#). The resolver will in each case take care of translating the name for you.

There's one application that has always used DNS, but it's one that doesn't usually spring to mind when you think about DNS: [electronic mail](#). Electronic mail is in fact more reliant on DNS than just about any other TCP/IP application. Consider that while you may *sometimes* type in an IP address for a command like traceroute, or even type it into a browser, you probably have never sent anyone mail by entering “joe@14.194.29.60” into your e-mail client. At least I never have in over a dozen years being online. You instead type “joe@xyzindustries.com”, and DNS takes care of figuring out where electronic mail for XYZ Industries is to go.

### ***Special Requirements for Electronic Mail Name Resolution***

Name resolution for electronic mail addresses is different from other applications in DNS, for [three reasons that I describe in the overview topic on TCP/IP e-mail addressing and address resolution](#). To summarize: first, we may not want electronic mail to go to the exact

---

machine specified by the address; second, we need to be able to change server names without changing everyone's e-mail address; and third, we need to be able to support multiple servers for handling mail.

For example, XYZ Industries might want to use a dedicated mail server called “mail.xyzindustries.com” to handle incoming mail, but actually construct all of its e-mail addresses to use “@xyzindustries.com”. This makes addresses shorter, and allows the server's name to be changed without affecting user addresses. If the company wishes, it might decide to use two servers, “mail1.xyzindustries.com” and “mail2.xyzindustries.com”, for redundancy, and again have just “@xyzindustries.com” for addresses.

### ***The Mail Exchange (MX) Record and Its Use***

To allow the flexibility needed for these situations, a special DNS resource record type is defined called a *mail exchange (MX)* record. Each *MX* record specifies a particular mail server that is to be used to handle incoming e-mail for a particular domain. Once this record is established, resolution of electronic mail messages is pretty much similar to how it works for regular resolution. Suppose we want to send an e-mail to “joe@xyzindustries.com”. The process, roughly, is as follows:

1. Our e-mail client invokes the resolver on our local machine to perform an e-mail resolution on “xyzindustries.com”.
2. Our local resolver and local DNS server follow the process described in [the topic on DNS name resolution](#) to find the authoritative server for “xyzindustries.com”, which is “ns1.xyzindustries.com”.
3. “ns1.xyzindustries.com” finds the *MX* record for “xyzindustries.com” and replies back indicating that “mail.xyzindustries.com” should be used for e-mail.

Of course, the e-mail client can't actually send anything to “mail.xyzindustries.com”; it needs its IP address. So, it would then have to resolve that name. Of course, this resolution request will likely end up right back at the same DNS name server that just handled the *MX* request. To eliminate the inefficiency of two separate resolutions, the DNS name server can combine the information. In our example above, “ns1.xyzindustries.com” will include the *A (Address)* resource record for “mail.xyzindustries.com” in the *Additional* section of the DNS message that it sends in step 3 above.

It is also possible to specify multiple *MX* records for a particular domain, each pointing to a different mail server's name. This provides redundancy, so if there is a problem with one mail server, another can pick up the slack. DNS allows each mail server to be specified with a *preference* value, so you can clearly indicate which is the main mail server, which is the first backup, the second backup, and so on. The DNS server will choose the mail server with the lowest preference value first, then the next highest one, and so on.

**Key Concept:** Since electronic mail is sent using host names and not IP addresses, DNS contains special provisions to support the transfer of e-mail between sites. Special *mail exchange (MX)* DNS resource records are set up that contain the names of mail servers that a domain wants to use for handling incoming e-mail. Before sending e-mail to a site, a device performs a name resolution to get that site's MX record, so it knows where to send the message.

---

### ***Obsolete Electronic Mail Resource Records***

Note that RFC 1035 originally defined several other resource record types related to electronic mail as well: the *mailbox (MB)*, *mail group (MG)* and *mail rename (MR)* resource records. These are called “experimental” in the standard. I think the experiment failed, whatever it was, because I don't believe these are used today. There are also two even older mail-related resource records, *mail destination (MD)* and *mail forwarder (MF)*, which must have been used at one time but were already obsolete at the time RFC 1035 itself was written.

---

## **DNS Messaging and Message, Resource Record and Master File Formats**

Networking is all about the communication of information between connected devices. In the case of the Domain Name System, information about names and objects on the inter-network is exchanged during each of the many types of operations DNS performs. This involves sending *messages* between devices. Like most protocols, DNS uses its own set of messages with distinct field formats, and follows a particular set of rules for generating them and transporting them over the internetwork.

In this section I explain how messages are generated and sent in DNS, and also describe the formats used for messages and resource records. I begin with an overview discussion of DNS messages and how they are generated and transported. I provide an overview of the general DNS message format, and the five sections it contains. I describe the notation used for names and the special compression method that helps keep DNS messages down in size. I then show the fields in the DNS message header and question section. I illustrate the common field format used for all resource records, and the specific fields in the most important record types. I conclude with a description of the format used for DNS text master files.

### **DNS Message Generation and Transport**

In the preceding sections we have explored the many different tasks that DNS servers and resolvers perform: regular name resolution, reverse name resolution, e-mail resolution, zone transfers, and more. Each of these operations requires that information be exchanged between a pair of DNS devices. Like so many other TCP/IP protocols, DNS is designed to accomplish this information transfer using a *client/server* model. All DNS exchanges begin with a client sending a request, and a server responding back with an answer.

### ***DNS Client/Server Messaging Overview***

In the [overview topic on TCP/IP's client/server nature](#), I explained a potential source of confusion regarding these terms: the fact that they refer to hardware roles, software roles and transactional roles. This issue definitely applies when it comes to DNS. We've already seen that DNS implementation consists of two sets of software elements: [resolvers](#) that act as clients and [name servers](#) that are of course the servers. Resolver software usually runs on client machines like PCs, while name server software often runs on dedicated server hardware.

However, these designations are based on the overall role of the hardware and software. From a messaging viewpoint, the “client” is the initiator of the communication, regardless of what type of machine does this initiating, and the “server” is the device that responds to the client. A resolver usually acts as a client and a name server as a server. However, in a particular exchange a DNS name server can in fact act as a client, in at least two cases. First, in [recursive name resolution](#), a server generates requests to other servers and therefore acts as a client. Second, in administrative functions like [zone transfers](#), one server acts like a client and sends a request to another server. (There are no cases in DNS that I know of where a resolver acts as a server, incidentally.)

---

Most transactions in DNS consist of the exchange of a single query message and a single response message. The device acting as client for the transaction creates the query and sends it to the server; the server then sends back a reply. This is done through the process described in the next topic. In certain cases where a great deal of data needs to be sent, such as zone transfers, the server may send back multiple messages. Multiple such transactions may be required to perform a complete name resolution, as [my example of the DNS resolution process](#) demonstrated.

### ***DNS Message Transport Using UDP and TCP***

TCP/IP of course has two different protocols for data transfer: the [User Datagram Protocol \(UDP\)](#) and [Transmission Control Protocol \(TCP\)](#). UDP and TCP “share” level 4 in TCP/IP because they are so different in terms of capabilities and operation. Some application protocols need the services of TCP and can use it to take advantage of them, while others are better off with the simpler UDP. DNS is itself a perfect example of the [valid reasons for having both UDP and TCP in the protocol suite](#), because it uses **both**.

#### **UDP Message Transport**

UDP is a simple connectionless protocol that provides no real features but is very fast. It is ideally suited for small, quick exchanges of information, and can be faster than TCP because there is no need to establish a connection. This makes it a good choice for most of the conventional queries used in DNS, because they are normally very short, and fast data exchange is important. For this reason, the DNS standards recommend use of UDP for queries and replies as part of regular and reverse name resolution. UDP DNS messages are limited to 512 bytes; longer messages are truncated and a [special bit in the header](#) is set to indicate that this has occurred. If a message being truncated causes a problem for its recipient, the query must be repeated using TCP, as described below.

**Note:** The 512 byte limit on DNS UDP messages can be surpassed if the optional *Extension Mechanisms for DNS (EDNS0)* are implemented. These are described in RFC 2671.

---

#### **TCP Message Transport**

Since UDP does not provide reliable delivery of messages, DNS clients must keep track of requests they have sent. If no response is received after a particular amount of time, the request must be retransmitted. The need to take care of these details is considered an acceptable trade-off for the lower setup costs involved with UDP, such as not requiring a connection. The rate at which retransmissions is sent is usually set at a minimum of 2 to 5 seconds to prevent excessive DNS traffic on the internetwork.

For certain special DNS transactions, UDP is simply inappropriate. The most common example of such a transaction is a zone transfer. While the query for a zone transfer is small in size, the amount of data sent in response can be quite large. The limit of 512 bytes for UDP is not even close to enough. Furthermore, we really do need to make sure that a zone

---

transfer is accomplished reliably and with flow control and other data transfer management features, or we risk having corrupted zone information in our secondary DNS server databases.

The solution is to use TCP for these types of exchanges. TCP allows messages to be of arbitrary length, and as a [connection-oriented, acknowledged, reliable protocol](#), automatically provides the mechanisms we need to ensure that zone transfers and other lengthy operations complete successfully. The cost is the small amount of overhead needed to establish the connection, but since zone transfers are infrequent (compared to the sheer volume of regular name resolutions) this is not a problem.

You can see how DNS nicely illustrates the roles of both TCP and UDP in TCP/IP. Since both transport protocols can be used, name servers listen for both UDP and TCP requests on the same [well-known port number](#), 53. The device acting as the client uses an [ephemeral port number](#) for the transaction. All DNS messages are sent [unicast](#) from one device directly to another.

**Key Concept:** DNS uses both UDP and TCP to send messages. Conventional message exchanges are “short and sweet” and thus well-suited to the use of the very fast UDP; DNS itself handles the detection and retransmission of lost requests. For larger or more important exchanges of information, especially zone transfers, TCP is used—both for its reliability and its ability to handle messages of any size.

---

## **DNS Message Processing and General Message Format**

The [previous topic](#) discussed DNS message exchanges and the fact that they are all based on the principle of client/server computing. In a particular exchange, one device acts as a client, initiating the communication by sending a query; the other acts as the server by responding to the query with an answer. This “query/response” behavior is an integral part of DNS, and is reflected in the format used for DNS messages.

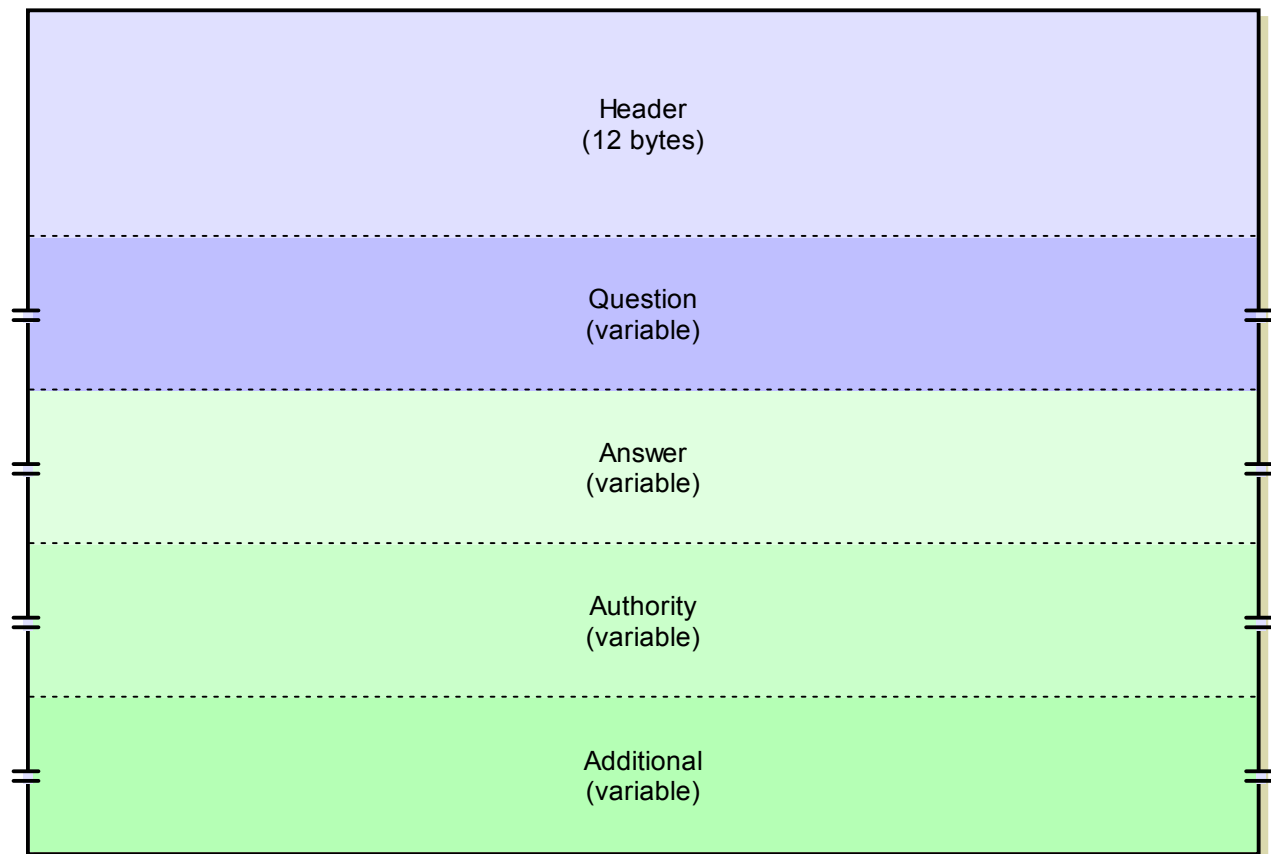

A common message format is used for DNS queries and responses. This message format contains five sections that provide a place for the query asked by the client; the answer(s) provided by the server; and header information that controls the entire process. [Table 169](#) describes the DNS general message format, providing a brief summary of each of its sections and how they are used. You can also see a simplified illustration of the message format in [Figure 247](#).

**Table 169: DNS General Message Format (Page 1 of 2)**

Section Name	Description
Header	Contains fields that describe the type of message and provide important information about it. Also contains fields that indicate the number of entries in the other sections of the message.
Question	Carries one or more “questions”, that is, queries for information being sent to a DNS name server.

**Table 169: DNS General Message Format (Page 2 of 2)**

Section Name	Description
<b>Answer</b>	Carries one or more resource records that answer the question(s) indicated in the <i>Question</i> section above.
<b>Authority</b>	Contains one or more resource records that point to authoritative name servers that can be used to continue the resolution process.
<b>Additional</b>	Conveys one or more resource records that contain additional information related to the query that is not strictly necessary to answer the queries (questions) in the message.

**Figure 247: DNS General Message Format**

### ***Header and Question Section***

The *Header* is always present in all messages and is fixed in length. In addition to containing important DNS control information, it has a flag (*QR*) that indicates whether a message is a query or a response. It also has four “count” fields that tell the recipient the number of entries in the other four sections.

---

When a client initiates a query, it creates a message with the fields in the *Header* filled in, and one or more queries (requests for information) in the *Question* section. It sets the *QR* flag to 0 to indicate that this is a query, and places a number in the *QDCount* field of the header that indicates the number of questions in the *Question* section. The number of entries in the others sections are usually zero, so their “count” fields (*ANCount*, *NSCount* and *ARCount*) are set to 0 in the header. (While more than one question can be put into a query, usually only one is included.)

When the server receives the query it processes it and performs the information retrieval operation requested (if it can). It then uses the query as the basis for its response message. The *Header* and *Question* sections are copied to the response message, and the *QR* flag is set to 1 to indicate that the message is a reply. Certain fields are also changed in the header to provide information back to the client. For example, the server sets the *RCode* (*Response Code*) field to indicate whether the query was successful or if an error occurred, and if one did occur, to indicate what the problem was. [The next topic](#) shows all the *Header* fields and indicates how each is used by both client and server.

### ***Resource Record Sections: Answer, Authority and Additional***

The server is also responsible for filling in the other three sections of the message: *Answer*, *Authority* and *Additional*. These sections share the same basic format, each carrying one or more resource records that use a common record format. The number of records in each section is indicated using the “count” fields in the message header. The sections differ only in terms of the types of records they carry. *Answer* records are directly related to the question asked, while *Authority* records carry resource records that identify other name servers. *Authority* records are thus the means by which name servers are hierarchically “linked” when the server doesn't have the information the client requested.

The *Additional* section exists for the specific purpose of improving DNS efficiency. There are cases where a server supplies an answer to a query that it has reason to believe will lead to a subsequent question that the server can also answer. For example, suppose a server provides the name of another name server in the *Authority* section (an *NS* resource record). The client may not have the address for that server, which would mean it has to perform an extra name resolution to contact the referenced server. If the server providing the *NS* record already knows the IP address for this name server, it can include it in the *Additional* section. The same goes for a server providing an *MX* record as I explained in [the topic on DNS mail support](#).

**Key Concept:** DNS uses a general message format for all messages. It consists of a fixed 12-byte *Header*, a *Question* section that contains a query, and then three additional sections that can carry resource records of different types. The *Answer* section usually contains records that directly answer the *Question* of the message; the *Authority* section holds the names of name servers being sent back to the client, and the *Additional* section holds extra information that may be of value to the client, such as the IP address of a name server mentioned in the *Authority* section.

---

---

**Note:** The special *Notify* and *Update* messages use a different format than the regular DNS query/response messages. These special messages (whose use is described in [the topic on DNS server enhancements](#)) are based on the regular format but with the meanings of certain fields changed. You can find these field formats in RFC 1996 and RFC 2136 respectively.

---

## DNS Message Header and Question Section Format

The client/server information exchange in DNS is facilitated using query/response messaging. Both queries and responses have the same general format, containing up to five individual sections carrying information. Of these, two are usually found in both queries and responses: the *Header* section and the *Question* section. I will start exploring the detailed format of DNS messages by looking at these two sections; the next topic will cover the resource record formats used by servers for the other three message sections.

### DNS Message Header Format

The header is the most important part of any message, since it is where critical control fields are carried. In DNS messages, the *Header* section carries several key control flags, and is also where we find out which of the other sections are even being used in the message. Examining the *Header* can help us understand several of the nuances of how messaging works in DNS.

The format of the *Header* section used in all DNS messages is described in detail in [Table 170](#) and shown in [Figure 248](#). Where fields are used differently by the client and server in an exchange, I have mentioned in the table how the use is differentiated between the two.

**Table 170: DNS Message Header Format (Page 1 of 4)**

Field Name	Size (bytes)	Description
<i>ID</i>	2	<b>Identifier:</b> A 16-bit identification field generated by the device that creates the DNS query. It is copied by the server into the response, so it can be used by that device to match that query to the corresponding reply received from a DNS server. This is used in a manner similar to how the <i>Identifier</i> field is used in many of the <a href="#">ICMP message types</a> .
<i>QR</i>	1/8 (1 bit)	<b>Query/Response Flag:</b> Differentiates between queries and responses. Set to 0 when the query is generated; changed to 1 when that query is changed to a response by a replying server.

Table 170: DNS Message Header Format (Page 2 of 4)

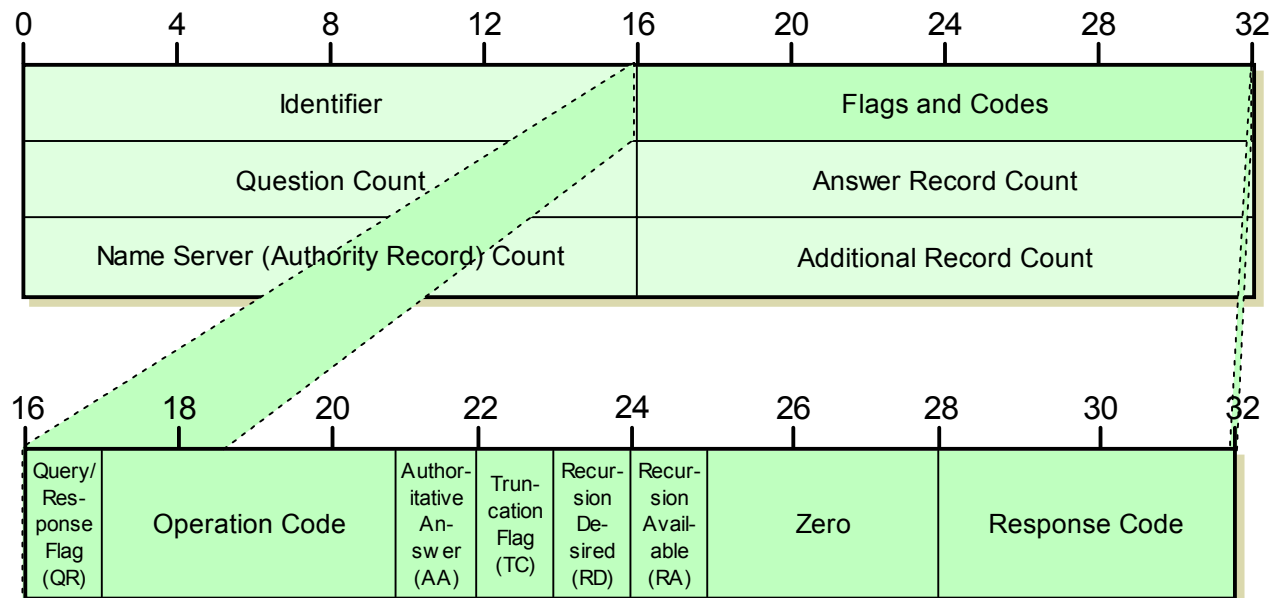

Field Name	Size (bytes)	Description																					
<b>Opcode</b>	1/2 (4 bits)	<p><b>Operation Code:</b> Specifies the type of query the message is carrying. This field is set by the creator of the query and copied unchanged into the response:</p> <table> <tr> <th>Opcode Value</th><th>Query Name</th><th>Description</th></tr> <tr> <td>0</td><td>QUERY</td><td>A standard query.</td></tr> <tr> <td>1</td><td>IQUERY</td><td>An inverse query; now obsolete. RFC 1035 defines the inverse query as an optional method for performing inverse DNS lookups, that is, finding a name from an IP address. Due to implementation difficulties, the method was never widely deployed, however, in favor of <a href="#">reverse mapping using the IN-ADDR.ARPA domain</a>. Use of this Opcode value was formally obsoleted in RFC 3425, November 2002.</td></tr> <tr> <td>2</td><td>STATUS</td><td>A server status request.</td></tr> <tr> <td>3</td><td>(reserved)</td><td>Reserved, not used.</td></tr> <tr> <td>4</td><td>NOTIFY</td><td>A special message type added by RFC 1996. It is used by a primary (master, authoritative) server to tell secondary servers that data for a zone has changed and prompt them to request a zone transfer. <a href="#">See the discussion of DNS server enhancements for more details.</a></td></tr> <tr> <td>5</td><td>UPDATE</td><td>A special message type added by RFC 2136 to implement "dynamic DNS". It allows resource records to be added, deleted or updated selectively. <a href="#">See the discussion of DNS server enhancements for more details.</a></td></tr> </table>	Opcode Value	Query Name	Description	0	QUERY	A standard query.	1	IQUERY	An inverse query; now obsolete. RFC 1035 defines the inverse query as an optional method for performing inverse DNS lookups, that is, finding a name from an IP address. Due to implementation difficulties, the method was never widely deployed, however, in favor of <a href="#">reverse mapping using the IN-ADDR.ARPA domain</a> . Use of this Opcode value was formally obsoleted in RFC 3425, November 2002.	2	STATUS	A server status request.	3	(reserved)	Reserved, not used.	4	NOTIFY	A special message type added by RFC 1996. It is used by a primary (master, authoritative) server to tell secondary servers that data for a zone has changed and prompt them to request a zone transfer. <a href="#">See the discussion of DNS server enhancements for more details.</a>	5	UPDATE	A special message type added by RFC 2136 to implement "dynamic DNS". It allows resource records to be added, deleted or updated selectively. <a href="#">See the discussion of DNS server enhancements for more details.</a>
Opcode Value	Query Name	Description																					
0	QUERY	A standard query.																					
1	IQUERY	An inverse query; now obsolete. RFC 1035 defines the inverse query as an optional method for performing inverse DNS lookups, that is, finding a name from an IP address. Due to implementation difficulties, the method was never widely deployed, however, in favor of <a href="#">reverse mapping using the IN-ADDR.ARPA domain</a> . Use of this Opcode value was formally obsoleted in RFC 3425, November 2002.																					
2	STATUS	A server status request.																					
3	(reserved)	Reserved, not used.																					
4	NOTIFY	A special message type added by RFC 1996. It is used by a primary (master, authoritative) server to tell secondary servers that data for a zone has changed and prompt them to request a zone transfer. <a href="#">See the discussion of DNS server enhancements for more details.</a>																					
5	UPDATE	A special message type added by RFC 2136 to implement "dynamic DNS". It allows resource records to be added, deleted or updated selectively. <a href="#">See the discussion of DNS server enhancements for more details.</a>																					
<b>AA</b>	1/8 (1 bit)	<b>Authoritative Answer Flag:</b> This bit is set to 1 in a response to indicate that the server that created the response is authoritative for the zone in which the domain name specified in the Question section is located. If it is 0, the response is non-authoritative.																					
<b>TC</b>	1/8 (1 bit)	<b>Truncation Flag:</b> When set to 1, indicates that the message was truncated due to its length being longer than the maximum permitted for the type of transport mechanism used. TCP doesn't have a length limit for messages, while UDP messages are limited to 512 bytes, so this bit being sent usually is an indication that the message was sent using UDP and was too long to fit. The client may need to establish a TCP session to get the full message. On the other hand, if the portion truncated was part of the <i>Additional</i> section, it may choose not to bother.																					
<b>RD</b>	1/8 (1 bit)	<b>Recursion Desired:</b> When set in a query, requests that the server receiving the query attempt to answer the query recursively, if the server supports <a href="#">recursive resolution</a> . The value of this bit is not changed in the response.																					

**Table 170: DNS Message Header Format (Page 3 of 4)**

Field Name	Size (bytes)	Description																																				
<b>RA</b>	1/8 (1 bit)	<b>Recursion Available:</b> Set to 1 or cleared to 0 in a response to indicate whether the server creating the response supports recursive queries. This can then be noted by the device that sent the query for future use.																																				
<b>Z</b>	3/8 (3 bits)	<b>Zero:</b> Three reserved bits set to zero.																																				
<b>RCode</b>	1/2 (4 bits)	<p><b>Response Code:</b> Set to zero in queries, then changed by the replying server in a response to convey the results of processing the query. This field is used to indicate if the query was answered successfully, or if some sort of error occurred:</p> <table border="1"> <thead> <tr> <th>RCode Value</th><th>Response Code</th><th>Description</th></tr> </thead> <tbody> <tr> <td>0</td><td>No Error</td><td>No error occurred.</td></tr> <tr> <td>1</td><td>Format Error</td><td>The server was unable to respond to the query due to a problem with how it was constructed.</td></tr> <tr> <td>2</td><td>Server Failure</td><td>The server was unable to respond to the query due to a problem with the server itself.</td></tr> <tr> <td>3</td><td>Name Error</td><td>The name specified in the query does not exist in the domain. This code can be used by an authoritative server for a zone (since it knows all the objects and subdomains in a domain) or by a caching server that implements negative caching.</td></tr> <tr> <td>4</td><td>Not Implemented</td><td>The type of query received is not supported by the server.</td></tr> <tr> <td>5</td><td>Refused</td><td>The server refused to process the query, generally for policy reasons and not technical ones. For example, certain types of operations, such as zone transfers, are restricted. The server will honor a zone transfer request only from certain devices.</td></tr> <tr> <td>6</td><td>YX Domain</td><td>A name exists when it should not.</td></tr> <tr> <td>7</td><td>YX RR Set</td><td>A resource record set exists that should not.</td></tr> <tr> <td>8</td><td>NX RR Set</td><td>A resource record set that should exist does not.</td></tr> <tr> <td>9</td><td>Not Auth</td><td>The server receiving the query is not authoritative for the zone specified.</td></tr> <tr> <td>10</td><td>Not Zone</td><td>A name specified in the message is not within the zone specified in the message.</td></tr> </tbody> </table>	RCode Value	Response Code	Description	0	No Error	No error occurred.	1	Format Error	The server was unable to respond to the query due to a problem with how it was constructed.	2	Server Failure	The server was unable to respond to the query due to a problem with the server itself.	3	Name Error	The name specified in the query does not exist in the domain. This code can be used by an authoritative server for a zone (since it knows all the objects and subdomains in a domain) or by a caching server that implements negative caching.	4	Not Implemented	The type of query received is not supported by the server.	5	Refused	The server refused to process the query, generally for policy reasons and not technical ones. For example, certain types of operations, such as zone transfers, are restricted. The server will honor a zone transfer request only from certain devices.	6	YX Domain	A name exists when it should not.	7	YX RR Set	A resource record set exists that should not.	8	NX RR Set	A resource record set that should exist does not.	9	Not Auth	The server receiving the query is not authoritative for the zone specified.	10	Not Zone	A name specified in the message is not within the zone specified in the message.
RCode Value	Response Code	Description																																				
0	No Error	No error occurred.																																				
1	Format Error	The server was unable to respond to the query due to a problem with how it was constructed.																																				
2	Server Failure	The server was unable to respond to the query due to a problem with the server itself.																																				
3	Name Error	The name specified in the query does not exist in the domain. This code can be used by an authoritative server for a zone (since it knows all the objects and subdomains in a domain) or by a caching server that implements negative caching.																																				
4	Not Implemented	The type of query received is not supported by the server.																																				
5	Refused	The server refused to process the query, generally for policy reasons and not technical ones. For example, certain types of operations, such as zone transfers, are restricted. The server will honor a zone transfer request only from certain devices.																																				
6	YX Domain	A name exists when it should not.																																				
7	YX RR Set	A resource record set exists that should not.																																				
8	NX RR Set	A resource record set that should exist does not.																																				
9	Not Auth	The server receiving the query is not authoritative for the zone specified.																																				
10	Not Zone	A name specified in the message is not within the zone specified in the message.																																				
<b>QDCount</b>	2	<b>Question Count:</b> Specifies the number of questions in the <i>Question</i> section of the message.																																				
<b>ANCount</b>	2	<b>Answer Record Count:</b> Specifies the number of resource records in the <i>Answer</i> section of the message.																																				

**Table 170: DNS Message Header Format (Page 4 of 4)**

Field Name	Size (bytes)	Description
NSCount	2	<b>Authority Record Count:</b> Specifies the number of resource records in the <i>Authority</i> section of the message. (“NS” stands for “name server”, of course. ☺)
ARCount	2	<b>Additional Record Count:</b> Specifies the number of resource records in the <i>Additional</i> section of the message.

**Figure 248: DNS Message Header Format**

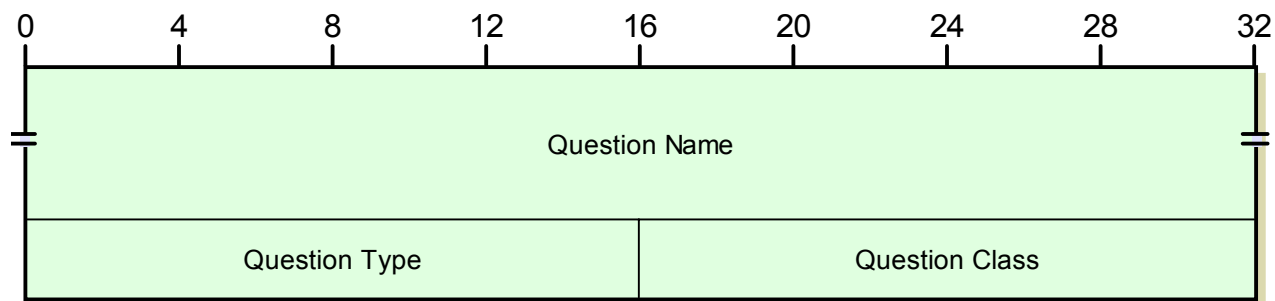

Note that the current lists of valid question types, query operation codes and response codes are maintained by IANA as one of its many lists of Internet parameters. Response codes 0 to 5 are part of “regular” DNS and are defined in RFC 1035; codes 6 to 10 implement dynamic DNS and are defined in RFC 2136.

---

## DNS Question Section Format

DNS queries always contain at least one entry in the *Question* section that specifies what the client in the exchange is trying to find out. These entries are copied to the response message unchanged, for reference on the part of the client if needed. [Table 171](#) and [Figure 249](#) show the format used for each entry in the *Question* section of a DNS message.

**Figure 249: DNS Message *Question* Section Format**

**Table 171: DNS Message *Question* Section Format (Page 1 of 2)**

Field Name	Size (bytes)	Description
<b><i>QName</i></b>	Variable	<b><i>Question Name:</i></b> Contains the object, domain or zone name that is the subject of the query, encoded using <a href="#">standard DNS name notation</a> .

**Table 171: DNS Message Question Section Format (Page 2 of 2)**

Field Name	Size (bytes)	Description																		
<b>QType</b>	2	<p><b>Question Type:</b> Specifies the type of question being asked by the device acting as a client. This field may contain a code number corresponding to a particular type of resource record being requested—<a href="#">Table 167</a> contains the numbers for the most common resource records. If so, this means the client is asking for that type of record to be sent for the domain name listed in <i>QName</i>. The <i>QType</i> field may also contain one of the following codes that correspond to “special” types of requests:</p> <table> <tr> <th>QType Value</th><th>Question Type</th><th>Description</th></tr> <tr> <td>251</td><td><i>IXFR</i></td><td>A request for an <a href="#">incremental (partial) zone transfer</a>, per RFC 1995.</td></tr> <tr> <td>252</td><td><i>AXFR</i></td><td>A request for a <a href="#">zone transfer</a>.</td></tr> <tr> <td>253</td><td><i>MAILB</i></td><td>A request for mailbox-related records (resource record types <i>MB</i>, <i>MG</i> or <i>MR</i>; now obsolete.)</td></tr> <tr> <td>254</td><td><i>MAILA</i></td><td>A request for mail agent resource records (now obsolete; <i>MX</i> records are used instead).</td></tr> <tr> <td>255</td><td>* (asterisk)</td><td>A request for all records.</td></tr> </table>	QType Value	Question Type	Description	251	<i>IXFR</i>	A request for an <a href="#">incremental (partial) zone transfer</a> , per RFC 1995.	252	<i>AXFR</i>	A request for a <a href="#">zone transfer</a> .	253	<i>MAILB</i>	A request for mailbox-related records (resource record types <i>MB</i> , <i>MG</i> or <i>MR</i> ; now obsolete.)	254	<i>MAILA</i>	A request for mail agent resource records (now obsolete; <i>MX</i> records are used instead).	255	* (asterisk)	A request for all records.
QType Value	Question Type	Description																		
251	<i>IXFR</i>	A request for an <a href="#">incremental (partial) zone transfer</a> , per RFC 1995.																		
252	<i>AXFR</i>	A request for a <a href="#">zone transfer</a> .																		
253	<i>MAILB</i>	A request for mailbox-related records (resource record types <i>MB</i> , <i>MG</i> or <i>MR</i> ; now obsolete.)																		
254	<i>MAILA</i>	A request for mail agent resource records (now obsolete; <i>MX</i> records are used instead).																		
255	* (asterisk)	A request for all records.																		
<b>QClass</b>	2	<p><b>Question Class:</b> Specifies the class of the resource record being requested, normally the value 1 for Internet (“IN”). <a href="#">See the topic on classes and resource record types for an explanation</a>. In addition, the <i>QClass</i> value 255 is defined to have the special meaning “any class”.</p>																		

### **DNS Message Resource Record Field Formats**

The exchange of information in DNS consists of a series of client/server transactions. Clients send requests, or *queries*, to servers, and the servers send back *responses*. DNS servers are of course [database servers](#), and store DNS name database information in the form of [resource records \(RRs\)](#). The questions asked by clients are requests for information from a DNS's servers database, and they are answered by the DNS server looking up the requested resource records and putting them into the DNS response message.

The *Answer*, *Authority* and *Additional* sections of the overall DNS message format are the places where servers put DNS resource records to be sent back to a client. Each section consists of zero or more records, and in theory, any record can be placed in any section. The sections only differ in the semantics (meaning) that the client draws from a record being in one section compared to the other. [The topic on DNS general messaging](#) contains more on these three sections and how they are used.

Resource records have two representations: binary and text. The text format is used for master files edited by humans, and is the subject of [a topic later in this section](#). The binary representation consists of regular numeric and text fields just like the other fields in the DNS message format.

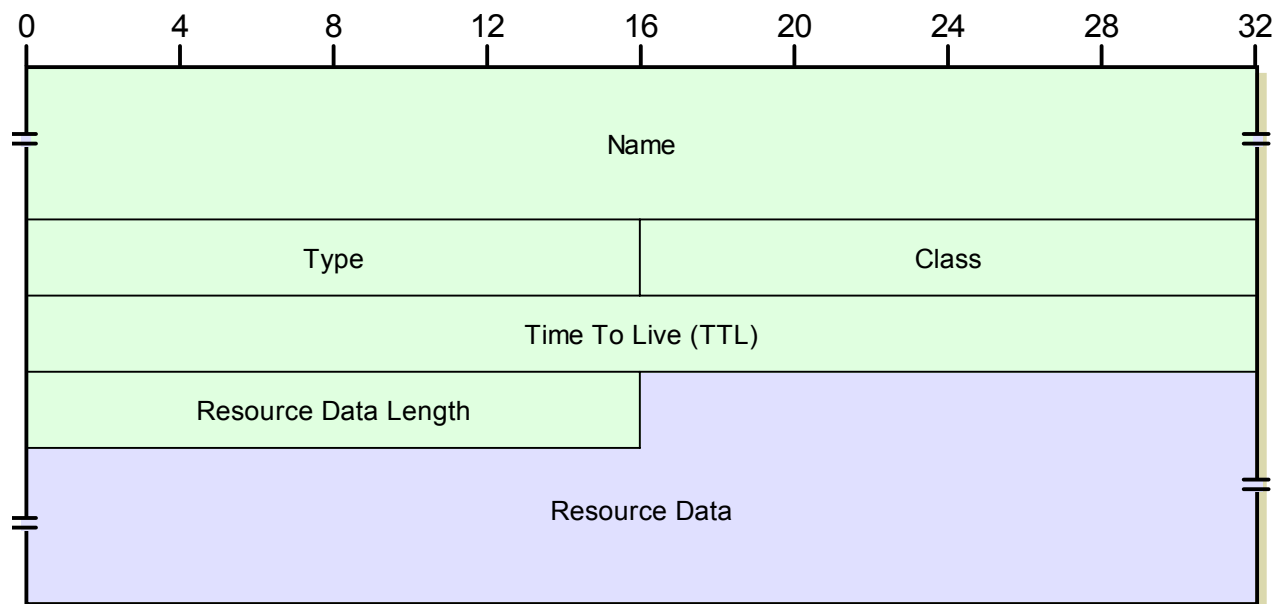

---

## DNS Common Resource Record Format

There are certain types of information that are common to all resource records, and others that are unique to each type of record. To handle this, all resource records are represented using a common field format, which contains a single *RData* field that varies by record type. The common resource record format is described in [Table 172](#) and [Figure 250](#).

**Table 172: DNS Common Resource Record Format**

Field Name	Size (bytes)	Description
<b>Name</b>	Variable	<b>Name:</b> Contains the object, domain or zone name that is the subject of the resource record, encoded using <a href="#">standard DNS name notation</a> . All of the information in the resource record is associated with this object, which I call the <i>named object</i> for the record.
<b>Type</b>	2	<b>Type:</b> A code value specifying the type of resource record. The type values for the most common kinds of resource records are shown in <a href="#">Table 167</a> and also in the list of resource record details in this topic.
<b>Class</b>	2	<b>Class:</b> Specifies the class of the resource record being requested, normally the value 1 for Internet (“IN”). <a href="#">See the end of the topic on classes and resource record types for an explanation.</a>
<b>TTL</b>	4	<b>Time To Live:</b> Specifies the number of seconds that the record should be retained in the cache of the device reading the record. <a href="#">See the topic on DNS name server caching for a full explanation.</a> A value of zero means “use this information for the current name resolution only; do not cache it”.
<b>RDLenght</b>	2	<b>Resource Data Length:</b> Indicates the size of the <i>RData</i> field, in bytes.
<b>RData</b>	Variable	<b>Resource Data:</b> The data portion of the resource record.

**Figure 250: DNS Common Resource Record Format**

---

## ***RData Field Formats For Common Resource Records***

The *RData* field consists of one or more subfields that carry the actual “payload” for the resource record. Below is a list of the most common resource record types. For each I have indicated the resource record text code, name, and *Type* value, provided a brief summary of the resource record’s use, and shown the structure of the *RData* field in a table:

### ***A / Address Resource Record (Type Value 1)***

This is the primary resource record type in DNS; it contains a 32-bit IP address associated with a domain name, as shown in [Table 173](#).

**Table 173: DNS Address Resource Record Data Format**

Subfield Name	Size (bytes)	Description
<b><i>Address</i></b>	4	<b><i>Address:</i></b> The 32-bit IP address corresponding to this record's named object.

### ***NS / Name Server Resource Record (Type Value 2)***

In this record, the data field carries the domain Carries the domain name of a name server ([Table 174](#)).

**Table 174: DNS Name Server Resource Record Data Format**

Subfield Name	Size (bytes)	Description
<b><i>NSDName</i></b>	Variable	<b><i>Name Server Domain Name:</i></b> A variable-length name of a name server that should be authoritative for this record's named object. Like all names, this name is encoded using <a href="#">standard DNS name notation</a> .  A request for this resource record type normally results in an <i>A</i> record for the name server specified also being returned in the <i>Additional</i> section of the response, if available.

### ***CName / Canonical Name Resource Record (Type Value 5)***

The data field contains the real name of an a named object that has been referenced using an alias ([Table 175](#)).

**Table 175: DNS Canonical Name Resource Record Data Format**

Subfield Name	Size (bytes)	Description
<b><i>CName</i></b>	Variable	<b><i>Canonical Name:</i></b> The canonical (real) name of the named object. This name is then resolved using the standard DNS resolution procedure to get the address for the originally-specified name.

---

## SOA / Start Of Authority Resource Record (Type Value 6)

This record marks the start of [DNS zone](#) and contains key information about how it is to be managed and used. The SOA record is the most complex of the DNS resource record types; its format can be found in [Table 176](#) and also in [Figure 251](#).

**Table 176: DNS Start Of Authority Resource Record Data Format**

Subfield Name	Size (bytes)	Description
<b>MName</b>	Variable	<b>Master Name:</b> The domain name of the name server that is the source of the data for the zone; this is of course normally the primary authoritative server for the zone. It is encoded using the <a href="#">standard DNS name format</a> .
<b>RName</b>	Variable	<b>Responsible Name:</b> The electronic mail address of the person responsible for this zone. E-mail addresses in DNS are encoded using a <a href="#">special variation of the regular DNS name notation</a> .
<b>Serial</b>	4	<b>Serial Number:</b> The serial number, or version number, of the resource record database for this zone. Used to determine when changes have been made to the database to trigger zone transfers. <a href="#">See the topic on zone transfers for information on how this field is used.</a>
<b>Refresh</b>	4	<b>Refresh Interval:</b> The number of seconds that secondary name servers for this zone will wait between attempts to check for changes made to the zone database on the primary name server. <a href="#">See the topic on zone transfers for information on how this field is used.</a>
<b>Retry</b>	4	<b>Retry Interval:</b> The number of seconds a secondary name server waits before trying again to check with a primary for changes if its previous attempt failed. <a href="#">See the topic on zone transfers for details.</a>
<b>Expire</b>	4	<b>Expire Interval:</b> The number of seconds that can elapse between successful contacts with the primary name server before a secondary name server must consider the information it holds “stale”.
<b>Minimum</b>	4	<b>Negative Caching TTL:</b> Originally carried the default <i>Time To Live</i> value for records where no explicit <i>TTL</i> value was specified. Now represents the zone’s negative cache TTL. <a href="#">See the topic on DNS name server caching.</a>

**Figure 251: DNS *Start Of Authority* Resource Record Data Format**

#### ***PTR* / *Pointer* Resource Record (*Type* Value 12)**

This record carries a pointer to a resource record; used for reverse address lookups. It contains one data field, shown in [Table 177](#).

**Table 177: DNS *Pointer* Resource Record Data Format**

Subfield Name	Size (bytes)	Description
<b><i>PTRDName</i></b>	Variable	<b><i>Pointer Domain Name:</i></b> A variable-length domain name. This is a name "pointed to" by the resource record; <a href="#">see the description of reverse resolution</a> for the most common way that this record type is used.

---

### ***MX / Mail Exchange Resource Record (Type Value 15)***

This special record contains [information about the mail server\(s\) to be used for sending e-mail to the domain](#). Each record contains two fields as [Table 178](#) illustrates.

**Table 178: DNS Mail Exchange Resource Record Data Format**

Subfield Name	Size (bytes)	Description
<b>Preference</b>	2	<b>Preference Value:</b> The preference level for this mail exchange. Lower values signify higher preference.
<b>Exchange</b>	Variable	<b>Exchange Domain Name:</b> The domain name, encoded using <a href="#">standard DNS name notation</a> , of a host willing to provide mail exchange services for this named object.

### ***TXT / Text Resource Record (Type Value 16)***

This descriptive record contains additional descriptive information about the named object ([Table 179](#)).

**Table 179: DNS Text Resource Record Data Format**

Subfield Name	Size (bytes)	Description
<b>TXT-Data</b>	Variable	<b>Text Data:</b> Variable-length descriptive text.

## **DNS Name Notation and Message Compression Technique**

Obviously, the entire Domain Name System protocol is oriented around dealing with names for domains, subdomains and objects. We've seen in the preceding topics that there are many fields in DNS messages and resource records that carry the names of objects, name servers and so forth. DNS uses a special notation for encoding names in resource records and fields, a variation of this notation for e-mail addresses, and a special compression method that reduces the size of messages for efficiency.

### ***Standard DNS Name Notation***

In [the section describing the DNS name space](#) we saw how DNS names are constructed. Each node in the name hierarchy has a label associated with it. The [fully-qualified domain name \(FQDN\)](#) for a particular device consists of the sequence of labels that starts from the root of the tree and progresses down to that device. The labels at each level in the hierarchy are listed in sequence, starting with the highest level, from right to left, separated by dots. This results in the domain names we are used to working with, such as "www.xyzindustries.com".

---

It would be possible to encode these names into resource records or other DNS message fields directly: put the letter “w” into each of the first three bytes of the name, then put a “.” into the fourth byte, an “x” into the fifth and so on. The disadvantage of this is that as a computer was reading the name, it wouldn’t be able to tell when each name was finished. We would need to include a length field for each name.

Instead, DNS uses a special notation for DNS names. Each label is encoded one after the next in the name field. Before each label, a single byte is used that holds a binary number indicating the number of characters in the label. Then, the label’s characters are encoded, one per byte. The end of the name is indicated by a null label, representing the root; this of course has a length of zero, so each name ends with just a “0” character, indicating this zero-length root label.

Note that the “dots” between the labels aren’t necessary, since the length numbers delineate the labels. The computer reading the name also knows how many bytes are in each label as it reads the name, so it can easily allocate space for the label as it reads it from the name.

For example, “www.xyzindustries.com” would be encoded as:

“[3] w w w [13] x y z i n d u s t r i e s [3] c o m [0]”

I have shown the label lengths in square brackets to distinguish them. Remember that these label lengths are binary encoded numbers, so a single byte can hold a value from 0 to 255; that “[13]” is one byte and not two, as you can see in [Figure 252](#). Labels are actually limited to a maximum of 63 characters, and we’ll see shortly why this is significant.

0	4	8	12	16	20	24	28	32
3	w	w	w					
13	x	y	z					
i	n	d	u					
s	t	r	i					
e	s	3	c					
o	m	0						

**Figure 252: DNS Standard Name Notation**

In DNS every named object or other name is represented by a sequence of label lengths and then labels, with each label length taking one byte and each label taking one byte per character. This example shows the encoding of the name “www.xyzindustries.com”.

---

## DNS Electronic Mail Address Notation

Electronic mail addresses are used in certain DNS resource records, such as the *RName* field in the *Start Of Authority* resource record. E-mail addresses of course take the form “<name>@<domain-name>”. DNS encodes these in exactly the same way as regular DNS domains, simply treating the “@” like another dot. So, “johnny@somewhere.org” would be treated as “johnny.somewhere.org” and encoded as:

“[6] j o h n n y [9] s o m e w h e r e [3] o r g [0]”.

Note that there is no specific indication that this is an e-mail address. The name is interpreted as an e-mail address instead of a device name based on context.

## DNS Message Compression

A single DNS message may contain many domain names. Now, consider that when a particular name server sends a response containing multiple domain names, they are all usually in the same zone, or are related to the zone. Most of these names will have common elements to their names.

Consider our [previous mail example](#) of a client asking for an MX record for “xyzindustries.com”. The response to this client will contain, among other things, these two records:

- ☛ **MX Record:** An *MX* record that has “xyzindustries.com” as the *Name* of the record, and “mail.xyzindustries.com” in the *RData* field.
- ☛ **A Record:** Assuming the name server knows the IP address of “mail.xyzindustries.com”, the *Additional* section will contain an *A* record that has “mail.xyzindustries.com” as the *Name* and its address in the *RData field*.

This is just one small example of name duplication; it can be much more extreme with other types of DNS messages, with certain string patterns being repeated many times. Normally this would require that each name be spelled out fully using the encoding method described above. But this would be wasteful, since a large portion of these names is common.

## Using Message Compression to Avoid Duplication of a Full Name

To cut down on duplication, a special technique called *message compression* is used. Instead of a DNS name encoded as above using the combination of labels and label-lengths, a two-byte subfield is used to represent a *pointer* to another location in the message where the name can be found. The first two bits of this subfield are set to one (the value “11” in binary), and the remaining 14 bits contain an *offset* that species where in the message the name can be found, counting the first byte of the message (the first byte of the *ID* field) as 0.

Let’s go back to our example. Suppose that in the DNS message above, the *RData* field of the MX record, containing “mail.xyzindustries.com”, begins at byte 47. In this first instance, we would find the name encoded in full as:

“[4] m a i l [13] x y z i n d u s t r i e s [3] c o m [0]”.

---

However, the second instance, where “mail.xyzindustries.com” shows up in the *Name* field of the A record, we would instead put two “1” bits, followed by the number 47 encoded in binary. So, this would be the 16-bit binary pattern “11000000 00101111”, or two numeric byte values “192” and “47”. This second instance now takes 2 bytes instead of duplicating the 24 bytes needed for the first instance of the name.

How does a device reading a name field differentiate a pointer from a “real” name? This is the reason that “11” is used at the start of the field. Doing this guarantees that the first byte of the pointer will always have a value of 192 or larger. Since labels are restricted to a length of 63 or less, when the host reads the first byte of a name, if it sees a value of 63 or less in a byte, it knows this is a “real” name; a value of 192 or more means it is a pointer.

### Using Message Compression to Avoid Duplication of Part of a Name

The example above shows how pointers can be used to eliminate duplication of a whole name: the name “mail.xyzindustries.com” was used in two places and a pointer was used instead of the second. Pointers are even more powerful than this, however. They can also be used to point to only *part* of a real name, or can be combined with additional labels to provide a compressed representation of a name related to another name in a resource record. This provides even greater space savings.

In the example above, this means that even the *first* instance of “mail.xyzindustries.com” can be compressed. Recall that the MX record will have “xyzindustries.com” in the *Name* field and “mail.xyzindustries.com” in the *RData* field. If the *Name* field of that record starts at byte 19, then we can encode the *RData* field as:

“[4] m a i l [pointer-to-byte-19]”.

The device reading the record will get “mail” for the first label and then read “xyzindustries.com” from the *Name* field to get the complete name, “mail.xyzindustries.com”.

Similarly, suppose we had a record in this same message that contained a reference to the parent domain for “xyzindustries.com”, which is of course “com”. This could simply be encoded as:

“[pointer-to-byte-33]”

The reason is that byte 33 is where we find the “[3] c o m [0]” part of the *Name* field containing “[13] x y z i n d u s t r i e s [3] c o m [0]”.

### **DNS Master File Format**

DNS servers answer queries from clients by sending reply messages containing resource records. We have already seen in this section [the binary message formats used to encode these resource records](#). These message formats are great for transmitted messages, because they are compact and efficient, and computers have no problem reading fields very quickly and knowing how to interpret a particular string of ones and zeroes.

---

Humans, on the other hand, don't deal well with cryptic codes in binary. Before a resource record can be provided by a server, it is necessary for a human administrator to tell the server what those records are and what information they contain. To make this job easier, DNS includes a special text representation for zones and resource records. Administrators edit special *master files* that describe the zone and the records it contains; these files are then read into memory by the server's DNS software, and converted into binary form for responding to client requests. This is described in more detail in [the overview topic on resource records](#).

Each master file consists of a simple “flat text” file that can be created with any sort of text editor. Each file contains a number of lines expressed using a simple set of syntax rules that describe a zone and the records within it. The basic syntactic rules for DNS master files are specified in RFC 1035, section 5.1. Certain DNS implementations use their own variations on the syntax in the standard, though they are all pretty similar.

### **DNS Common Master File Record Format**

Just as all resource records are stored internally using a common field format, they also use a common master file format. Each record normally appears on a separate line of the file. This format is as follows, with optional fields shown in square brackets:

`<domain-name> [<ttl>] <class> <type> <rdata>`

The fields are as follows:

- ❶ **<domain-name>**: A DNS domain name, which may be either a fully-qualified domain name (FQDN) or a partially-qualified name (PQDN). See below.
- ❷ **<ttl>**: A *Time To Live* value, in seconds, for the record. If omitted, the default *TTL* value for the zone is used. In fact, most resource records do not have a specified *TTL*, just using the default provided by the *Start Of Authority* record.
- ❸ **<class>**: The resource record class. For modern DNS this field is optional, and defaults to “IN” for “Internet”
- ❹ **<type>**: The resource record type, specified using a text code such as “A” or “NS”, not the numeric code.
- ❺ **<rdata>**: Resource record data, which is a set of space-separated entries that depends on the record type.

The “<rdata>” can be either a single piece of information or a set of entries, depending on the record type. In the case of longer record types, especially the *Start Of Authority* record, multiple entry “<rdata>” fields are spread over several lines and enclosed in parentheses; the parentheses make all the entries act as if they were on a single line. Note that if the “<ttl>” field is present, the order of it and the “<class>” field may be switched; this causes no problems because one is a number and the other text (“IN”).

---

## Use and Interpretation of Partially-Qualified Domain Names

Domain names may be mixed between [FQDNs](#) and [PQDNs](#). Partially-qualified names are used to make master files faster to create and more readable, by cutting down on the common parts of names; they are sort of the “human equivalent” of DNS message compression. A FQDN is shown as a full domain name ending in a dot (“.”) to represent the DNS name tree root. A PQDN is given as just a partial name with no root, and is interpreted as a FQDN by the software reading the master file (see the *\$ORIGIN* directive below for more.)

It is important to remember the trailing dot to mark FQDNs; if the origin is “xyzindustries.com” and in its zone file the name “bigisp.net” appears, the server will read this as “bigisp.net.xyzindustries.com”—probably not what you want. Also, e-mail addresses, such as the <r-name> field in the SOA record, have the “@” of the e-mail address converted to a dot, following the standard DNS convention.

### Master File Directives

In addition to resource records, most master file implementations also support the use of *directives*. These are commands that specify certain important pieces of information to guide how the master file is to be interpreted. Three of the most common directives are:

- ☉ **\$ORIGIN:** Specifies the domain name that is appended to unqualified specifications; this is the “base” used to convert PQDNs to FQDNs. For example, if the origin is “xyzindustries.com.”, then a PQDN such as “sales” will be interpreted as “sales.xyzindustries.com.”. Once defined, the origin can be referenced by just using “@” in place of a name, as we will see in the example at the end of this topic.
- ☉ **\$TTL:** Specifies the default *Time To Live* value to be used for any resource records that do not specify a *TTL* value in the record itself. (This value was formerly specified by the *Minimum* field in the *Start Of Authority* record.)
- ☉ **\$INCLUDE:** Allows one master file to include the contents of another. This is sometimes used to save the duplication of certain entries that are common between zones.

### Syntax Rules for Master Files

There are a few other syntax rules for DNS master files, some of which are intended to save further time or energy on the part of administrators:

- ☉ **Multiple-Record Shorthand:** If multiple consecutive records pertain to the same domain, the “<domain-name>” is specified for the first one, and can be then be left blank for the subsequent ones. The server will assume that any resource records without a “<domain-name>” indicated apply to the last “<domain-name>” it saw.
- ☉ **Comments:** A semicolon (“;”) marks a comment. Any text from the semicolon until the end of the line is ignored.
- ☉ **Escape Character:** A backslash (“\”) is used to “escape” the special meaning of a character. For example, a double-quote (“”) is used to delimit text strings; a literal double-quote character is indicated by a backslash-double-quote combination (“\”).

- ☉ **White Space:** Tabs and spaces are used as delimiters and blank lines are ignored. For readability, most smart administrators indent using tabs to make more clear which records belong with which names, and group records using blank lines and comments.
- ☉ **Case:** Like DNS domain names, master file entries are case-insensitive.

### Specific Resource Record Syntax and Examples

Table 180 shows the specific formats and examples for each of the common resource record types. The fields are basically the same as the ones explained in the DNS binary record formats. I have included explanatory “comments” using the DNS comment format. Assume that the examples in this table are for the zone “googleplex.edu”:

**Table 180: DNS Master File Format Syntax and Examples**

Resource Record Text Code	Resource Record Type	Resource Record Format / Example
<b>A</b>	<i>Address</i>	<code>&lt;domain-name&gt; [&lt;t1&gt;] IN A &lt;ip-address&gt;</code>  <code>admin1.googleplex.edu IN A 204.13.100.3 ; A FQDN.</code> <code>admin2 IN A 204.13.100.44 ; A PQDN equivalent to</code> <code>admin2.googleplex.edu</code>
<b>NS</b>	<i>Name Server</i>	<code>&lt;domain-name&gt; [&lt;t1&gt;] IN NS &lt;name-server-name&gt;</code>  <code>googleplex.edu. IN NS custns.bigisp.net ; Secondary NS</code>
<b>CNAME</b>	<i>Canonical Name</i>	<code>&lt;domain-name&gt; [&lt;t1&gt;] IN CNAME &lt;canonical-name&gt;</code>  <code>www IN CNAME bigserver ; www.googleplex.edu is really</code> <code>bigserver.googleplex.edu.</code>
<b>SOA</b>	<i>Start Of Authority</i>	<code>&lt;domain-name&gt; [&lt;t1&gt;] IN SOA &lt;m-name&gt; &lt;r-name&gt; (</code> <code>    &lt;serial-number&gt;</code> <code>    &lt;refresh-interval&gt;</code> <code>    &lt;retry-interval&gt;</code> <code>    &lt;expire-interval&gt;</code> <code>    &lt;default-t1&gt;)</code>  <code>googleplex.edu. IN SOA ns1.googleplex.edu it.googleplex.edu (</code> <code>    42 ; Version 42 of the zone.</code> <code>    21600 ; Refresh every 6 hours.</code> <code>    3600 ; Retry every hour.</code> <code>    604800 ; Expire after one week.</code> <code>    86400) ; Negative Cache TTL is one day.</code>
<b>PTR</b>	<i>Pointer</i>	<code>&lt;reverse-domain-name&gt; [&lt;t1&gt;] IN PTR &lt;domain-name&gt;</code>  <code>3.100.13.204.IN-ADDR.ARPA. IN PTR admin1.googleplex.edu.</code>
<b>MX</b>	<i>Mail Exchange</i>	<code>&lt;domain-name&gt; [&lt;t1&gt;] IN MX &lt;preference-value&gt; &lt;exchange-name&gt;</code>  <code>googleplex.edu. IN MX 10 mainmail.googleplex.edu.</code> <code>IN MX 20 backupmail.googleplex.edu</code>
<b>TXT</b>	<i>Text</i>	<code>&lt;domain-name&gt; [&lt;t1&gt;] IN TXT &lt;text-information&gt;</code>  <code>googleplex.edu. IN TXT "Contact Joe at X321 for more info."</code>

---

Note that the *PTR* record would actually be in the *IN-ADDR.ARPA* domain, of course.

**Table 181** contains a “real-world” example of a DNS master file, taken from my own “pcguide.com” server (slightly modified), hosted by (and DNS information provided by) the fine folks at *pair.com*. Note the use of “@” as a short-cut to mean “this domain” (“pcguide.com”):

**Table 181: Sample DNS Master File**

```
$ORIGIN pcguide.com.
@ IN SOA ns23.pair.com. root.pair.com. (
    2001072300 ; Serial
    3600       ; Refresh
    300        ; Retry
    604800     ; Expire
    3600 )     ; Minimum

@ IN NS ns23.pair.com.
@ IN NS ns0.ns0.com.

localhost IN A      127.0.0.1

          IN MX 50    qs939.pair.com.

www        IN CNAME  @
ftp        IN CNAME  @
mail       IN CNAME  @
relay      IN CNAME  relay.pair.com.
```

---

## DNS Changes To Support IP Version 6

Version 4 of the Internet Protocol (IPv4) is the basis of today's Internet, and the foundation upon which the TCP/IP protocol suite is built. While IPv4 has served us well for over two decades, it has certain important drawbacks that would limit internetworks of the future if it were to continue to be used. For this reason, the next generation of IP, the Internet Protocol version 6 (IPv6), has been in development for many years. IPv6 will eventually replace IPv4 and take TCP/IP into the future.

The change from IPv4 to IPv6 will have effects that “ripple” to other TCP/IP protocols, including the Domain Name System. DNS is a higher-level protocol, so you might think that based on the principle of layering, a change to IP should not affect it. However, this is another example of how “strict layering” doesn't always apply. DNS works directly with IP addresses, and one of the most significant modifications that IPv6 makes to IP is in the area of addressing, so this means that using DNS on IPv6 requires some changes to how the protocol works.

### IPv6 DNS Extensions

Since DNS is so “architecturally distant” from IP down there at layer three, the changes required are not extensive. RFC 1886, entitled *IPv6 DNS Extensions* and published in December 1995, was the IETF's first formalized attempt to describe the changes needed in DNS to support IPv6. It defines three specific modifications to DNS for IPv6:

- ☉ **New Resource Record Type—AAAA (IPv6 Address):** The regular DNS *Address resource record* is defined for a 32-bit IPv4 address, so a new one was created to allow a domain name to be associated with a 128-bit IPv6 address. The four “A”s (“AAAA”) are a mnemonic to indicate that the IPv6 address is four times the size of the IPv4 address. The AAAA record is structured in very much the same way as the A record in both binary and master file formats; it is just much larger. The DNS resource record *Type* value for AAAA is 28.
- ☉ **New Reverse Resolution Hierarchy:** A new hierarchical structure similar to *IN-ADDR.ARPA* is defined for IPv6 *reverse lookups*, but the IETF put it in a different top-level domain. The new domain is *IP6.INT*, and is used in a way similar to how *IN-ADDR.ARPA* works. However, since IPv6 addresses are expressed in hexadecimal instead of dotted-decimal, IP6.INT has sixteen subdomains “0” through “F”, and each of those has sixteen subdomains “0” through “F”, and so on, sixteen layers deep. Yes, this leads to a potentially frightfully large reverse resolution database!
- ☉ **Changes To Query Types And Resolution Procedure:** All query types that work with A records or result in A records being included in the *Additional* section of a reply must be changed to also handle AAAA records. Also, queries that would normally result in A records being returned in the *Additional* section must return the corresponding AAAA records only in the *Answer* section, not the *Additional* section.

**Key Concept:** Even though DNS resides far above the Internet Protocol in the TCP/IP protocol suite architecture, it works intimately with IP addresses. For this reason, changes are required to allow it to support the new IPv6. These changes include the definition of a new IPv6 address resource record (AAAA), a new reverse resolution domain hierarchy, and certain changes to how messaging is performed.

---

### ***Proposed Changes to the IPv6 DNS Extensions***

In 2000, the IETF published RFC 2874, *DNS Extensions to Support IPv6 Address Aggregation and Renumbering*. This standard proposed a replacement for the IPv6 support introduced in RFC 1886, using a new record type, *A6*, instead of 1886's *AAAA*. The main difference between *AAAA* and *A6* records is that the former are just whole addresses like *A* records, while *A6* records can contain either a whole or partial address.

The idea behind RFC 2874 was that *A6* records could be set up in a manner that complements [the IPv6 format for unicast addresses](#). Then, name resolution would involve a technique called *chaining* to determine a full address for a name from a set of partially-specified address components. In essence, this would make the addresses behave much the way hierarchical names themselves work, providing some potential flexibility benefits.

For a couple of years, both RFC 1886 and RFC 2874 were proposed standards, and this led to considerable confusion. In August 2002, RFCs 3363 and 3364 were published, which clarified the situation with these two proposals. RFC 3363 represents the “Supreme Court decision”, which was that RFC 2874 and the *A6* record be changed to experimental status and the *AAAA* record of RFC 1886 be kept as the DNS IPv6 standard.

The full explanation for the decision can be found in RFC 3364. In a nutshell, it boiled down to the IETF believing that there were significant potential risks in the successful implementation of RFC 2874. While the capabilities of the *A6* record were “interesting”, it was not clear that they were needed, and given those risks, they felt sticking with RFC 1886 was the better move.

---

## Network File and Resource Sharing Protocols and the TCP/IP Network File System (NFS)

To the typical end user, networks were created for one main reason: to permit the sharing of information. Most information on computers exists in the form of files that reside on storage devices such as hard disks; thus, one primary purpose of networks is to let users share files. File transfer and message transfer protocols exist that allow users to “manually” move files from one place to the next, but a more automated method is preferable in many cases. Internetworking protocols provide such capabilities in the form of *network file and resource sharing protocols*.

In this section, I provide a description of network file and resource sharing protocols from the standpoint of TCP/IP networks. I begin with a brief overview of the concepts and operation of this class of protocols, discussing some of the elements common to the different types. I then describe the most common one defined specifically for TCP/IP: the Network File System (NFS).

**Related Information:** Obviously, network file and resource sharing protocols and services are closely related to the file and message transfer protocols I mentioned earlier. For example, NFS can be used to accomplish tasks similar to those performed by [TCP/IP file and message transfer applications](#) such as [FTP](#) and [HTTP](#). I consider those protocols more like specific end-user application unto themselves, and therefore describe them in [the section on application protocols](#). I realize that this distinction between “manual” and “automatic” file transfer is somewhat arbitrary, but then, so are a lot of other things in the great world of networking. ☺

---

---

## **Overview of File and Resource Sharing Protocol Concepts and Operation**

Networking is a pretty complicated subject—if you don't believe me, try glancing at the topic list for this Guide. To people like you, who are probably reading this Guide to learn about networks to enhance your ability to make a living in the technology world, this complexity means enhanced job security, so don't knock it. ☺ On the other hand, the main body of “regular users” just want to be able to do things on the network, without being forced to understand how everything works underneath. This is only common sense.

### ***Contrasting "Manual" and "Automatic" File and Resource Sharing***

A primary reason why networks and internetworks are created is to allow files and other resources to be shared between computers. Thus, in any internetworking protocol stack, we need some mechanism by which users can easily move files across a network in a simple way. Application-layer file and message transfer protocols like FTP and HTTP were created for just this purpose: to let users access resources across a network while hiding the details of how the network operates at the layers below them.

However, even though these protocols hide the lower layers, they are somewhat “manual” in nature: they require a user to invoke an application protocol and use specific commands that accomplish network-based resource access. In fact, the problem with such protocols isn't so much that they require manual intervention, but that they make sharing more difficult because they don't allow a file to be used directly on another resource. To see what I mean, consider a protocol like FTP. It does let me share files between machines, but draws a clear distinction between a file that is mine and a file that is someone else's. If I want to use a file on Joe's machine, I have to transfer it to mine, use it, and then transfer it back. Also, if I don't transfer the file back, Joe might never even see the updated version.

The ultimate in file and resource sharing is achieved when we can hide even the details of how the files are located and the commands required to move them around. Such a system would use an “automatic” sharing protocol that lets files and resources be used over a network seamlessly. Once set up, a network resource in such a scheme can be used in much the same way that one on a local computer is. Such protocols are sometimes called *network file and resource sharing protocols*.

It is this “blurring” of the line between a local file and a remote one that makes file and resource sharing protocols so powerful. Once the system is set up, a user can access resources on another host as readily as on his own host. This is an extremely powerful capability, especially in the modern era of client/server computing. For example, it allows a company to store information that is used by many individuals in a common place, such as in a directory on a server, and allow each of those individuals to access it. In essence, a “virtual file system” is created that spans network devices, instead of being simply on one storage device on a single computer.

---

## ***Components of a File and Resource Sharing Protocol***

Network file and resource sharing protocols allow users to share files “effortlessly”, but that doesn't mean the work doesn't still have to happen. It is still there, but shouldered by those who write the protocol, and those who administer its operation. Generally speaking, these protocols require at least the following general components:

- ☉ **File System Model and Architecture:** A mechanism for defining resources and files to be shared, and for describing how the “virtual file system” works.
- ☉ **Resource Access Method:** Procedures that describe how a user can attach or detach a distant resource from his or her local host.
- ☉ **Operation Set:** A set of operations for accomplishing various tasks that the user needs to perform on files on other hosts.
- ☉ **Messaging Protocol:** Message formats that carry operations to be performed, status information and more, and a protocol for exchanging these messages between devices.
- ☉ **Administrative Tools:** Miscellaneous functionality needed to support the operation of the protocol and tie the other elements together.

The most common file and resource sharing protocol used in TCP/IP today is the Network File System (NFS). It is described in more detail in the next section.

---

## TCP/IP Network File System (NFS)

[File and resource sharing protocols](#) are important because they let users seamlessly share files over a network. Due to the dominance of Microsoft operating systems in the industry, many people are familiar with the way Microsoft Networking can be used in this way. However, Microsoft is somewhat of a “Johnny come lately” to file sharing protocols. Long before Microsoft Windows even existed, the *Network File System (NFS)* was letting users share files over a network using the UNIX operating system.

In this section, I provide a brief look at the operation of NFS. I begin with an overview and history of the protocol, and discussion of its common versions and standards. I describe the architecture of NFS and the three components that comprise it. I then describe the NFS file system model, and how data is encoded using the External Data Representation (XDR) standard. I explain the client/server operation of NFS using Remote Procedure Calls (RPCs). I then list the procedures and operations used in NFS, and conclude with a description of the separate NFS Mount protocol, used to attach network resources to a device.

---

**Note:** As I said above, NFS was originally developed specifically for the UNIX operating system, and is still most closely associated with UNIX. As with all protocol descriptions, I have attempted to keep my discussion of NFS “OS-independent” as much as possible, but in some places in this section, it is not entirely possible.

---

### NFS Overview, History, Versions and Standards

The histories of TCP/IP and the Internet are inextricably linked, as you can read for yourself in my [discussion of the history of TCP/IP](#). However, there is a third partner that is less-often mentioned, but very much part of the development history of these technologies. That is the operating system that ran on the machines in the early Internet, still used on a large percentage of Internet servers today: the *UNIX* operating system.

Sun Microsystems was one of the early pioneers in the development of UNIX, and in TCP/IP networking. Early in the evolution of TCP/IP, certain tools were created to allow a user to access another machine over the network—after all, this is arguably the entire point of networking. Remote access protocols such as [Telnet](#) allowed a user to log in to another host computer and use resources there. The [File Transfer Protocol \(FTP\)](#) allowed someone to copy a file from a distant machine to their own and edit it.

However, neither of these solutions really fit the bill of allowing a user to access a file on a remote machine in a way similar to how a local file is used. To fill this need, Sun created the *Network File System (NFS)*. NFS was specifically designed with the goal of eliminating the distinction between a local and a remote file. To a user, after the appropriate setup is performed, a file on a remote computer can be used as if it were on a hard disk on the

---

user's local machine. Sun also crafted NFS specifically to be vendor-independent, to ensure that both hardware made by Sun and that made by other companies could interoperate.

### **Overview of NFS Architecture and General Operation**

NFS follows the [classical TCP/IP client/server model of operation](#). A hard disk or a directory on a storage device of a particular computer can be set up by an administrator as a shared resource. This resource can then be accessed by client computers, which *mount* the shared drive or directory, causing it to appear like a local directory on the client machine. Some computers may act as only servers or only clients, while others may be both: sharing some of their own resources and accessing resources provided by others.

NFS uses an architecture that includes three main components that define its operation. The [External Data Representation \(XDR\) standard](#) defines how data is represented in exchanges between clients and servers. The [Remote Procedure Call \(RPC\) protocol](#) is used as a method of calling procedures on remote machines. Then, a set of [NFS procedures and operations](#) works using RPC to carry out various requests. The separate [Mount protocol](#) is used to mount resources as mentioned above.

One of the most important design goals of NFS was **performance**. Obviously, even if you set up a file on a distant machine as if it were local, the actual read and write operations have to travel across a network. Usually this takes more time than simply sending data within a computer, so the protocol itself needed to be as “lean and mean” as possible. This decision led to some interesting decisions, such as the use of the unreliable [User Datagram Protocol \(UDP\)](#) for transport in TCP/IP, instead of the reliable TCP like most file transfer protocols do. This in turn has interesting implications on how the protocol works as a whole.

Another key design goal for NFS was **simplicity** (which of course is related to performance). NFS servers are said to be *stateless*, which means that the protocol is designed so that servers do not need to keep track of which files have been opened by which clients. This allows requests to be made independently of each other, and allows a server to gracefully deal with events such as crashes without the need for complex recovery procedures. The protocol is also designed so that if requests are lost or duplicated, file corruption will not occur.

**Key Concept:** The *Network File System (NFS)* was created to allow client hosts to access files on remote servers as if they were local. It was designed primarily with the goals of performance, simplicity and cross-vendor compatibility.

---

---

## ***NFS Versions and Standards***

Since it was initially designed and marketed by Sun, NFS began as a [de facto standard](#). The first widespread version of NFS was version 2, and this is still the most common version of the protocol. NFS version 2 was eventually codified as an official TCP/IP standard when RFC 1094, [NFS: Network File System Protocol Specification](#), was published in 1989.

NFS Version 3 was subsequently developed, and published in 1995 as RFC 1813, [NFS Version 3 Protocol Specification](#). It is similar to version 2 but makes a few changes and adds some new capabilities. These include support for larger file transfers, better support for setting file attributes, and several new file access and manipulation procedures. NFS version 3 also provides support for larger files than version 2 did.

NFS Version 4 was published in 2000 as RFC 3010, [NFS version 4 Protocol](#). Where version 3 of NFS contained only relatively small changes to version 2, NFSv4 is virtually a rewrite of NFS. It includes numerous changes, most notably the following:

- ☉ Reflecting the needs of modern internetworking, NFSv4 puts greater emphasis on security.
- ☉ NFSv4 introduces the concept of a *Compound* procedure, which allows several simpler procedures to be sent from a client to server as a group.
- ☉ NFSv4 almost doubles the number of individual procedures that a client can use in accessing a file on an NFS server.
- ☉ Version 4 also makes a significant change in messaging, with the specification of [TCP](#) as the transport protocol for NFS.
- ☉ Finally, NFS integrates the functions of the Mount protocol into the basic NFS protocol, eliminating it as a separate protocol as it is in versions 2 and 3.

The version 4 standard also has a lot more details about implementation and optional features than the earlier standards—it's 275 pages long. So much for simplicity! ☺ RFC 3010 was later updated by RFC 3530, [Network File System \(NFS\) version 4 Protocol](#), in April 2003. This standard makes several further revisions and clarifications to the operation of NFS version 4.

## **NFS Architecture and Components**

Considered from the perspective of the TCP/IP protocol suite as a whole, the Network File System (NFS) is a single protocol that resides at the application layer of the [TCP/IP \(DOD\) model](#). This TCP/IP layer encompasses the session, presentation and application layers of the [OSI Reference Model](#). As I have said before in this Guide, I don't see much value in trying to differentiate between layers 5 through 7 most of the time. In some cases, however, these layers can be helpful in understanding the architecture of a protocol, and that's the case with NFS.

---

## NFS Architecture and Main Components

The operation of NFS is defined in the form of three main components that can be viewed as logically residing at each of the three OSI model layers corresponding to the TCP/IP application layer (see [Figure 253](#)). These components are:

- 🕒 **Remote Procedure Call (RPC):** RPC is a generic [session layer](#) service used to implement client/server internetworking functionality. It extends the notion of a program calling a local procedure on a particular host computer, to the calling of a procedure on a remote device across a network.
- 🕒 **External Data Representation (XDR):** XDR is a descriptive language that allows data types to be defined in a consistent manner. XDR conceptually resides at the [presentation layer](#); its universal representations allow data to be exchanged using NFS between computers that may use very different internal methods of storing data.
- 🕒 **NFS Procedures and Operations:** The actual functionality of NFS is implemented in the form of procedures and operations that conceptually function at [layer seven](#) of the OSI model. These procedures specify particular tasks to be carried out on files over the network, using XDR to represent data and RPC to carry the commands across an internetwork.

These three key “subprotocols” if you will, comprise the bulk of the NFS protocol. Each is described in more detail in a separate topic of this section on NFS.

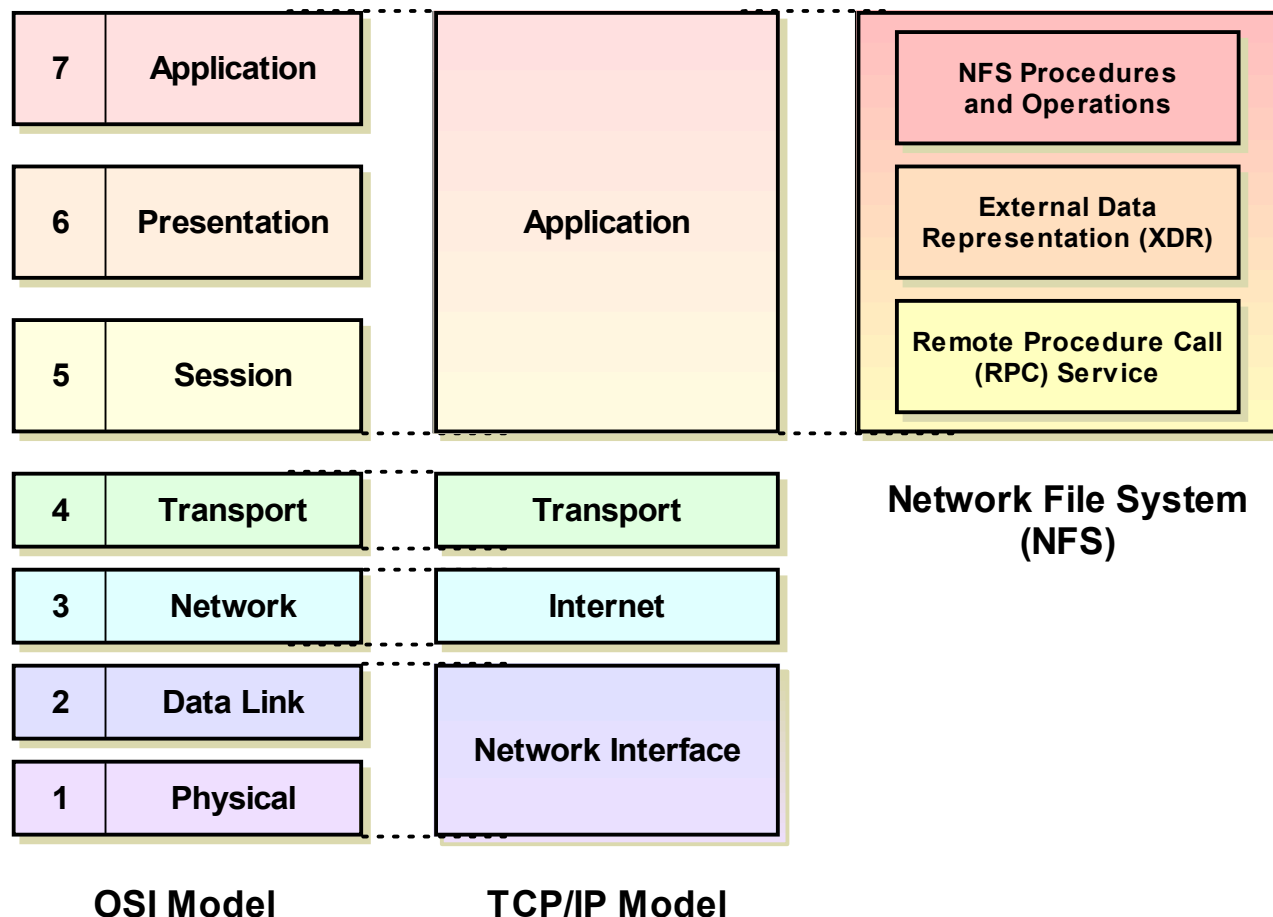

**Key Concept:** NFS resides architecturally at the application layer of the TCP/IP model. Its functions are implemented primarily through three distinct functional components that implement the functions of layers five through seven of the OSI reference model: the *Remote Procedure Call (RPC)*, which provide session-layer services; the *External Data Representation (XDR)* standard, which manages data representation and conversion, and *NFS procedures and operations*, which allow application-layer tasks to be performed using the other two components.

---

## Other Important NFS Functions

Aside from these three components, the NFS protocol as a whole involves a number of other functions, some of which I think are worth specific mention:

- 🕒 **Mount Protocol:** A specific decision was made by the creators of NFS to not have NFS deal with the particulars of file opening and closing. Instead, a separate protocol called the *Mount* protocol is used for this purpose. Accessing a file or other resource over the network involves first *mounting* it using this protocol. The Mount Protocol is architecturally distinct, but obviously closely related to NFS, and is even defined in an appendix of the NFS standard. [I describe it in the last topic of this section.](#) (Note that in NFSv4 the functions of the Mount Protocol have been incorporated into NFS “proper”.)
- 🕒 **NFS File System Model:** NFS uses a particular model to implement the directory and file structure of the systems that use it. This model is closely based on the file system model of UNIX but is not specific to only that operating system. [It is discussed in conjunction with the explanation of the Mount Protocol.](#)

**Figure 253: NFS Architectural Components**

NFS resides architecturally at the TCP/IP application layer. Even though in the TCP/IP model no clear distinction is made generally between the functions of layers five through seven of the OSI Reference Model, NFS's three subprotocols correspond well to those three layers as shown.

- ☉ **Security:** Versions 2 and 3 of NFS include only limited security provisions. They use UNIX style authentication to check permissions for various operations. NFS version 4 greatly increases the security options available for NFS implementations. This includes both the option of multiple authentication and encryption algorithms, and many changes made to the protocol as a whole to make it more "security minded".

Like other TCP/IP protocols, NFS is implemented in the form of client and server software that implements the functions above. The NFS standards, especially for versions 3 and 4, discuss numerous issues related to proper NFS client/server implementation, including interaction between servers and clients, file locking, permission issues, caching, retransmission policies, international support and more. Many of these issues require extensive discussion that is beyond the scope of this Guide. You will want to refer to the standards for NFS, especially versions 3 and 4, for full details.

---

## **NFS Data Storage and Data Types, and the External Data Representation (XDR) Standard**

The overall idea behind NFS is to allow someone on one computer to read from or write to a file on another computer as readily as they do on a local machine. Of course, the files on your local machine are all stored in the same file system, using the same file structure and the same means of representing different types of data. You can't be sure that this will be the case when accessing a remote device, and this creates a bit of a "Tower of Babel" problem that NFS has to deal with.

### ***Creating a Method of Universal Data Exchange: XDR***

One approach to representation consistency would be to simply restrict access only to remote files on machines that use the same operating system. However, this would remove much of the effectiveness of NFS. It would also be highly impractical to require every computer to understand the internal representation of every other one. A more general method was needed to allow even very dissimilar machines to share data. To this end, the creators of NFS defined it so that it deals with data using a universal data description language. This language is called the *External Data Representation (XDR)* standard, and was originally described in RFC 1014; it was updated in RFC 1832, *XDR: External Data Representation Standard*, in 1995.

The idea behind XDR is simple, and can be easily understood in the form of an analogy. If you had delegates speaking 50 different languages at a convention, they would have a hard time communicating. You could hire translators to facilitate, but you'd never find translators to handle all the different possible combinations of languages. A more practical solution is to declare one language, such as English, to be a common language. You then only need 49 translators: one to translate from English to each of the non-English languages and back again. To translate from Swedish to Portuguese, you translate from Swedish to English and then from English to Portuguese. The common language could be French, or Spanish, or something else, as long as a translator could be found from all the other languages to that common language.

XDR works in the same manner. When information about how to access a file is to be transferred from device *A* to device *B*, device *A* first converts it from *A*'s internal representation to the XDR representation of those data types. The information is transmitted across the network using XDR encoding. Then, device *B* translates from XDR back to its own internal representation, so it can be presented to the user as if it were on the local file system. Each device needs to know only how to convert from its own "language" to XDR and back again; device *A* doesn't need to know device *B*'s internal details and vice-versa. This sort of translation is of course a classic job of the presentation layer, which is where XDR resides in the OSI Reference Model. XDR is itself based on an ISO standard called the *Abstract Syntax Notation*.

---

Incidentally, the idea described here is also used in other protocols to allow the exchange of data independent of the nature of the underlying systems. For example, a similar idea is behind [the way management information is exchanged using the Simple Network Management Protocol \(SNMP\)](#). The same basic idea underlies the important *Network Virtual Terminal (NVT)* paradigm used in the [Telnet protocol](#).

**Key Concept:** The purpose of the *External Data Representation (XDR)* standard is to define a common method for representing common data types. Using this universal representation, data can be exchanged between devices regardless of what internal file system each uses. This enables NFS to exchange file data between clients and servers that may be implemented using very different hardware and software platforms.

---

### ***XDR Data Types***

For XDR to be universal, it must allow the description of all the common types of data that are used in computers. For example, it must allow integers, floating point numbers, strings and other data constructs to be exchanged. The XDR standard describes the structure of many data types using a notation somewhat similar to the language “C”. As you may know, this is one of the most popular languages in computing history, and is closely associated with UNIX and, as a result, certain TCP/IP technologies as well.

[Table 182](#) shows the data types defined by XDR, which can be used by NFS in exchanging data between client and server. For each I have included the data type code, its size in bytes, and a name and a brief description.

**Table 182: NFS External Data Representation (XDR) Data Types (*Page 1 of 2*)**

Data Type Code	Size (bytes)	Description
int	4	<b>Signed Integer:</b> A 32-bit signed integer in two's complement notation, capable of holding a value from -2,147,483,648 to +2,147,483,647.
unsigned int	4	<b>Unsigned Integer:</b> A 32-bit unsigned integer, from 0 to 4,294,967,295.
enum	4	<b>Enumeration:</b> An alternate way of expressing a signed integer where some of the integer values are used to stand for particular constant values. For example, you could represent the colors of the rainbow, by defining the value 1 to stand for “PURPLE”, 2 to stand for “BLUE” and so on.
bool	4	<b>Boolean:</b> A logical representation of an integer, analogous to a two-level enumeration where a value of 0 is defined as “FALSE” and 1 is “TRUE”.
hyper	8	<b>Signed Hyper Integer:</b> Same as a regular signed integer, but 8 bytes wide to allow much larger numbers.
unsigned hyper	8	<b>Unsigned Hyper Integer:</b> Same as a regular unsigned integer but 8 bytes wide to allow much larger numbers.

**Table 182: NFS External Data Representation (XDR) Data Types (Page 2 of 2)**

Data Type Code	Size (bytes)	Description
<b>float</b>	4	<b>Floating-Point Number:</b> A 32-bit signed floating-point number. 1 bit holds the sign (positive or negative), 8 bits hold the exponent (power), in base 2, and 23 bits hold the mantissa (fractional part of the number).
<b>double</b>	8	<b>Double-Precision Floating-Point Number:</b> The same as <i>float</i> but with more bits to allow greater precision. 1 bit is for the sign, 11 bits for the exponent and 52 bits for the mantissa.
<b>quadruple</b>	16	<b>Quadruple-Precision Floating-Point Number:</b> The same as <i>float</i> and <i>double</i> but with still more bits to allow greater precision. 1 bit is for the sign, 15 bits for the exponent and 112 bits for the mantissa.
<b>opaque</b>	Variable	<b>Opaque Data:</b> Data that is to be passed between devices without being given a specific representation using XDR. The term <i>opaque</i> means that the data is treated like a “black box” whose insides cannot be seen. Obviously, any machines using this data type must themselves know how to deal with it, since NFS does not.
<b>string</b>	Variable	<b>String:</b> A variable-length string of ASCII characters.
<b>(array)</b>	Variable	<b>Arrays:</b> A group of any single type of the elements above, such as integers, floating point numbers and so on, may be specified in an array to allow many to be referenced as a single unit. They are not indicated using a separate data type code.
<b>struct</b>	Variable	<b>Structure:</b> An arbitrary structure containing other data elements from this table. This allows the definition of complex data types.
<b>union</b>	Variable	<b>Discriminated Union:</b> A complex form of structure that I cannot do justice to with a short description here. ☺
<b>void</b>	0	<b>Void:</b> A “null” data type that contains nothing.
<b>const</b>	0	<b>Constant:</b> Doesn't declare data, just defines a constant value used in other representations.

As you can see, XDR provides considerable data description capability. If you know the “C” language, much of what is in that table is probably familiar to you. Unfortunately, I can't really describe many of the more complex data types in the table above in detail without turning this into a guide to C programming.

In addition to the above, XDR also provides a means of defining new data types, and a method for specifying optional data. This provides even more flexibility beyond the large number of specific types already specifically described. Each version of NFS has a slightly different list of data types it supports.

## **NFS Client/Server Operation Using Remote Procedure Calls (RPCs)**

Almost all applications deal with files and other resources. When a software program on a particular computer wants to read a file, write a file or perform related tasks, it needs to use the correct software instructions for this purpose. It would be inefficient to require each software program to contain a copy of these instructions, so instead, they are encoded as

---

standardized software modules, sometimes called *procedures*. To perform an action, a piece of software *calls* the procedure; the procedure temporarily takes over for the main program and performs a task such as reading or writing data. The procedure then returns control of the program back to the software that called it, and optionally, returns data as well.

Since the key concept of NFS was to make remote file access look like local file access, it was designed around the use of a network-based version of the procedure calling method just described. A software application that wants to do something with a file still makes a procedure call, but it makes the call to a procedure on a different computer instead of the local one. A special set of routines is used to handle the transmission of the call across the network, in a way largely invisible to software performing the call.

This functionality could have been implemented directly in NFS, but instead Sun created a separate session-layer protocol component called the *Remote Procedure Call (RPC)* specification, which defines how this works. RPC was originally created as a subcomponent of NFS, but is generic enough and useful enough that it has been used for other client/server applications in TCP/IP. For this reason, it is really considered in many respects a distinct protocol.

Because RPC is the actual process of communicating in NFS, NFS itself is different from many other TCP/IP protocols. Its operation can't be described in terms of specific message exchanges and state diagrams the way a protocol like HTTP or DHCP or even TCP can, because RPC does all of that. NFS is in fact defined in terms of a set of [RPC server procedures and operations](#) that an NFS server makes available to NFS clients. These procedures and operations each allow a particular type of action to be taken on a file, such as reading from it, writing to it or deleting it.

### ***RPC Operation and Transport Protocol Usage***

When a client wants to perform some type of action on a file on a particular machine, it uses RPC to make a call to the NFS server on that machine. The server accepts the request and performs the action required, then returns a result code and possibly data back to the client, depending on the request. The result code indicates if the action was successful. If it was, the client can assume that whatever it asked to be done was completed. For example, in the case of writing data, the client can assume the data has been successfully written to long-term storage.

NFS can operate over any transport mechanism that has a valid RPC implementation at the session layer. Of course in TCP/IP we have [two transport protocols, UDP and TCP](#). It's interesting to see that NFS has seen an evolution of sorts in its use of transport protocol. The NFSv2 standard says that it operates “normally” using UDP, and this is still a common way that NFS information is carried. NFSv3 says that either UDP or TCP may be used, but NFSv4 specifies TCP to carry data. The nominal registered port number for use by NFS is 2049, but in fact other port numbers are sometimes used for NFS, through the use of RPC's “port mapper” capability.

**Key Concept:** NFS does not use a dedicated message format, like most other protocols do. Instead, clients and servers use the *Remote Procedure Call (RPC)* protocol to exchange file operation requests and data.

---

### ***Client and Server Responsibilities in NFS***

Since UDP is unreliable, the use of that protocol to transport important information may seem strange. For example, we obviously don't want data that we are trying to write to a file to be lost in transit. Remember, however, that UDP doesn't preclude the use of measures to ensure reliable communications, it simply doesn't provide those capabilities itself. UDP can be used by NFS because the protocol itself is designed to tolerate loss of transmitted data and to recover from it.

Consistent with this concept, the general design of NFS puts most of the responsibility for implementing the protocol on the client, not the server. As the NFSv3 standard says, “NFS servers are dumb and NFS clients are smart.” What this means is that the servers focus only on responding to requests, while clients must take care of most of the “nitty-gritty” details of the protocol, including recovery from failed communications. This is in fact a common requirement when UDP is used, because if a client request is lost in transit, the server has no way of knowing that it was ever sent.

As mentioned in [the NFS overview](#), NFS servers are designed to be “stateless”. In simplified terms, this means that the NFS server does not keep track of the state of the clients using it from one request to another. Each request is independent of the previous one, and the server in essence has “no memory” of what it did before when it gets a new command from a client. This again requires more “smarts” to be put into the clients, but has the important advantage of simplifying recovery in the case that the server crashes. Since there is nothing that the server was keeping track of for the client, there's nothing that can be lost. This is an important part of ensuring that files are not damaged as a result of network problems or congestion.

### ***Client and Server Caching***

Both NFS clients and servers can make use of caching to improve performance. Servers may use caching to store recently-requested information in case it is needed again. They may also use *predictive* caching, sometimes called *prefetching*. In this technique, a server that receives a request to read a block of data from a file may load into memory the next block after it, on the theory that it will likely be requested next. Client-side caching is used to satisfy repeat NFS requests from applications while avoiding additional RPC calls. Like almost everything else about NFS, caching is implemented much more thoroughly in NFS version 4 than in the previous versions.

**Key Concept:** NFS is designed to be a *stateless* protocol, with intelligent clients and relatively “dumb” servers that respond to requests and do not maintain status information about what files are in use. NFS was originally designed to use UDP for transport, for efficiency purposes. This requires that NFS clients take care of detecting lost requests and retransmitting them. NFS version 4 uses TCP to take advantage of TCP’s reliability and other features.

## **NFS Server Procedures and Operations**

The actual exchange of information between an NFS client and server is performed by the underlying [Remote Procedure Call \(RPC\) protocol](#). NFS functionality is therefore described not in terms of specific protocol operations, but by delineating the different actions that a client may take on files residing on a server. In the original version of NFS, NFSv2, these are called *NFS server procedures*.

Each procedure represents a particular action that a client may perform, such as reading from a file, writing to a file, or creating or removing a directory. The operations performed on the file require that the file be referenced using a data structure called a *file handle*. As the name suggests, the file handle, like the handle of a real object, lets the client and server “grasp” onto the file. The [Mount protocol](#) is used to mount a file system, to enable a file handle to be accessed for use by NFS procedures.

NFS version 3 uses the same basic model for server procedures, but makes certain changes. Two of the NFSv2 procedures were removed, and several new ones added to support new functionality. The numbers assigned to identify each procedure were also changed.

### ***NFS Version 2 and Version 3 Server Procedures***

[Table 183](#) shows the server procedures defined in versions 2 and 3 of NFS. The table shows the procedure numbers for both NFSv2 and NFSv3, as well as the name of each procedure and a description of what it does. I have kept the descriptions short so the table can serve as a useful summary of what NFS can do. They are listed in order of the procedure number used in NFSv2.

**Table 183: NFS Version 2 and Version 3 Server Procedures (Page 1 of 3)**

Procedure # (v2)	Procedure # (v3)	Procedure Name	Procedure Summary	Description
0	0	<i>null</i>	Do Nothing	Dummy procedure provided for testing purposes.
1	1	<i>getattr</i>	Get File Attributes	Retrieves the attributes of a file on a remote server.
2	2	<i>setattr</i>	Set File Attributes	Sets (changes) the attributes of a file on a remote server.

**Table 183: NFS Version 2 and Version 3 Server Procedures (Page 2 of 3)**

Procedure # (v2)	Procedure # (v3)	Procedure Name	Procedure Summary	Description
3	—	<i>root</i>	Get Filesystem Root (obsolete)	This procedure was originally defined to allow a client to find the root of a remote file system, but is now obsolete. This function is instead now implemented as part of the <a href="#">Mount protocol</a> . It was removed in NFSv3.
4	3	<i>lookup</i>	Look Up File Name	Returns the file handle of a file for the client to use.
5	5	<i>readlink</i>	Read From Symbolic Link	Reads the name of a file specified using a symbolic link.
6	6	<i>read</i>	Read From File	Reads data from a file.
7	—	<i>writecache</i>	Write To Cache	Proposed for future use in version 2 but abandoned and removed from version 3.
8	7	<i>write</i>	Write To File	Writes data to a file.
9	8	<i>create</i>	Create File	Creates a file on the server.
10	12	<i>remove</i>	Remove File	Deletes a file from the server.
11	14	<i>rename</i>	Rename File	Changes the name of a file.
12	15	<i>link</i>	Create Link To File	Creates a "hard" (non-symbolic) link to a file.
13	10	<i>symlink</i>	Create Symbolic Link	Creates a symbolic link to a file.
14	9	<i>mkdir</i>	Create Directory	Creates a directory on the server.
15	13	<i>rmdir</i>	Remove Directory	Deletes a directory.
16	16	<i>readdir</i>	Read From Directory	Reads the contents of a directory.
17	—	<i>statfs</i>	Get File System Attributes	Provides to the client general information about the remote file system, including the size of the file system and the amount of free space remaining.  In NFSv3 this was replaced by <i>fsstat</i> and <i>fsinfo</i> .
—	4	<i>access</i>	Check Access Permission	(New in NFSv3.) Determines the access rights that a user has for a particular file system object.
—	11	<i>mknod</i>	Create A Special Device	(New in NFSv3.) Creates a special file such as a named pipe or device file.
—	17	<i>readdirplus</i>	Extended Read From Directory	(New in NFSv3.) Retrieves additional information from a directory.

**Table 183: NFS Version 2 and Version 3 Server Procedures (Page 3 of 3)**

Procedure # (v2)	Procedure # (v3)	Procedure Name	Procedure Summary	Description
—	18	<i>fsstat</i>	Get Dynamic File System Information	(New in NFSv3.) Returns volatile (dynamic) file system status information such as the current amount of file system free space and the number of free file slots.
—	19	<i>fsinfo</i>	Get Static File System Information	(New in NFSv3.) Returns static information about the file system, such as general data about how the file system is used, and parameters for how requests to the server should be structured.
—	20	<i>pathconf</i>	Retrieve POSIX Information	(New in NFSv3.) Retrieves additional information for a file or directory.
—	21	<i>commit</i>	Commit Cached Data On A Server To Stable Storage	(New in NFSv3.) Flushes any data that the server is holding in a write cache to storage. This is used to ensure that any data that the client has sent to the server but that the server has held pending write to storage is in fact written out.

#### **NFS Version 4 Server Procedures and Operations**

It is common that a client may want to perform multiple actions on a file: several consecutive reads, for example. One of the problems with the server procedure system in NFSv2 and NFSv3 is that each client action required a separate procedure call. This was somewhat inefficient, especially when NFS was used over a high-latency link.

To improve the efficiency of server procedures, NFS version 4 makes a significant change to the way that server procedures are implemented. Instead of each client action being a separate procedure, a single procedure called *compound* is defined. Within this “compound” procedure, a large number of *server operations* are encapsulated. These are all sent as a single unit and the server interprets and follows the instructions in each operation in sequence.

This change means there are actually only two RPC procedures in NFSv4, as shown in [Table 184](#).

**Table 184: NFS Version 4 Server Procedures**

Procedure #	Procedure Name	Procedure Summary	Description
0	<i>null</i>	Do Nothing	Dummy procedure provided for testing purposes.
1	<i>compound</i>	Compound Operations	Combines a number of NFS operations into a single request, as described above.

All the real client actions are defined as operations within the *compound* procedure, as shown in [Table 185](#). You'll notice that the number of NFSv4 operations is much larger than the number of procedures in NFSv2 and NFSv3. This is due both to the added features in version 4 and the fact that NFSv4 incorporates functions formerly performed by the separate Mount protocol into NFS itself.

**Table 185: NFS Version 4 Server Operations (Page 1 of 2)**

Operation #	Operation Name	Operation Summary	Description
3	<i>access</i>	Check Access Rights	Determines the access rights a user has for an object.
4	<i>close</i>	Close File	Closes a file.
5	<i>commit</i>	Commit Cached Data	Flushes any data that the server is holding in a write cache to storage, to ensure that any pending data is permanently recorded.
6	<i>create</i>	Create A Non-Regular File Object	This is similar to the <i>mknod</i> procedure in NFSv3; it creates a "non-regular" (special) object file. (Regular files are created using the <i>open</i> operation.)
7	<i>delepurge</i>	Purge Delegations Awaiting Recovery	NFSv4 has a feature where a server may delegate to a client responsibility for certain files. This operation removes delegations awaiting recovery from a client.
8	<i>delegreturn</i>	Return Delegation	Returns a delegation from a client to the server that granted it.
9	<i>getattr</i>	Get Attributes	Obtains the attributes for a file.
10	<i>getfh</i>	Get Current Filehandle	Returns a <i>file handle</i> , which is a logical object used to allow access to a file.
11	<i>link</i>	Create Link To A File	Creates a "hard" (non-symbolic) link to a file.
12	<i>lock</i>	Create Lock	Creates a lock on a file. Locks are used to manage access to a file, for example, to prevent two clients from trying to write to a file simultaneously and thus corrupting it.
13	<i>lockt</i>	Test For Lock	Tests for the existence of a lock on an object and returns information about it.
14	<i>locku</i>	Unlock File	Removes a lock previously created on a file.
15	<i>lookup</i>	Lookup Filename	Looks up or finds a file.
16	<i>lookupp</i>	Lookup Parent Directory	Returns the filehandle of an object's parent directory.
17	<i>nverify</i>	Verify Difference In Attributes	Checks to see if attributes have changed on a file.
18	<i>open</i>	Open A Regular File	Opens a file.
19	<i>openattr</i>	Open Named Attribute Directory	Opens an attribute directory associated with a file.

**Table 185: NFS Version 4 Server Operations (Page 2 of 2)**

Operation #	Operation Name	Operation Summary	Description
20	<i>open_confirm</i>	Confirm Open	Confirms information related to an opened file.
21	<i>open_downgrade</i>	Reduce Open File Access	Adjusts the access rights for a file that is already open.
22	<i>putfh</i>	Set Current Filehandle	Replaces one filehandle with another.
23	<i>putpubfh</i>	Set Public Filehandle	Sets the current filehandle to be the “public” filehandle of the server. This may or may not be the same as the root filehandle (see below).
24	<i>putrootfh</i>	Set Root Filehandle	Sets the current filehandle to be the root of the server's file system.
25	<i>read</i>	Read From File	Reads data from a file.
26	<i>readdir</i>	Read Directory	Reads the contents of a directory.
27	<i>readlink</i>	Read Symbolic Link	Reads the name of a file specified using a symbolic link.
28	<i>remove</i>	Remove Filesystem Object	Removes (deletes) an object.
29	<i>rename</i>	Rename Directory Entry	Changes the name of an object.
30	<i>renew</i>	Renew A Lease	Renews an NFS delegation made by a server. (Note that these leases have nothing to do with <a href="#">DHCP leases</a> !)
31	<i>restorefh</i>	Restore Saved Filehandle	Allows a filehandle previously saved to be made the current filehandle.
32	<i>savefh</i>	Save Current Filehandle	Allows a filehandle to be saved so it can later be restored when needed.
33	<i>secinfo</i>	Obtain Available Security	Retrieves NFS security information.
34	<i>setattr</i>	Set Attributes	Changes one or more attributes of a file.
35	<i>setclientid</i>	Negotiate Clientid	Allows a client to communicate information to the server regarding how the client wants to use NFS.
36	<i>setclientid_confirm</i>	Confirm Clientid	Used to confirm the results of a previous negotiation using setclientid.
37	<i>verify</i>	Verify Same Attributes	Allows a client to verify certain attributes before proceeding with a particular action.
38	<i>write</i>	Write To File	Writes data to a file.
39	<i>release_lockowner</i>	Release Lockowner State	Used by a client to tell a server to release certain information related to file locks.
10044	<i>illegal</i>	Illegal Operation	A “placeholder” (dummy) operation used to support error reporting when an invalid operation is used in a request from a client.

**Key Concept:** File operations in NFS are carried out using NFS *server procedures*. In versions 2 and 3 of NFS, each procedure performs one action, such as reading data from a file. In version 4, a special *compound* action is defined that allows many individual *operations* to be sent in a single request to a server.

---

## **NFS File System Model and the Mount Protocol**

Since NFS is used by a client to simulate access to remote directories of files as if they were local, the protocol must “present” the files from the remote system to the local user. Just as files on a local storage device are arranged using a particular file system, NFS too uses a *file system model* to represent how files are shown to a user.

### ***The NFS File System Model***

The file system model used by NFS is the same one that most of us are familiar with: a hierarchical arrangement of directories that contain files and subdirectories. The top of the hierarchy is the *root*, which contains any number of files and first level directories. Each directory may contain more files or other directories, allowing an arbitrary tree structure to be created.

A file can be uniquely specified by using its *file name* and a *path name* that shows the sequence of directories one must traverse from the root to find the file. Since NFS is associated with UNIX, files in NFS discussions are usually shown in UNIX notation; for example, “/etc/hosts”. The same basic tree idea can also be expressed using the method followed by Microsoft operating systems: “C:\WINDOWS\HOSTS”.

### ***The Mount Protocol***

Before NFS can be used to allow a client to access a file on a remote server, the client must be given a way of accessing the file. This means that a portion of the remote file system must be made available to the client, and the file opened for access. A specific decision was made when NFS was created to **not** put file access, opening and closing functions into NFS proper. Instead, a separate protocol was created to work with NFS, so that if in the future the method of providing file access needed to be changed, it wouldn't require changes to NFS itself. This separate mechanism is called the *Mount Protocol*, and is described in Appendix A of RFC 1094 (NFSv2). Note that while functionally distinct, Mount is considered part of the overall NFS package.

When NFS was revised to version 3, the Mount Protocol was similarly modified. The NFSv3 version of the Mount Protocol is defined in Appendix I of RFC 1813 (NFSv3). It contains some changes to how the protocol works, but the overall operation of the two versions of Mount is pretty much the same.

---

The term “mount” is actually an analog to a hardware term that refers to making a physical storage volume available. In the “olden days” storage devices were usually removable disk packs, and to use one you mounted it onto a drive unit. In a similar manner, NFS resources are logically mounted using the Mount protocol, which makes the shared file system available to the client. A file can then be opened and a file handle returned to the NFS client so it can reference the file for operations such as reading and writing.

**Key Concept:** Versions 2 and 3 of NFS do not include procedures for opening or closing resources on a remote server. Before NFS tasks can be accomplished on these versions, the special *Mount* protocol must be employed to mount a filesystem and create a file handle to access a file on it; the protocol is also used to unmount the file system when no longer required. The Mount protocol is implemented in a manner very similar to NFS itself, defining procedures that use RPC and XDR. In version 4 of NFS, Mount is no longer needed; the tasks it performs are implemented as NFSv4 operations.

---

### **Mount Protocol Server Procedures**

The actual implementation of the Mount protocol is very similar to that of NFS itself. Like NFS, the Mount protocol uses [XDR](#) to define data types to be exchanged between client and server, and [RPC](#) to define a set of [server procedures](#) that clients may use to perform different operations. The main difference between Mount and NFS is simply that Mount defines procedures related to opening and closing filesystems rather than file access operations. [Table 186](#) shows the server procedures used in the Mount protocol.

**Table 186: NFS Mount Protocol Server Procedures**

Procedure #	Procedure Name	Procedure Summary	Description
0	<i>null</i>	Do Nothing	Dummy procedure provided for testing purposes.
1	<i>mnt</i>	Add Mount Entry	Performs a mount operation by mapping a path on a server to a file handle for the client to use.
2	<i>dump</i>	Return Mount Entries	Returns a list of remotely mounted file systems.
3	<i>umnt</i>	Remove Mount Entry	Performs an “unmount” by removing a mount entry. (It should be “dismount”. Techies are rarely into grammar. ☺)
4	<i>umntall</i>	Remove All Mount Entries	Removes all mount entries, thus eliminating all mounted file systems between server and client.
5	<i>export</i>	Return Export List	Returns a list of exported file systems and indicates which clients are allowed to mount them. This is used to let the client see what served file systems are available for use.

As mentioned in other topics in this section, NFS version 4 does away with the notion of a separate Mount protocol, incorporating file mounting operations into NFS directly.

---

# **TCP/IP Network Configuration and Management**

## **Protocols (BOOTP, DHCP, SNMP and RMON)**

Some folks study the [OSI Reference Model](#) just to pass a test and otherwise consider it “useless”. I think it's important because it shows how the different hardware and software components of an internetwork fit together. One aspect of this is that the model lets us see clearly how the functions of networks are implemented by building the higher-layer ones upon those at lower layers. We start at the bottom layers dealing primarily with hardware, and build upon them the software and protocols that make networks and internetworks in the middle layers. The highest layers of the OSI model, especially the application layer, run on top of the internetwork implemented by the layers below. It is therefore at this level that we normally talk about the protocols and applications that permit end users to perform different network communication tasks.

Of course, the users are why we create networks and internetworks in the first place. But while the application layer is indeed where we find user-oriented protocols, users are not the only ones who need to make use of network applications at this level. Network administrators have a number of functions that they must perform on a daily basis to keep networks running smoothly and efficiently, and many of these use support protocols at higher layers.

Decades ago, an administrator was probably responsible for only a small number of computers, all in the same building or even the same room. When something in the network needed to be fixed or changed, the techie would walk over to it and “administer” it. Today, a company's computers are probably not close at hand; they are likely spread out across a campus, a country or the entire world. It is no longer feasible to travel to each computer to perform various maintenance tasks. And with larger networks, trying to manually maintain thousands of computers, even if they were in the same building, would not be possible.

To make administration practical on modern networks, special application-level protocols were created that allow administrators to work with distance devices in a more automated manner over the internetwork itself. It may seem ironic to be using the internetwork to help administer the internetwork, but many tasks such as device configuration and management can be performed effectively using software protocols. Using these protocols yields significant advantages over manual processes, and is part of what keeps the internetworks we rely on running smoothly.

This section takes a look at two classes of administrative tasks that are served by application-layer protocols. The first subsection deals with host configuration, describing the concepts behind the process, and two protocols used for accomplishing automated configuration of internetwork hosts. The second describes protocols used to remotely manage, monitor and control remote hardware devices on an internetwork.

As part of this discussion, I describe in detail four TCP/IP protocols that implement host configuration and management functions. These are the TCP/IP Boot Protocol (BOOTP) and Dynamic Host Configuration Protocol (DHCP) for host configuration, and the Simple Network Management Protocol (SNMP) and Remote Network Monitoring Protocol (RMON) for network management.

---

## Host Configuration and TCP/IP Host Configuration Protocols (BOOTP and DHCP)

Each host that is placed on a network or internetwork must be set up and configured before it can be used. Configuration ensures that the host functions properly, and that it is told the parameters needed for it to successfully communicate with other hosts and devices. In the “good old days”, administrators would manually set up each host as it was added to the network, and would also manually make changes to the configuration as they were required. Modern networks, however, are very large, and manual configuration of hosts is a time-consuming chore. Furthermore, we often need to make use of features that only automated configuration can provide, particularly for special hosts that have no internal storage. It is for these reasons that *host configuration* protocols were developed.

In this section I describe the concepts behind host configuration protocols, and then illustrate the operation of two of the most important ones in use today. I begin with a topic that provides an overview of host configuration concepts and issues. I describe the TCP/IP Bootstrap Protocol (BOOTP), the first truly capable automated configuration tool for IP hosts. I then describe BOOTP's successor, the feature-filled Dynamic Host Configuration Protocol (DHCP), which is used extensively in modern TCP/IP hardware and software.

**Related Information:** Technically, the very first host configuration protocol for TCP/IP was the [Reverse Address Resolution Protocol \(RARP\)](#). RARP is a very simple, crude protocol that allows very basic host configuration to be performed, but little else. RARP is very different from BOOTP and DHCP, not only because of its more limited capabilities, but because it operates between layers two and three like the [Address Resolution Protocol \(ARP\)](#) upon which it is based. It is therefore covered in [the same section](#) that describes ARP.

---

---

## **Host Configuration Concepts, Issues and Motivation**

Putting a host on an internetwork requires that certain setup and configuration procedures be followed. Hardware must be selected and set up, and software too must be chosen and installed on the hardware. Once the software is set up, we aren't finished, however: we must also perform other configuration tasks that tell the software how we want it to operate, and give it certain parameters so it knows its role on the network and how to function.

### ***The Purposes of Host Configuration***

Probably the most important configuration task that must be performed for each host on an internetwork is to give it an *identity*, in the form of an address that is unique to it alone. In TCP/IP networks, each device must be given an IP address. Hosts also often require other parameters to ensure that they operate properly. For a TCP/IP network, we might want to tell each host some of the following:

- The address of a default router on the local network.
- The network mask the host should use.
- The addresses of servers providing particular services to the host, such as a [mail server](#) or a [DNS](#) name server.
- The [maximum transmission unit \(MTU\)](#) of the local network.
- What [Time To Live \(TTL\)](#) value to use for IP datagrams.

And possibly, a lot more; there are dozens of different parameters that must be set up for certain networks. Many of these may be common to all the machines on a network, but IP addresses must be unique. The administrator must therefore ensure that each is assigned to only one computer, even as machines are added to and removed from the network.

### ***The Inefficiency of Manual Host Configuration***

If you're an administrator in charge of a small ten-host LAN, performing setup and configuration is simple: for each host, you set up the hardware, install the software, and then configure the software. Even changes and keeping track of IP addresses wouldn't be a big deal; a single sheet of paper would suffice. However, what happens when your network has not ten computers but a hundred? How about a thousand? Ten thousand?

As the size of the network grows, the work needed for manual configuration grows with it. And while initial hardware setup may be time-consuming, at least it is done mainly when the host is first set up, and rarely changed thereafter. This is not the case with configuration parameters. If the address of the local router changes on a network with a thousand hosts, do you really want to go to each host to edit a configuration file? I sure don't!

### ***Cases Where Manual Configuration Is Not Feasible***

The drudge work associated with manual configuration is significant, but the problems with manual configuration go well beyond the inefficiency issue. There are situations where manual configuration is not just inconvenient, it's actually ***impossible***:

- 
- 🕒 **Remote Configuration:** An administrator cannot be everywhere; modern networks can span cities or nations. Unless we want to train every user on how to configure network hosts, we must use an automated protocol.
  - 🕒 **Mobile Device Configuration:** IP was designed when computers were large and attached to each other using heavy cables; today we have computers that fit in a shirt pocket and communicate using radio waves. IP addresses must be assigned based on the network to which they are attached, and this makes reconfiguration required when a device is moved. This is not conducive to manual configuration at all.
  - 🕒 **“Dumb” Host Configuration:** Most of the hosts we use today are full-fledged computers, with their own internal storage. We can assign such a device an address by entering it into a file that the device reads when it starts up. There are certain devices, however, that do not include any form of storage. Since they are mass-produced, they are all identical and cannot have individualized parameters stored within them. Such a device relies on a configuration protocol to learn what it needs to function on a network—especially including its individual identity, as we saw above.
  - 🕒 **Address Sharing:** The proliferation of devices attached to the global Internet has led to a situation where IP addresses must be carefully managed to ensure that they are not wasted on devices that aren't using them. Some organizations even find themselves with more potential hosts than they have addresses. A host configuration protocol can allow an address to be automatically assigned to a host when needed, and then returned to a common “pool” for reuse when the host leaves the network. This permits addresses to be shared and reduces the need for more address space.

### ***Automating the Process: Host Configuration Protocols***

Even though most of us don't have robots that can automate the hardware portions of the setup and configuration job, we **can** employ tools that will make the rest of the job easier. This includes the use of special *host configuration* protocols. These protocols allow hosts to be automatically configured when they are set up, and to have additional parameters assigned when needed.

Host configuration protocols generally function by having a host send a request for an address and other parameters, which is satisfied by a response from a server. The information in the response is used by the client to set its address, identify a local router, and perform other necessary setup so it can communicate.

The use of an automated protocol solves all of the problem situations mentioned above. We can configure devices remotely, rather than having to walk to each one. We can instantly assign a valid address to mobile devices. We can have “dumb” hosts boot up and obtain the information they need to operate. Finally, we can maintain a pool of addresses that is shared by a group of hosts.

**Key Concept:** *Host configuration protocols* enable administrators to set up hosts so that they can automatically determine their address and other key parameters. They are useful not only because of the effort they save over manual configuration, but because they enable the automatic setup of remote, storageless or mobile devices.

---

---

## ***The Role of Host Configuration Protocols in TCP/IP***

You might find it strange that host configuration protocols would exist up here in the “lofty heights” of the application layer. It certainly sounds like host configuration is a function related more to the network layer, where internetwork addresses such as IP addresses function.

In fact, some host configuration protocols, like the rudimentary [Reverse Address Resolution Protocol \(RARP\)](#), do exist down at that level. However, there are advantages to having host configuration protocols reside at higher levels. A major one is that the operation of the protocol is not dependent on the hardware upon which the protocol runs, making it more universal. Another is being able to convey host configuration messages between networks, which is not possible with a low-level protocol operating on the local network.

This leads to another fair question: how can a device send and receive messages if it doesn't know its own address? As we'll see, the answer to this is the local [broadcast capabilities of networks](#). By broadcasting messages, it is possible for a device with no assigned IP address to receive configuration information: including an IP address. We'll see in the next section, discussing the Bootstrap Protocol (BOOTP), how this is done.

---

## **TCP/IP Bootstrap Protocol (BOOTP)**

Before a device on a TCP/IP network can effectively communicate, it needs to know its IP address. While a conventional network host can read this information from its internal disk, some devices have no storage, and so do not have this luxury. They need help from another device on the network to provide them with an IP address and other information and/or software they need to become active IP hosts. This problem of getting a new machine up and running is commonly called *bootstrapping*, and to provide this capability to IP hosts, the TCP/IP *Bootstrap Protocol (BOOTP)* was created.

In this section I provide a fairly detailed look at the TCP/IP Bootstrap Protocol. I begin with an overview and history of the protocol and a look at the standards that define it. I then discuss the general client/server nature of BOOTP and how addressing is done in communication between the client and the server. I describe the operation of BOOTP step by step, and illustrate the format of BOOTP messages. I conclude with a description of BOOTP vendor extensions, which are used to allow the information sent in BOOTP messages to be customized, and a discussion of BOOTP relay agents, which allow the protocol to operate even when the BOOTP server and client are on different networks.

**Related Information:** BOOTP was the predecessor of the [Dynamic Host Configuration Protocol](#). DHCP was built to be substantially compatible with BOOTP and so the two protocols have a fair degree of commonality. To avoid duplication, certain information has been included only in the DHCP section, with links provided from the BOOTP topics where appropriate. On the other hand, some of the historical background information behind features like vendor information extensions and relay agents, which were first developed for BOOTP and adopted by DHCP, is in this section and linked from the DHCP topics. Why structure the sections this way? DHCP is far more popular than BOOTP today, so I wanted its description to be complete, but some features only really make sense if initially explained in the context of BOOTP's operation.

If you plan to read about DHCP as well as BOOTP, I recommend reading this section first. If you don't plan to read up on DHCP, you may wish to check the topic in [the DHCP topic on DHCP/BOOTP interoperability](#).

---

## **BOOTP Overview, History and Standards**

The [TCP/IP protocol suite](#) has been with us for over two decades, and the problem of how to automate the configuration of parameters on IP hosts has been around almost as long. Back in the early 1980s, networks were small and relatively simple. Automated host configuration wasn't considered an important capability so much because of the difficulty of manual configuration. It was needed because there is no other way to configure devices like diskless workstations.

---

As I discussed in [the overview topic on host configuration](#), without a form of internal storage, a device must rely on someone or something to tell it “who it is” (its address) and how to function each time it is powered up. When a device like this is turned on, it is in a difficult position: it needs to use IP to communicate with another device that will tell it how to communicate using IP! This process, called *bootstrapping* or *booting*, comes from an analogy to a person “pulling himself up using his own bootstraps”. You've likely encountered this term before, if at no other time then at least when some tech support person has told you to “reboot” your computer.

### ***BOOTP: Correcting the Weaknesses of RARP***

The [Reverse Address Resolution Protocol \(RARP\)](#) was the first attempt to resolve this “bootstrap problem”. Created in 1984, RARP is a direct adaptation of the low-level [Address Resolution Protocol \(ARP\)](#) that binds IP addresses to link-layer hardware addresses. RARP is capable of providing a diskless device with its IP address, using a simple client/server exchange of a request and reply between a host and an RARP server.

The difficulty with RARP is that it has so many limitations. It operates at a fairly low level using hardware broadcasts, so it requires adjustments for different hardware types. An RARP server is also required on every physical network to respond to layer-two broadcasts. Each RARP server must have address assignments manually provided by an administrator. And perhaps worst of all, RARP only provides an IP address to a host and none of the other information a host may need. (I describe these issues in detail in [the topic on RARP](#).)

RARP clearly wasn't sufficient for the host configuration needs of TCP/IP. To support both the needs of diskless hosts and other situations where the benefits of autoconfiguration were required, the *Bootstrap Protocol (BOOTP)* was created. BOOTP was standardized in RFC 951, published September 1985. This relatively straight-forward protocol was designed specifically to address the shortcomings of RARP:

- ☉ It is still based on a client/server exchange, but is implemented as a higher-layer software protocol, using [UDP](#) for message transport. It is not dependent on the particular hardware of the network like RARP.
- ☉ It supports sending additional configuration information to a client beyond just an IP address. This extra information can usually all be sent in one message for efficiency.
- ☉ It can handle having the client and server on different networks of an internetwork. This allows the administration of the server providing IP addresses to be more centralized, saving money as well as administrative time and hassle.

### ***BOOTP Deals With the First Phase of Bootstrapping***

It should be noted that even though the name of BOOTP implies that it defines everything needed for a storageless device to “boot”, this isn't really the case. As the BOOTP standard itself describes, “bootstrapping” generally requires two phases. In the first, the client is provided with an address and other parameters. In the second, the client downloads software, such as an operating system and drivers, that let it function on the network and

---

perform whatever tasks it is charged with. BOOTP really only deals with the first of these phases: address assignment and configuration. The second is assumed to take place using a simple file transfer protocol like the [Trivial File Transfer Protocol \(TFTP\)](#).

**Key Concept:** The first widely-used host configuration protocol for TCP/IP was the *Boot Protocol (BOOTP)*. It was created specifically to enable host configuration while addressing many of the weaknesses of RARP. BOOTP is intended to be used as the first phase of a two-phase boot procedure for storageless devices—after obtaining an IP address and other configuration parameters using BOOTP, the device employs a protocol such as TFTP to download software necessary to function on the network.

---

### ***Vendor-Specific Parameters***

One smart decision made when BOOTP was created was the inclusion of a *vendor-specific area*. This was intended to provide a place where hardware vendors could define parameters relevant to their own products. As the complexity of TCP/IP increased, it was realized that this field could be used to define a method of communicating certain parameters that were commonly needed by IP hosts, and were in fact vendor-independent. This was first proposed in RFC 1048, *BOOTP Vendor Information Extensions*, published February 1988.

The fact that BOOTP can be used to provide information to a client beyond just an IP address makes it useful even in cases where a device already knows its address. BOOTP can be used to send parameters that the administrator wants all hosts to have, to ensure that they use the network in a consistent manner. Also, in the case of devices that do have local storage (and therefore do not need BOOTP to get an IP address), BOOTP can still be used to let these devices get the name of a boot file for the “phase two” of bootstrapping described above.

### ***Changes to BOOTP and the Development of DHCP***

BOOTP was the TCP/IP host configuration of choice from the mid-1980s through the end of the 1990s. The vendor extensions introduced in RFC 1048 were popular, and over the years, additional vendor extensions were defined; RFC 1048 was replaced by RFCs 1084, 1395 and 1497 in succession. Some confusion also resulted over the years in how some sections of RFC 951 should be interpreted, and how certain features of BOOTP work.

RFC 1542, *Clarifications and Extensions for the Bootstrap Protocol*, was published in October 1993 to address this, and also made some slight changes to the protocol's operation. (RFC 1542 is actually a correction of the nearly-identical RFC 1532 that had some small errors in it.)

While BOOTP was obviously quite successful, it also had certain weaknesses of its own. One of the most important of these is lack of support for *dynamic* address assignment. The need for dynamic assignment became much more pronounced when the Internet really started to take off in the late 90s. This led directly to the development of the [Dynamic Host Configuration Protocol \(DHCP\)](#).

---

While DHCP replaced BOOTP as the TCP/IP host configuration protocol of choice, it would be inaccurate to say that BOOTP is “gone”. It is still used to this day in various networks. Furthermore, DHCP was based directly on BOOTP, and they share many attributes, including a common message format. BOOTP vendor extensions were used as the basis for DHCP *options*, which work in the same way but include extra capabilities. In fact, the successor to RFC 1497 is RFC 1533, which officially merges BOOTP vendor extensions and BOOTP options into the same standard.

## **BOOTP Client/Server Messaging and Addressing**

While BOOTP can be used for a variety of devices, one of the prime motives behind its creation was to provide a way to automatically configure “dumb” devices that have no storage. Most of these devices are relatively limited in their capabilities, and so requiring them to support a fancy boot protocol would not make sense. BOOTP is thus an uncomplicated protocol, which accomplishes host configuration without a lot of fancy concepts or implementation requirements.

### ***BOOTP Clients and Servers***

Like so many other TCP/IP protocols, BOOTP is [client/server in nature](#). The operation of the protocol consists of a single exchange of messages between a *BOOTP client* and a *BOOTP server*. A BOOTP client can be any type of device that needs to be configured. A BOOTP server is a network device that has been specially set up to respond to BOOTP client requests, and has been programmed with addressing and other information it can provide to clients when required.

The BOOTP server maintains a special set of information about the clients it serves. One key part of this is a table that maps the hardware (layer two, data link layer) addresses of each client to an assigned IP address for that device. The client specifies its hardware address in its request, and the server uses that address to look up the client's IP address and return it to the client. (Other techniques can also be used, but a mapping table is most common.)

### ***Messaging and Transport***

BOOTP messaging uses the [User Datagram Protocol \(UDP\)](#) as its layer four transport protocol, for a couple of reasons. First, UDP is a lot less complex than the other layer-four transport protocol ([TCP](#)) and is ideal for simple “request/reply” protocols like BOOTP. Second, since the client obviously doesn't know the address of a BOOTP server, the request is broadcast on its local network; UDP supports broadcasts while TCP does not.

UDP uses a special [well-known \(reserved\) port number](#) for BOOTP servers: UDP port 67. BOOTP servers “listen” on port 67 for these broadcast BOOTP requests sent by clients. After processing the request, the server sends a reply back to the client. How this is handled depends on whether the client knows its own address or not:

- 
- ☉ **Client Knows Its Address:** There are some cases where the BOOTP client already knows its own address. In this case, the address can be used by the BOOTP server to send back its reply directly.
  - ☉ **Client Does Not Know Its Own Address:** BOOTP is of course often used to provide an IP address to a client that doesn't know its address. This is sometimes called a “chicken and egg” problem, because it represents a “loop” of sorts like the old conundrum of “which came first, the chicken or the egg”. To resolve this dilemma, the BOOTP server has two choices. If the operating system supports it, the server can use the client's hardware address to create an [ARP](#) entry for the device, and then use a layer-two unicast to deliver the reply. Otherwise, it must send the reply as a broadcast as well on the local network.

### ***Use of Broadcasts and Ports***

The fact that BOOTP servers may need to broadcast back to the client necessitates a bit of a change from the way most TCP/IP protocols use client ports. Recall that normally, the client in a client/server transaction using UDP or TCP generates a [temporary, or ephemeral port number](#) that it uses as the source port in its request. The server sends the reply back to the client's IP address using that ephemeral port number. Ephemeral port numbers must be unique for a particular IP address, but may not necessarily be unique across all the devices on a network. For example, device *A* may be using ephemeral port number 1,248 for an HTTP request to a Web server, while device *B* may be using port number 1,248 on its TCP/IP stack to send a DNS request.

Since the server in BOOTP is broadcasting, it is not targeting a particular device with a unicast transmission. This means it cannot safely send to an ephemeral port number: some other device on the network may have selected the same ephemeral port number for some other transaction and may mistake the BOOTP server's response as being intended for itself. To avoid this problem, another well-known port number is used just for BOOTP clients: UDP port 68. Clients listen on this port for broadcast or unicast transmissions, while of course devices that have not sent a BOOTP request will ignore it. This “dual broadcast” BOOTP communication process is illustrated in [Figure 254](#).

**Key Concept:** A BOOTP client use broadcasts to send its requests to any listening BOOTP server. In most cases, the BOOTP client device does not know its own IP address when it uses the protocol. For this reason, a BOOTP server will also typically use broadcast in sending its reply, to be sure it reaches the client.

---

### ***Retransmission of Lost Messages***

The drawback of the simplicity of using UDP for BOOTP messaging is that we get no transport quality features. UDP is unreliable, which means a BOOTP request might be lost before it gets to the server, or the server's response may similarly not get back to the client. Like many other protocols using UDP, BOOTP clients take care of this by using a retransmission timer. If after a certain period of time the client has not received a response, it re-sends its request.

**Figure 254: General Operation Of the Boot Protocol**

BOOTP is a relatively simple client/server protocol that relies on broadcasts to permit communication with devices that do not have an assigned IP address. In this example Device A is trying to determine its IP address and other parameters. It broadcasts a BOOTP request on the local network using UDP port 67 and then listens for a reply on port 68. Device D is configured as a BOOTP server and listens on this port. When it receives the request it sends a broadcast on port 68 telling A what its IP address is.

However, BOOTP clients must take care in how they implement their retransmission strategy. Consider a scenario where a network with 200 BOOTP clients loses power. These machines are all pretty much the same, so when the power comes back on they all restart, and all try to send BOOTP requests at about the same time. Most likely, problems will occur due to all these requests; some will be lost, or the server may have to drop some due to overload.

If all the clients use the same amount of time for retransmission, then after that time elapses, a whole bunch of machines will again send requests and recreate the original problem. To avoid this, the BOOTP standard recommends using an exponential backoff scheme for retransmissions, starting with a retransmission interval of 4 seconds and doubling it for successive tries. A randomness element is also added to prevent many devices from overlapping their retransmissions. The idea is very similar to the backoff method used by Ethernet (in fact, the standard even refers to the Ethernet specification).

---

For example, the first retransmission would occur after a random period of time between 0 and 4 seconds (plus or minus a random amount); a second retransmission, if needed, after a random time interval between 0 and 8 seconds, plus or minus, and so forth. This helps reduce the chances of retransmissions being lost, and also helps ensure BOOTP traffic doesn't bog down the network.

**Key Concept:** BOOTP uses UDP for transport, which provide no reliability features. For this reason, the BOOTP client must detect when its requests are lost and if necessary, retransmit them.

---

## **BOOTP Detailed Operation**

Now that we have seen [how BOOTP messaging works in general terms](#), let's take a closer look at the detailed operation of the protocol. This will let us more clearly see how clients and servers create and process messages, and also help make sense of some of the important fields in the BOOTP message field format. Understanding the basic operation of BOOTP will also be of use when we examine [BOOTP relay agents](#), and even when we discuss [DHCP](#).

### ***BOOTP Bootstrapping Steps***

The following are the basic steps performed by the client and server in a regular BOOTP bootstrapping procedure (see [Figure 255](#)).

#### **1. Client Creates Request**

The client machine begins the procedure by creating a BOOTP request message. In creating this message, it fills in the following information:

- ☉ It sets the message type (*Op*) to the value 1, for a *BOOTREQUEST* message.
- ☉ If it knows its own IP address that it plans to keep using, it specifies it in the *CIAddr* field. Otherwise, it fills this field with zeroes. (See below for more on this.)
- ☉ It puts its own layer-two hardware address in the *CHAddr* field. This is used by the server to determine the right address and other parameters for the client.
- ☉ It generates a random transaction identifier, and puts this in the *XID* field.
- ☉ The client may specify a particular server that it wants to send it a reply and put that into the *SName* field. It may also specify the name of a particular type of boot file that it wants the server to provide in the *File* field.
- ☉ The client may specify vendor-specific information, if programmed to do so.

#### **2. Client Sends Request**

The client broadcasts the *BOOTREQUEST* message by transmitting it to address 255.255.255.255. Alternately, if it already knows the address of a BOOTP server, it may send the request unicast.

**Figure 255: Boot Protocol Operation**

The Boot Protocol uses a simple two-step message exchange consisting of a broadcast request and broadcast reply. After the client receives configuration information from the BOOTP server, it completes the bootstrapping process using a protocol such as TFTP.

### 3. Server Receives Request and Processes It

A BOOTP server, listening on UDP port 67, receives the broadcasted request and processes it. If a name of a particular server was specified and this name is different than the name of this server, the server may discard the request. This is especially true if the server knows that the server the client asked for is also on the local network. If no particular server is specified, or this particular server was the one the client wanted, the server will reply.

### 4. Server Creates Reply

The server creates a reply message by copying the request message and changing several fields:

- ☉ It changes the message type (*Op*) to the value 2, for a *BOOTREPLY* message.
- ☉ It takes the client's specified hardware address from the *CHAddr* field, and uses it in a table lookup to find the matching IP address for this host. It then places this value into the *YIAddr* ("your IP address") of the reply.

- 
- ☉ It processes the *File* field and provides the filename type the client requested, or if the field was blank, the default filename.
  - ☉ It puts its own IP address and name in the *SIAddr* and *SName* fields.
  - ☉ It sets any vendor-specific values in the *Vend* field.

## 5. Server Sends Reply

The server sends the reply, the method depending on the contents of the request:

- ☉ If the *B* (*Broadcast*) flag is set, this indicates that the client can't have the reply sent unicast, so the server will broadcast it.
- ☉ If the *CIAddr* field is non-zero, the server will send the reply unicast back to that *CIAddr*.
- ☉ If the *B* flag is zero and the *CIAddr* field is also zero, the server may either use an ARP entry or broadcast, as described in [the previous topic](#).

## 6. Client Processes Reply

The client receives the server's reply and processes it, storing the information and parameters provided. (See below for one important issue related to this processing.)

## 7. Client Completes Boot Process

Once configured, the client proceeds to “phase two” of the bootstrapping process, by using a protocol such as TFTP to download its boot file containing operating system software, using the filename the server provided.

### ***Interpretation of the Client IP Address (CIAddr) Field***

A complication can arise when a client chooses to specify an IP address in the *CIAddr* field in its request. The problem is how exactly to interpret this field. Does it mean that the client is already using this IP address? Or is it just the one it used last time it was booted? Then there is the related problem of what to do if the server supplies an address in the *YIAddr* that is different from the one the client is using. Should the server's provided address override the client's address? Or should the client ignore it? Who makes the decision, the server or the client?

Much confusion occurred due to the vagueness of the original standard in this regard, and this led to non-uniformity in how different implementations chose to handle this issue. There were even some implementations that used the *CIAddr* to mean “the client requests this IP address”, which was never part of BOOTP functionality. This is an especially bad idea since it could lead directly to BOOTP replies never reaching the client.

RFC 1542 was written in part to try to clean up this mess. It suggests that the following is the best way to handle the meaning of these fields:

- ☉ If a client is willing to accept whatever IP address the server provides, it sets *CIAddr* to all zeroes, even if it knows a previous address.

- ☉ If the client fills in a value for the field, it is saying it will use this address, and must be prepared to receive unicast messages sent to that address.
- ☉ If the client specifies an address in *CIAddr* and receives a different address in the *YIAddr* field, the server-provided address is ignored.

Note that not all hardware devices may necessarily agree with this interpretation as provided by RFC 1542, so there are still potential interoperability issues here with older equipment. RFC 1542 was written in 1993, so this is probably not much of an issue any more.

## **BOOTP Message Format**

The exchange of information in BOOTP takes the form of a request sent by a client, and a reply sent back by the server. BOOTP, like a number of other request/reply protocols, uses a common message format for requests and replies. The client starts by setting aside memory space for the message and clearing it to all zeroes. It then fills in the fields of the message and sends the request, as we saw in [the previous topic](#). The server creates its reply not from scratch, but by copying the request and changing certain fields.

BOOTP messages contain a considerable number of fields, so the message format is rather large. It is described fully in [Table 187](#) and illustrated in [Figure 256](#).

**Table 187: BOOTP Message Format (Page 1 of 3)**

Field Name	Size (bytes)	Description																				
Op	1	<b>Operation Code:</b> Specifies the type of message. A value of 1 indicates a request ( <i>BOOTREQUEST</i> message) while a value of 2 is a reply ( <i>BOOTREPLY</i> message).																				
HType	1	<b>Hardware Type:</b> This field specifies the type of hardware used for the local network, and is used in exactly the same way as the equivalent field ( <i>HRD</i> ) in the <a href="#">Address Resolution Protocol (ARP) message format</a> . Some of the most common values for this field: <table><tr><th>HType Field Value</th><th>Hardware Type</th></tr><tr><td>1</td><td>Ethernet (10 Mb)</td></tr><tr><td>6</td><td>IEEE 802 Networks</td></tr><tr><td>7</td><td>ARCNET</td></tr><tr><td>15</td><td>Frame Relay</td></tr><tr><td>16</td><td>Asynchronous Transfer Mode (ATM)</td></tr><tr><td>17</td><td>HDLC</td></tr><tr><td>18</td><td>Fibre Channel</td></tr><tr><td>19</td><td>Asynchronous Transfer Mode (ATM)</td></tr><tr><td>20</td><td>Serial Line</td></tr></table>	HType Field Value	Hardware Type	1	Ethernet (10 Mb)	6	IEEE 802 Networks	7	ARCNET	15	Frame Relay	16	Asynchronous Transfer Mode (ATM)	17	HDLC	18	Fibre Channel	19	Asynchronous Transfer Mode (ATM)	20	Serial Line
HType Field Value	Hardware Type																					
1	Ethernet (10 Mb)																					
6	IEEE 802 Networks																					
7	ARCNET																					
15	Frame Relay																					
16	Asynchronous Transfer Mode (ATM)																					
17	HDLC																					
18	Fibre Channel																					
19	Asynchronous Transfer Mode (ATM)																					
20	Serial Line																					

Table 187: BOOTP Message Format (Page 2 of 3)

Field Name	Size (bytes)	Description									
<b>HLen</b>	1	<b>Hardware Address Length:</b> Specifies how long hardware addresses are in this message. For Ethernet or other networks using IEEE 802 MAC addresses, the value is 6. This too is the same as the field with a similar name ( <i>HLN</i> ) in the <a href="#">ARP field format</a> .									
<b>Hops</b>	1	<b>Hops:</b> Set to 0 by a client before transmitting a request and used by <a href="#">BOOTP relay agents</a> to control the forwarding of BOOTP messages.									
<b>XID</b>	4	<b>Transaction Identifier:</b> A 32-bit identification field generated by the client, to allow it to match up the request with replies received from BOOTP servers.									
<b>Secs</b>	2	<p><b>Seconds:</b> According to RFC 951, the client enters into this field the number of seconds “elapsed since [the] client started trying to boot”. This is supposed to provide information to BOOTP servers to help them decide which requests to respond to first.</p> <p>Unfortunately, this definition was somewhat vague; it wasn't clear if this meant the amount of time since the machine was powered on, or since the first <i>BOOTREQUEST</i> message was sent. In addition, some devices incorrectly implemented this field. As a result, it is not always used.</p>									
<b>Flags</b>	2	<p><b>Flags:</b> In the original BOOTP standard (RFC 951), this was an empty two-byte field. RFC 1542 changed this to a <i>Flags</i> field, which at present contains only one flag. The structure of the field is thus as follows:</p> <table> <tr> <th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr> <tr> <td><b>B</b></td><td>1/8 (1 bit)</td><td><b>Broadcast Flag:</b> A client that doesn't know its own IP address at the time it sends its BOOTP request sets this flag to 1. This serves as an immediate indicator to the BOOTP server or relay agent that receives the request that it definitely should send its reply by broadcast.</td></tr> <tr> <td><b>Reserved</b></td><td>1 7/8 (15 bits)</td><td><b>Reserved:</b> Set to zero and not used.</td></tr> </table>	Subfield Name	Size (bytes)	Description	<b>B</b>	1/8 (1 bit)	<b>Broadcast Flag:</b> A client that doesn't know its own IP address at the time it sends its BOOTP request sets this flag to 1. This serves as an immediate indicator to the BOOTP server or relay agent that receives the request that it definitely should send its reply by broadcast.	<b>Reserved</b>	1 7/8 (15 bits)	<b>Reserved:</b> Set to zero and not used.
Subfield Name	Size (bytes)	Description									
<b>B</b>	1/8 (1 bit)	<b>Broadcast Flag:</b> A client that doesn't know its own IP address at the time it sends its BOOTP request sets this flag to 1. This serves as an immediate indicator to the BOOTP server or relay agent that receives the request that it definitely should send its reply by broadcast.									
<b>Reserved</b>	1 7/8 (15 bits)	<b>Reserved:</b> Set to zero and not used.									
<b>CIAddr</b>	4	<b>Client IP Address:</b> If the client has a current IP address that it plans to keep using, it puts it in this field. By filling in this field, the client is committing to responding to unicast IP datagrams sent to this address. Otherwise, it sets this field to all zero to tell the server it wants an address assigned. <a href="#">See the end of the detailed operation topic for important information on this field.</a>									
<b>YIAddr</b>	4	<b>“Your” IP Address:</b> The IP address that the server is assigning to the client. This may be different than the IP address currently used by the client. <a href="#">See the topic describing BOOTP operation in detail for an explanation of what happens in that case.</a>									
<b>SIAddr</b>	4	<b>Server IP Address:</b> The IP address of the BOOTP server sending a <i>BOOTREPLY</i> message.									

Table 187: BOOTP Message Format (*Page 3 of 3*)

Field Name	Size (bytes)	Description
<b>GIAddr</b>	4	<p><b>Gateway IP Address:</b> This field is used to route BOOTP messages when <a href="#">BOOTP relay agents</a> facilitate the communication of BOOTP requests and replies between a client and a server on different subnets or networks. To understand the name, remember that the old TCP/IP term for “router” is “gateway”; BOOTP relay agents are typically routers.</p> <p>Note that this field is set to 0 by the client and should be ignored by the client when processing a <i>BOOTREPLY</i>. It specifically does <b>not</b> represent the server giving the client the address of a default router address to be used for general IP routing purposes.</p>
<b>CHAddr</b>	16	<p><b>Client Hardware Address:</b> The hardware (layer two) address of the client sending a <i>BOOTREPLY</i>. It is used both to look up a device's assigned IP address and also possibly in delivery of a reply message.</p>
<b>SName</b>	64	<p><b>Server Name:</b> The server sending a <i>BOOTREPLY</i> may optionally put its name in this field. This can be a simple text “nickname” or a <a href="#">fully-qualified DNS domain name</a> (such as “myserver.organization.org”).</p> <p>Note that a client may specify a name in this field when it creates its request. If it does so, it is saying that it wants to get a reply only from the BOOTP server with this name. This may be done to ensure that the client is able to access a particular boot file stored on only one server</p>
<b>File</b>	128	<p><b>Boot Filename:</b> Contains the full directory path and file name of a boot file that can be downloaded by the client to complete its bootstrapping process. The client may request a particular type of file by entering a text description here, or may leave the field blank and the server will supply the filename of the default file.</p>
<b>Vend</b>	64	<p><b>Vendor-Specific Area:</b> Originally created to allow vendors to customize BOOTP to the needs of different types of hardware, this field is now also used to hold additional vendor-independent configuration information. <a href="#">See the next topic, on BOOTP vendor information extensions</a>. It may be used by the client and/or the server.</p>

As I mentioned in [the topic on BOOTP messaging](#), both requests and replies are encapsulated into UDP messages for transmission. The BOOTP standard specifies that the use of UDP checksums is optional. Using the checksum provides protection against data integrity errors and is thus recommended. This may cause unacceptable processing demands on the part of very simple clients, so the checksum can legally be skipped.

Similarly, for simplicity, BOOTP assumes that its messages will not be [fragmented](#). This is to allow BOOTP clients to avoid the complexity of reassembling fragmented messages. Since BOOTP messages are only 300 bytes in length, under the minimum MTU required for all TCP/IP links, this is not normally an issue.

**Figure 256: BOOTP Message Format**

---

## **BOOTP Vendor-Specific Area and Vendor Information Extensions**

The creators of the Boot Protocol realized that certain types of hardware might require additional information to be passed from the server to the client in order for the client to boot up. For this reason, they put into the BOOTP field format the 64-byte *Vend* field, also called the *Vendor-Specific Area*. Including this field makes BOOTP flexible, since it allows vendors to decide for themselves how they want to use the protocol, and to tailor it to their needs.

### ***Traditional Use of the Vendor-Specific Area***

A client can use the *Vend* field by asking for certain types of information in the field when composing its request. The server can then respond to these requests, and may also include parameters it wants the client to have even if they were not requested. The original BOOTP protocol does not define any structure for the *Vendor-Specific Area*, leaving this up to each manufacturer to decide.

Obviously, there is nothing preventing a client made by one manufacturer from trying to send a request to a server made by another one. If each one is expecting the *Vend* field to contain something different, the results will be less than satisfactory. Thus, for the *Vend* field to be used properly, both devices must be speaking the same “language” when it comes to the meaning of this field. This is done by setting the first four bytes of the field to a special value. Each manufacturer chooses its own “magic number” for this four-byte subfield, which is also sometimes called a “magic cookie”.

**Note:** Why is it called a magic “cookie”? I’m not sure, to be honest. I have heard tale that its origin may be the cookie that Alice ate to grow or shrink in the story *Alice in Wonderland*. Who knows. 😊

---

### ***BOOTP Vendor Information Extensions***

Including the *Vend* field in BOOTP gives the protocol extensibility for vendor-specific information. Unfortunately, the original field format didn’t include any way of extending the information sent from a server to a client for **generic**, non-vendor-specific TCP/IP information.

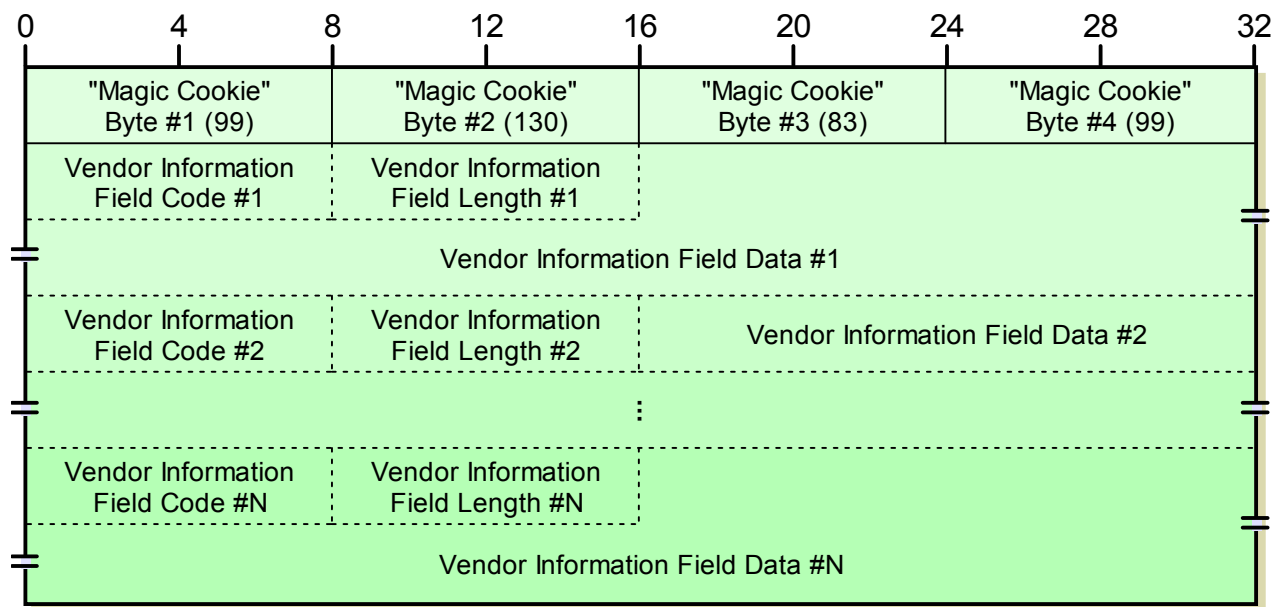

This was a significant oversight in the creation of the protocol, because there are many types of information that a TCP/IP host needs when it starts up that really have nothing to do with its vendor. For example, when a host boots, we probably want it to be told the address of a [default router](#); the [subnet mask](#) for its local subnet; the address of a local [DNS server](#); the [MTU](#) of the local network; and much more. None of these things are vendor-specific, but there is no place to put them in the BOOTP reply message.

Since there was no “non-vendor-specific area” field in BOOTP, the decision was made to define a way of using the *Vendor-Specific Area* for communicating this additional generic information. This was first standardized in RFC 1048, and then refined in later RFCs as I explained in [the BOOTP overview](#). This scheme basically represents one particular way of

---

using the *Vend* field that most TCP/IP BOOTP implementations have chosen to adopt, regardless of their vendor. This enhancement is formally referred to as *BOOTP vendor information extensions*.

To clearly mark that this particular meaning of the *Vend* field is being used, a special, universal “magic cookie” value of “99.130.83.99” is inserted into the first four bytes of the field. Then, the remaining 60 bytes can contain a sequence of one or more *vendor information fields*. The overall structure of the *Vendor-Specific Area* when vendor information extensions are used is shown in [Figure 257](#).

**Figure 257: BOOTP Vendor-Specific Area Format Showing Vendor Information Fields**

The BOOTP Vendor-Specific Area begins with the four-byte “magic cookie” and then contains a number of variable-length vendor information fields, each of which has the format shown above and in [Table 188](#).

**Note:** Despite the use of [dotted decimal notation](#) to represent the value “99.130.83.99”, this is **not** an IP address. It's just a marker, a “magic number” that is universally recognized.

**Key Concept:** The BOOTP message format includes a *Vend* field that was originally intended for vendor-specific customized fields. It was later changed to a place where additional generic information could be sent from a BOOTP server to a BOOTP client. Each such parameter is carried in a BOOTP *vendor information field*.

---

## BOOTP Vendor Information Fields

Each vendor information field specifies a particular type of information to be communicated, and is encoded using a special subfield structure that specifies the field's type, length and value. This is a common method of specifying options, called *TLV-encoding* (for *type*, *length*, *value* of course). The same basic method is used for encoding IPv4 and IPv6 options. [Table 188](#) shows the structure and the common names for the subfields of each vendor information field.

**Table 188: BOOTP Vendor Information Field Format**

Subfield Name	Size (bytes)	Description
<b>Code</b>	1	<b>Vendor Information Field Code:</b> A single octet that specifies the vendor information field type.
<b>Len</b>	1	<b>Vendor Information Field Length:</b> The number of bytes in this particular vendor information field. This does not include the two bytes for the <i>Code</i> and <i>Len</i> fields.
<b>Data</b>	Variable	<b>Vendor Information Field Data:</b> The data being sent, which has a length indicated by the <i>Len</i> subfield, and which is interpreted based on the <i>Code</i> subfield.

There are two special cases that violate the field format of [Table 188](#). A *Code* value of 0 is used as a *pad*, when subfields need to be aligned on word boundaries; it contains no information. The value 255 is used to mark the end of the vendor information fields. Both of these codes contain no actual data, so to save space, when either is used just the single *Code* value is included; the *Len* and *Data* fields are omitted. A device seeing a *Code* value of 0 just skips it as filler; a device seeing a *Code* value of 255 knows it has reached the end of the vendor information fields in this *Vend* field.

The vendor information extensions of BOOTP have become so popular that the use of this field for sending extra generic information is pretty much standard. In fact, I am not even sure if anyone today still uses the *Vend* field solely for vendor-specific information at all.

When the vendor information extensions were introduced, one was created that points to a file where vendor-specific information can be found. This lets devices have the “best of both worlds”—they can use the standard vendor-independent fields and also incorporate vendor-specific fields (through the referenced file) where needed. Later, another field type was created that lets vendor-specific fields be mixed with vendor-independent ones right in a BOOTP message.

When DHCP was created, the same vendor extension mechanism was maintained and enhanced further, but instead of the field being called “vendor information extensions”, it was renamed to *Options*. (A much better name!) The BOOTP vendor information fields were retained in DHCP and new DHCP-specific options were defined. To avoid duplication, I have listed all the BOOTP vendor information fields and DHCP options in [a set of tables in the section on DHCP](#). This includes a discussion of how vendor-specific and vendor-

---

independent information can be mixed as I mentioned in the previous paragraph. You may also want to read [the topic describing DHCP options](#) and discussing how they were created from BOOTP vendor information extensions.

## **BOOTP Relay Agents (Forwarding Agents)**

One reason why the [Reverse Address Resolution Protocol \(RARP\)](#) was quickly replaced by BOOTP is that RARP required the client being configured and the server providing it with an IP address to be on the same physical network. Sure, this is fine when you run a small organization with 10 machines. In this case, all 10 are probably on the same physical network anyway. Larger networks must be divided into multiple physical networks for efficiency, however. RARP would require a separate RARP server for each network, meaning having to duplicate all the functions of a single server onto multiple machines. Worse yet, all the configuration information would also be duplicated, and any changes would have to be made to all the different servers each time.

### ***Why BOOTP Relay Agents Are Necessary***

Unlike RARP, BOOTP is designed to allow the BOOTP server and the clients it serves to be on different networks. This centralizes the BOOTP server and greatly reduces the amount of work required of network administrators. However, implementing this feature means increasing the complexity of the protocol. In particular, we need to involve a “third party” device in the configuration process.

You might rightly wonder why this would be the case. Sure, RARP is a low-level protocol that works at the link layer, so that explains why it would have problems putting the client and server on different physical networks. But wasn't the whole point of making BOOTP a high-level protocol that it was able to use IP? And if BOOTP uses IP, can't we send from one network to another arbitrarily just like any IP-based messaging protocol?

The answer is that even though we are indeed using IP and UDP, BOOTP still has one of the same issues that RARP had: a reliance on *broadcasts*. The client usually doesn't know the address of a server, so it has to [send out its request as a broadcast](#), saying in essence, “can anyone hear this and give me the information I need?” For efficiency reasons, routers do not route such broadcasts, as they would clog the network. This means that if the server and client are not on the same network, the server can't hear the client's broadcast. Similarly, if the server ever did get the request and broadcast its reply back to the client, the client would never get it anyway.

### ***The Function of BOOTP Relay Agents***

To make this all work, then, we need ***something*** to act as an intermediary between the client and the server: a *BOOTP relay agent*. The job of a BOOTP relay agent is to sit on a physical network where BOOTP clients may be located and act as a proxy for the BOOTP server. The agent gets its name because it relays messages between the client and server, and thus enables them to be on different networks.

**Note:** BOOTP relay agents were originally called *forwarding agents*. That name was considered too easy to cause confusion between BOOTP operation and the general “forwarding” behavior of regular routers. RFC 1542 changed the name to make explicit the fact that BOOTP relaying was not the same as conventional IP datagram forwarding.

---

In practice, a BOOTP relay agent is not usually a separate piece of hardware. It's a software module that runs on an existing piece of hardware that performs other functions. It is common for BOOTP relay agent functionality to be implemented on an IP router. In that case, the router is acting both as a “regular” router and also playing the **role** of a BOOTP agent. The forwarding functions required of a BOOTP relay agent are distinct from the normal IP datagram forwarding tasks of a router (though there are certain similarities as we will see.)

Naturally, the placement of the client and server on different networks and the presence of a relay agent changes [the normal request/reply process of BOOTP](#) significantly. A couple of specific fields in the BOOTP message format are used to control the process. RFC 951 was rather vague in describing how this process works, so RFC 1542 described it in much more detail.

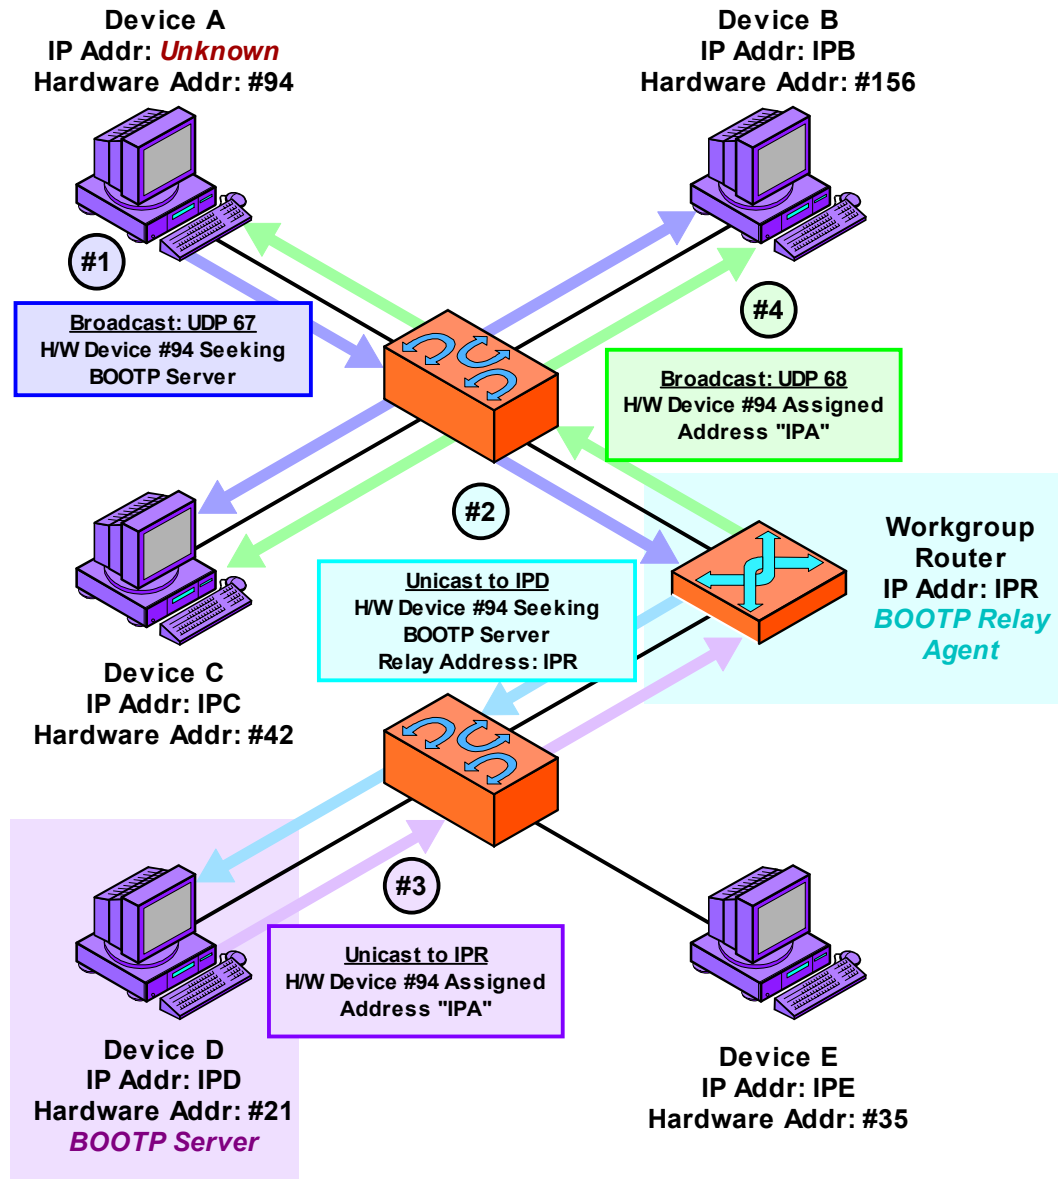

**Key Concept:** Since BOOTP uses broadcasts, the BOOTP client and BOOTP server must be on the same physical network to be able to hear each others broadcasted transmissions. For a client and server on different networks to communicate, a third party is required to facilitate the transaction: a *BOOTP relay agent*. This device, which is often a router, listens for transmissions from BOOTP clients and relays them to the BOOTP server. The server responds back to the agent, which then sends the server's response back to the client.

---

### ***Normal BOOTP Operation Using a Relay Agent***

The following shows, in simplified form, a revised set of BOOTP operation steps when a relay agent is involved. To keep the size of this topic manageable I have omitted the details of the basic request/reply process to focus on the relaying functionality, which you can also see graphically in [Figure 258](#):

1. **Client Creates Request:** The client machine creates its request normally. The existence of a relay agent is totally transparent to the client.
2. **Client Sends Request:** The client broadcasts the *BOOTREQUEST* message by transmitting it to address 255.255.255.255. (Note that in the case where a client already knows both its own address and the address of a BOOTP server, we don't need the relay agent at all—both the request and reply can be sent unicast over an arbitrary internetwork.)

**Figure 258: BOOTP Operation Using A Relay Agent**

In this example, Device A is trying to access a BOOTP server, but the only one is on a different network; the two are connected by a workgroup router that is configured to act as a BOOTP relay agent. Device A broadcasts its request, which the router receives. It relays the request to the BOOTP server, Device D, and puts its own IP address (IPR) into the BOOTP *GIAddr* field. The BOOTP server sends the reply back to the router using address *IPR*. The router then broadcasts it on Device A's local network so that A can receive it.

3. **Relay Agent Receives Request and Processes It:** The BOOTP relay agent on the physical network where the client is located is listening on UDP port 67 on the server's behalf. It processes the request as follows:
  - It checks the value of the *Hops* field. If the value is less than or equal to 16, it increments it. If the value is greater than 16, it discards the request and does nothing further.

- 
- It examines the contents of the *GIAddr* field. If this field is all zeroes, it knows it is the first relay agent to handle the request and puts its own IP address into this field. (If the agent is a router it has more than one IP address, so it chooses the one of the interface upon which it received the request.)
4. **Relay Agent Relays Request:** The relay agent sends the BOOTP request to the BOOTP server. If the relay agent knows the server's IP address it will send it unicast directly to the server. Otherwise, if the agent is a router, it may choose to broadcast the request on a different interface from the one on which it received the request. In the latter case, it is possible that multiple relay agents may be required to convey the request to the server. See below for more on this.
  5. **Server Receives Request and Processes It:** The BOOTP server receives the relayed request from the BOOTP relay agent. It processes it as normal.
  6. **Server Creates Reply:** The server creates a reply message as normal.
  7. **Server Sends Reply:** Seeing that the *GIAddr* field in the request was non-zero, the server knows the request was relayed. Instead of trying to send its reply back to the client that sent the request, it transmits the reply unicast back to the relay agent specified in *GIAddr*.
  8. **Relay Agent Relays Reply:** The BOOTP relay agent transmits the *BOOTREPLY* message back to the client. It does this either unicast or broadcast, depending on the value of the *CIAddr* field and the *B* (*Broadcast*) flag, just like a server does in the non-relay case.

### **Relaying BOOTP Requests Using Broadcasts**

The simplest case of relaying is when each network has a relay agent that knows the IP address of the BOOTP server. The relay agent “captures” the request in step 3 above, and sends it directly to the BOOTP server, wherever it may be on the network. The request is relayed as a regular unicast UDP message and routed to the BOOTP server. The BOOTP server's reply is routed back to the BOOTP relay agent just like any UDP message in an IP datagram, and the relay agent forwards the reply.

It is also possible to set up BOOTP relay agents to relay requests even if they don't know the BOOTP server's address. These agents take requests received on one network and relay them to the next, where they expect another agent to continue the relaying process until a BOOTP server is reached. For example, suppose we have a set of three networks. Network *N1* is connected to Network *N2* using Router *RA*, and *N2* connects to *N3* using Router *RB*. Both of these routers function as relay agents but don't know the IP address of the BOOTP server. Here's what would happen if a client on *N1* sent a request and the server was on *N3*:

1. The client would send its request.
2. *RA* would capture the request and put its address into *GIAddr*. It would increment the *Hops* field to a value of 1 and then broadcast the request out on Network *N2*.
3. *RB* would capture this request. It would see there is already an address in *GIAddr* so it would leave that alone. It would increment the *Hops* field to 2 and broadcast the request on Network *N3*.

- 
4. The BOOTP server would receive the request, process it and return the reply directly back to *RA*.
  5. *RA* would relay the reply back to the client.

As you can see, the purpose of the *Hops* field is to ensure that errant requests don't circle around the network endlessly. Each relay agent increments it and if the value of 16 is ever exceeded, the request is dropped. You can also see that any relay agents other than the first are involved only for handling the request; the reply is sent unicast back to the agent closest to the client.

Incidentally, if this multiple-step relaying process sounds like IP routing (only using broadcasts), and the *Hops* field sounds like the *Time To Live* field in an [IP datagram](#), then you've been paying attention. It is essentially the same idea.

---

## **TCP/IP Dynamic Host Configuration Protocol (DHCP)**

In some ways, technological advancement can be considered more a journey than a destination. When a particular technology is refined or replaced with a superior one, it's usually only a matter of time before it too is replaced with something better. And so it was with the [TCP/IP Boot Protocol](#). While BOOTP was far more capable than the protocol it replaced ([RARP](#)), after a number of years BOOTP itself was replaced with a new TCP/IP configuration protocol: the *Dynamic Host Configuration Protocol (DHCP)*.

Where BOOTP represented a revolutionary change from RARP, DHCP is more of an evolution of BOOTP. It was built using BOOTP as a foundation, with the same basic message format. The most significant addition in DHCP is the ability to *dynamically* assign addresses to clients and to centrally manage them. It is this capability that both gives DHCP its name, and makes it so powerful. DHCP today is the standard TCP/IP host configuration protocol and is used in everything from single-client home networks to enterprise-class internetworks.

In this section I describe the concepts behind DHCP and explain how it works in detail. I begin with a topic that provides an overview of the protocol, discussing its history and the standards that define it. I then have four subsections that describe DHCP concepts and operation. The first talks about the different ways DHCP can assign addresses, with a focus on dynamic addressing. The second discusses how DHCP operates, including a look at configuration parameter management and the procedures for allocating addresses and managing those allocations. The third describes DHCP messaging and illustrates the DHCP message format. The fourth gets into more of the details of DHCP clients and servers, and also looks at special features and issues with DHCP. Finally, I conclude with a topic describing how DHCP changes to support the new IP version 6.

**Related Information:** Since DHCP builds upon BOOTP, they have a number of things in common. For example, DHCP makes use of [BOOTP relay agent functionality](#), and DHCP options are basically the same as [BOOTP vendor information fields](#). Since DHCP is the more common of the two protocols, I have tried to be complete in describing the operation of these features here, highlighting especially any differences between how they work for DHCP compared to BOOTP.

However, I have avoided duplicating the history and reasoning for the existence of many of these features. Since BOOTP came first, I have placed more of the historical information in the BOOTP section. In general, if you plan to read about DHCP as well as BOOTP, I recommend reading [the section on BOOTP first](#). If you don't plan to read up on BOOTP, you may wish to check [the topic on DHCP/BOOTP interoperability](#) instead.

---

---

## **DHCP Overview, Motivation, History and Standards**

**BOOTP** represents a significant improvement over RARP because it solves so many of RARP's problems. BOOTP is a higher-layer protocol, not hardware-dependent like RARP. It can support sending extra information beyond an IP address to a client to enable customized configuration. Also, through the use of **BOOTP relay agents**, it allows a large organization to use just one or two BOOTP servers to handle clients spread out over many physical networks.

In so doing, BOOTP effectively solves one of the major classes of problems that administrators have with manual configuration: the “I have to go configure each host myself” issue. It allows “dumb” (storageless) hosts to configure themselves automatically, and saves techies the hassles of needing to trek to each host individually to specify important configuration parameters.

### ***The Need for Dynamic Address Assignment***

BOOTP normally uses a static method of determining what IP address to assign to a device. When a client sends a request, it includes its hardware address, which the server looks up in a table to determine the IP address for that client. (It is possible for BOOTP to use other methods of determining the relationship between an IP and hardware address, but static mapping is usually used.) This means BOOTP works well in relatively static environments, where changes to the IP addresses assigned to different devices are infrequent. Such networks were basically the norm in the 1980s and early 1990s.

Over time, many networks quickly started to move away from this model, for a number of reasons. As computers became smaller and lighter, it was more common for them to move from one network to another, where they would require a different address using the new network's **network ID**. Laptop and even palmtop computers could literally move from one network to another many times per day. Another major issue was the **looming exhaustion of the IP address space**. In many organizations, permanently assigning a static IP address to each and every computer that might connect to their network was a luxury they could not afford.

In many organizations, trying to keep track of constant IP address changes became a daunting task in and of itself. BOOTP, with its static table of mappings between hardware addresses and IP addresses, simply wasn't up to the task. It also offered no way to reuse addresses; once an address had been assigned, a device could keep it forever, even if it were no longer needed.

### ***DHCP: Building on BOOTP's Strengths***

A new host configuration protocol was needed to serve modern networks, which would move away from static, permanent IP address assignment. The IETF supplied this in the form of the *Dynamic Host Configuration Protocol (DHCP)*, first formalized in RFC 1541, October 1993. (Actually, it was really originally specified in RFC 1531 in that same month, but due to minor errors in 1531 the standard was quickly revised and 1541 published.)

---

Of course, it's not like BOOTP was a bad protocol or anything. It certainly worked well, for what it was capable of doing. It was also already widely deployed. Given these factors, it really made no sense to start over from scratch with DHCP. This was especially so given that such a decision would have meant dealing with the inevitable “painful” transition, as well as compatibility problems associated with having both BOOTP and DHCP around for many years.

So, instead of tossing out BOOTP, DHCP was built upon it as a foundation. In its simplest form, DHCP consists of two major components: an address allocation mechanism, and a protocol that allows clients to request, and servers to provide, configuration information. DHCP performs both functions in a manner similar to BOOTP, but with improvements.

### **Overview of DHCP Features**

The most significant changes are in the area of [address allocation](#), which is enhanced through the support for *dynamic* address assignment mentioned above. Rather than using a static table that absolutely maps hardware addresses to IP addresses, a *pool* of IP addresses is used to dynamically allocate addresses. This allows addresses to be shared amongst many machines, as well as providing other benefits. Dynamic addressing allows IP addresses to be efficiently allocated, and even shared amongst devices. At the same time, DHCP still supports static mapping of addresses for devices where this is needed.

The [overall operation and communication between clients and servers](#) is again similar to that used by BOOTP, but with changes. The same basic request/reply protocol using UDP was retained for communicating configuration information, but additional message types were created to support DHCP's enhanced capabilities. BOOTP relay agents can be used by DHCP in a manner very similar to how they are used by BOOTP clients and server. The vendor information extensions from BOOTP were retained as well, but were formalized, renamed *DHCP options*, and extended to allow the transmission of much more information.

The result of all of this development effort is a widely-accepted, universal host configuration protocol for TCP/IP that retains compatibility with BOOTP while significantly extending its capabilities. Today, DHCP is found on millions of networks worldwide. It is used for everything from assigning IP addresses to multi-thousand-host corporate networks, to allowing a home Internet access router to automatically providing the correct Internet configuration information to a single user's computer.

The original DHCP specification was revised in March 1997 with the publishing of RFC 2131, also entitled *Dynamic Host Configuration Protocol*. This standard defined another new DHCP message type to allow [active IP hosts to request additional configuration information](#). It also made several other small changes to the protocol. Since that time numerous other DHCP-related RFCs have been published, most of which either define new DHCP option types (other kinds of information DHCP servers can send to DHCP clients) or slightly refine the way that DHCP is used in particular applications.

**Key Concept:** The *Dynamic Host Configuration Protocol (DHCP)* is the host configuration protocol currently used on modern TCP/IP internetworks. It was based on BOOTP and is similar to its predecessor in many respects, including the use of request/reply message exchanges and a nearly-identical message format. However, DHCP includes added functionality, the most notable of which is *dynamic address assignment*, which allows clients to be assigned IP addresses from a shared pool managed by a DHCP server.

---

---

## **DHCP Address Assignment and Dynamic Address Allocation and Management**

The Dynamic Host Configuration Protocol (DHCP) was created as an extension of the older Boot Protocol (BOOTP). The first word in “DHCP” describes the most important new capability that was added to BOOTP: the ability to assign IP addresses *dynamically*. Moving from a static to a dynamic address allocation model dramatically changes the way we deal with IP addresses in DHCP. Host configuration is transformed from a simple way to tell a host what its address and other parameters are, to a complete tool for managing IP addresses in an organization.

In this section I begin my detailed look at DHCP by describing the concepts behind DHCP address assignment and leases. I begin with a look at how DHCP address assignment works, and a description of the three DHCP address allocation mechanisms. I then delve into DHCP leases and the policies and techniques used to decide how to implement DHCP leasing. I provide an overview of the lease “life cycle” from start to finish, and describe the two DHCP lease timers that help control the process. Finally, I describe DHCP lease address pools and ranges and the general concepts behind address management.

### **DHCP Address Assignment and Allocation Mechanisms**

The two main functions of the Dynamic Host Configuration Protocol are to provide a mechanism for assigning addresses to hosts, and a method by which clients can request addresses and other configuration data from servers. Both functions are based on the ones implemented in DHCP's predecessor, BOOTP, but the changes are much more significant in the area of address assignment than they are in communication. It makes sense to start our look at DHCP here, since this will naturally lead us into a detailed discussion of defining characteristic of DHCP: *dynamic addressing*.

#### ***DHCP Address Allocation Mechanisms***

Providing an IP address to a client is the most fundamental configuration task performed by a host configuration protocol. To provide flexibility for configuring addresses on different types of clients, the DHCP standard includes three different address allocation mechanisms:

- ☉ **Manual Allocation:** A particular IP address is pre-allocated to a single device by an administrator. DHCP only communicates the IP address to the device.
- ☉ **Automatic Allocation:** DHCP automatically assigns an IP address permanently to a device, selecting it from a pool of available addresses.
- ☉ **Dynamic Allocation:** DHCP assigns an IP address from a pool of addresses for a limited period of time chosen by the server, or until the client tells the DHCP server that it no longer needs the address.

I don't really care for the names “automatic” and “dynamic” allocation, because they don't do a good job of clearly conveying the differences between these methods. Both can be considered “automatic” because in each the DHCP server assigns an address with no

---

administrator intervention required. The real difference between them is only in how long the IP address is retained, and therefore, whether a host's address varies over time. I think better names would be “static/permanent automatic allocation” and “dynamic/temporary automatic allocation”. But then, nobody really cares much what I think. ☺

Regardless of what you call them, all three of these methods exist for configuring IP hosts using DHCP. It is not necessary for an administrator to choose one over the others. Instead, he or she will normally combine the methods, using each for the devices where it makes the most sense.

### ***Manual Allocation***

Manual allocation is the simplest method, and is equivalent to [the method BOOTP uses for address assignment](#). Each device has an address that an administrator gives it ahead of time, and all DHCP does is look up the address in a table and send it to the client for which it is intended. This technique makes the most sense for devices that are “mainstays” of the network, such as servers and routers. It is also appropriate for other devices that for whatever reason must have a stable, permanent IP address.

Okay, now here's a fair question you might have. DHCP acts basically like BOOTP in the case of manual allocation. But BOOTP was created for devices that needed help with configuration. Servers and routers are complex devices with their own internal storage, and obviously don't need a DHCP server to tell them their IP address like a diskless workstation does, so why bother using DHCP for them at all?

Well, in fact, you could just manually assign the address to the device directly and tell DHCP to ignore those addresses. However, using DHCP for manual assignments yields a different benefit: an **administrative** one. It keeps all the IP address information centralized in the DHCP address database, instead of requiring an administrator to go from machine to machine checking addresses and ensuring there are no duplicates. Updates can also be made in a single place as well.

### ***Dynamic Allocation***

While manual allocation is possible in DHCP, dynamic allocation is its real “raison d'être”. An administrator sets up a *pool* (usually a range or set of ranges) of IP addresses that are available for use. Each client that is configured to use DHCP contacts the server when it needs an IP address. The server keeps track of which IP addresses are already assigned, and *leases* one of the free addresses from the pool to the client. The server decides the amount of time that the lease will last. When the time expires, the client must either request permission to keep using the address (renewing the lease) or must get a new one. This matter of leases and how they are handled will be the subject of most of the rest of this section.

Dynamic allocation is the method used for most client machines in modern DHCP-enabled IP internetworks. It offers numerous benefits, including the following:

- 
- ☉ **Automation:** Each client can be automatically assigned an IP address when it is needed with no intervention and no need for an administrator to manually decide which address goes with which client.
  - ☉ **Centralized Management:** All the IP addresses are managed by the DHCP server. An administrator can easily look to see which devices are using which addresses and perform other network-wide maintenance tasks.
  - ☉ **Address Reuse and Sharing:** By limiting the amount of time that each device holds an IP address, the DHCP server can ensure that the pool of IP addresses is only used by devices actively using the network. After a period of time, addresses no longer being used are returned to the pool, allowing other devices to use them. This allows an internetwork to support a total number of devices larger than the number of IP addresses available, as long as not all the devices connect to the internetwork at the same time.
  - ☉ **Portability and Universality:** BOOTP (and DHCP manual allocation) both require that the DHCP server “know” the identity of each client that connects to it, so the server can find the client's assigned address. With dynamic allocation, there are no predefined allocations, so any client can request an IP address. This inherently makes dynamic allocation the ideal choice for supporting mobile devices that travel between networks.
  - ☉ **Conflict Avoidance:** Since IP addresses are all assigned from a pool that is managed by the DHCP server, IP address conflicts are avoided.

The last point, of course, assumes that all the clients use DHCP. The administrator must ensure that the address pool is not used by non-DHCP devices. More about this in [a later topic on DHCP address ranges and address management](#).

### ***Automatic Allocation***

The third option, automatic allocation, can be used in cases where there are enough IP addresses for each device that may connect to the network, but where devices don't really care what IP address they use. Once an address is assigned to a client, that device will keep using it. Automatic allocation can be considered a “special case” of dynamic allocation: it is essentially dynamic allocation where the time limit on the use of the IP address by a client (the lease length) is “forever”.

In practice, automatic allocation is not used nearly as much as dynamic allocation, for a simple reason: automatically assigning an IP address to a device permanently is a risky move. Most administrators feel it is better to use manual allocation for the limited number of machines that really need a permanent IP address assignment, and dynamic addressing for others. We'll discuss this more in the next topic.

**Key Concept:** DHCP defines three basic mechanisms for address assignment. *Dynamic allocation* is the method most often used, and works by having each client *lease* an address from a DHCP server for a period of time; the server chooses the address dynamically from a shared address pool. *Automatic allocation* is like dynamic allocation but the address is assigned permanently instead of being leased. *Manual allocation* pre-assigns an address to a specific device, just as BOOTP does, and is normally used only for servers and other permanent, important hosts.

---

## **DHCP Leases, Lease Length Policies and Management**

Of the [three address allocation methods](#) supported by DHCP, dynamic address allocation is by far the most popular and important. The significance of the change that dynamic addressing represents to how IP addresses are used in TCP/IP can be seen in the semantics of how addresses are treated in DHCP. Where conventionally a host was said to **own** an IP address, when dynamic address allocation is used, hosts are said instead to **lease** an address.

The notion of a “lease” conveys very accurately the difference between dynamic allocation and the other types. A host no longer is strictly “entitled” to a particular address, with a server merely telling it what the address is. In DHCP, the server remains the real owner of all the IP addresses in the address pool, and merely gives permission for a client to use the address for a period of time. The server guarantees that it will not try to use the address for another client only during this time. The client is responsible for taking certain actions, as we will see later in this section, if it wants to continue using the address. If it does not successfully reacquire permission for using the address after a period of time, it must stop using it, or risk creating an IP address conflict on the network.

**Key Concept:** DHCP’s most significant new feature is dynamic allocation, which changes the way that IP addresses are managed. Where in traditional IP each device owns a particular IP address, in DHCP the server owns all the addresses in the address pool, and each client *leases* an address from the server, usually only for a limited period of time.

---

## ***DHCP Lease Length Policy and Choosing Lease Durations***

When dynamic address allocation is used, the administrator of the network must provide parameters to the DHCP server to control how leases are assigned and managed. One of the most important decisions to be made is the *lease length policy* of the internetwork: how long the administrator wants client leases to last. There of course is no “right answer”—the right lease length interval depends on the network, the server, and the clients. The choice of lease time, like so many other networking parameters, boils down to a trade-off between *stability* and *allocation efficiency*.

---

The primary benefit of using long lease times is that the addresses of devices are relatively stable. A device doesn't have to worry about its IP address changing all the time—and neither does its user. This is a significant advantage in many cases, especially when it is necessary for the client to perform certain server functions, accept incoming connections, or use a DNS domain name (ignoring for the moment [dynamic DNS](#) capabilities). In those situations, having the IP address of a device moving all over the place can cause serious complications.

The main drawback of using long leases is that they substantially increase the amount of time that an IP address, once no longer needed, is “tied up” before it can be reused. In the worst case scenario, the amount of “wasted time” for an allocation can be almost as long as the lease itself. If we give a device a particular address for six months and after two weeks the device is shut down and no longer used, the IP address that it was using is still “unavailable” for another five and a half more months.

For this reason, many administrators prefer to use short leases. This forces a client to continually renew the lease as long as it needs it. When it stops asking for permission again, the address is quickly put back into the pool. This makes shorter leases a better idea in environments where the number of addresses is limited and must be conserved. The drawback, of course, is the opposite of the benefit of long leases: constantly-changing IP addresses.

### ***Common Lease Durations***

The administrator need not pick from “short” and “long” lease durations. He or she can “compromise” by choosing a number that best suits the network. Some examples of lease times and the reasoning behind them:

- ☉ **One Hour Or Less:** Ensures maximum IP address allocation efficiency in a very dynamic environment where there are many devices connecting and disconnecting from the network, and the number of IP addresses is limited.
- ☉ **One Day:** Suitable for situations where “guest” machines typically stay for a day, to increase IP efficiency when many employees work part-time, or otherwise to ensure that every day each client must ask again for permission to use an address.
- ☉ **Three Days:** This is the default used by Microsoft. This alone makes it a popular choice.
- ☉ **One Week:** A reasonable “compromise” between the shorter and longer times.
- ☉ **One Month:** Another “compromise”, closer to the longer end of the lease time range.
- ☉ **Three Months:** Provides reasonable IP address stability so that addresses don't change very often in reasonably static environments. Also a good idea if there are many IP addresses available and machines are often turned off for many days or weeks at a time. May be used in a university setting to ensure that IP addresses of returning students are maintained over the summer recess.
- ☉ **One Year:** An approximation of an “infinite” lease; see below.

---

## ***Assigning Lease Length By Client Type***

In fact, not only is the administrator not restricted to a limited number of possible lease durations, it is not necessary for the administrator to choose a constant lease length policy for all clients. Depending on the capabilities of the DHCP server, an administrator may select different lease lengths for certain clients than others. For example, the administrator may decide to use long leases for desktop computers that are permanently assigned to a particular subnet and not moved, and a pool of short-leased addresses for notebooks and “visitors”. In some DHCP implementations this can be done by assigning clients to particular “classes”. Of course, this requires more work (and may even require multiple servers.)

## ***Factoring Lease Renewal Into Lease Length Selection***

In selecting a lease time policy, the administrator must also bear in mind that by default, after half the length of a lease, the client will begin attempting to renew the lease. This may make it more advisable to use a longer lease time, to increase the amount of time between when a client tries to renew the lease and when the lease expires. For example, in a network with a single DHCP server, an administrator may want to use leases no shorter than eight hours. This provides a four-hour “window” for maintenance on the server without leases expiring.

When a lease is very short, such as minutes or hours, it will typically expire when a client machine is turned off for a period of time, such as overnight. Longer leases will persist across reboots. The client in this case will still contact the DHCP server each time it is restarted to *reallocate* the address—confirm that it may continue using the address it was assigned.

**Key Concept:** A key decision that a network administrator using DHCP must make is what the network’s lease length policy will be. Longer leases allow devices to avoid changing addresses too often, while shorter leases are more efficient in terms of reallocating addresses that are no longer required. An administrator can choose from a variety of different lease times, and may choose longer leases for some devices than for others.

---

## ***Issues With “Infinite” Leases***

In addition to choosing a particular lease length number, it is possible to specify an “infinite” lease length duration for certain clients. This effectively turns dynamic allocation into automatic allocation for a particular client. As I said in [the previous topic](#), however, this is generally not done. The reason is that an infinite lease never expires, and as the old saw goes, “never is a long time”. ☺

Permanently assigning an IP address from a pool is a somewhat “risky” move, because once assigned, if anything occurs that causes that address to be no longer used, it can never be recovered. A worst-case scenario would be a visitor to a company site who plugs

---

a notebook computer in to the network to check e-mail or transfer a file. If that machine is assigned an IP address using automatic allocation, the visitor will “take it with him” when he leaves. Obviously, not a great idea.

For this reason, most administrators prefer to use dynamic allocation instead, with addresses set to a very long time frame, such as a year or two years. This is considered “near enough to infinity” that it approximates a permanent assignment, but allows an IP address to *eventually* be recovered if a device for whatever reason stops using it. In such a policy, anything that really, truly needs a permanent assignment is given an address using *manual* assignment, which requires a conscious decision to dedicate the address to a particular device.

**Related Information:** For a little more information related to lease length selection, see [the topic on DHCP server implementation problems and issues](#).

---

## **DHCP Lease "Life Cycle" Overview (Allocation, Reallocation, Renewal, Rebinding and Release) and Lease Timers**

The use of dynamic address allocation in DHCP means a whole new way of thinking about addresses. A client no longer owns an address, but rather *leases* it. This means that when a client machine is set to use DHCP dynamic addressing, it can never assume that it has an address on a permanent basis. Each time it powers up, it must engage in communications with a DHCP server to begin or confirm the lease of an address. It also must perform other activities over time to manage this lease and possibly terminate it.

### ***The DHCP Lease "Life Cycle"***

Calling dynamic address assignments *leases* is a good analogy, because a DHCP IP address lease is similar to a “real world” lease in a number of respects. For example, when you rent an apartment, you sign the lease. Then you use the apartment for a period of time. Typically, assuming you are happy with the place, you will *renew* the lease before it expires, so you can keep using it. If by the time you get near the end of the lease the owner of the apartment has not allowed you to renew it, you will probably lease a different apartment to ensure you have somewhere to live. And if you decide, say, to move out of the country, you may terminate the lease and not get another at all.

DHCP leases follow a similar lease “life cycle”, which generally consists of the following phases:

- ☉ **Allocation:** A client begins with no active lease, and hence, no DHCP-assigned address. It acquires a lease through a process of *allocation*.
- ☉ **Reallocation:** If a client already has an address from an existing lease, then when it reboots or starts up after being shut down, it will contact the DHCP server that granted it the lease to confirm the lease and acquire operating parameters. This is sometimes called *reallocation*; it is similar to the full allocation process but shorter.

- 
- ☉ **Normal Operation:** Once a lease is active, the client functions normally, using its assigned IP address and other parameters during the “main part” of the lease. The client is said to be *bound* to the lease and the address.
  - ☉ **Renewal:** After a certain portion of the lease time has expired, the client will attempt to contact the server that initially granted the lease, to *renew* the lease so it can keep using its IP address.
  - ☉ **Rebinding:** If renewal with the original leasing server fails (because, for example, the server has been taken offline), then the client will try to *rebind* to any active DHCP server, trying to extend its current lease with any server that will allow it to do so.
  - ☉ **Release:** The client may decide at any time that it no longer wishes to use the IP address it was assigned, and may terminate the lease, *releasing* the IP address. Like the apartment-renter moving out of the country, this may be done if a device is moving to a different network, for example. Of course, unlike DHCP servers, landlords usually don't let you cancel a lease at your leisure, but hey, no analogy is perfect.

Figure 259 illustrates the DHCP life cycle using an example that spans three leases.

### **Renewal and Rebinding Timers**

The processes of renewal and rebinding are designed to ensure that a client's lease can be extended before it is scheduled to end, so no loss of functionality or interruption occurs to the user of the client machine. Each time an address is allocated or reallocated, the client starts two timers that control the renewal and rebinding process:

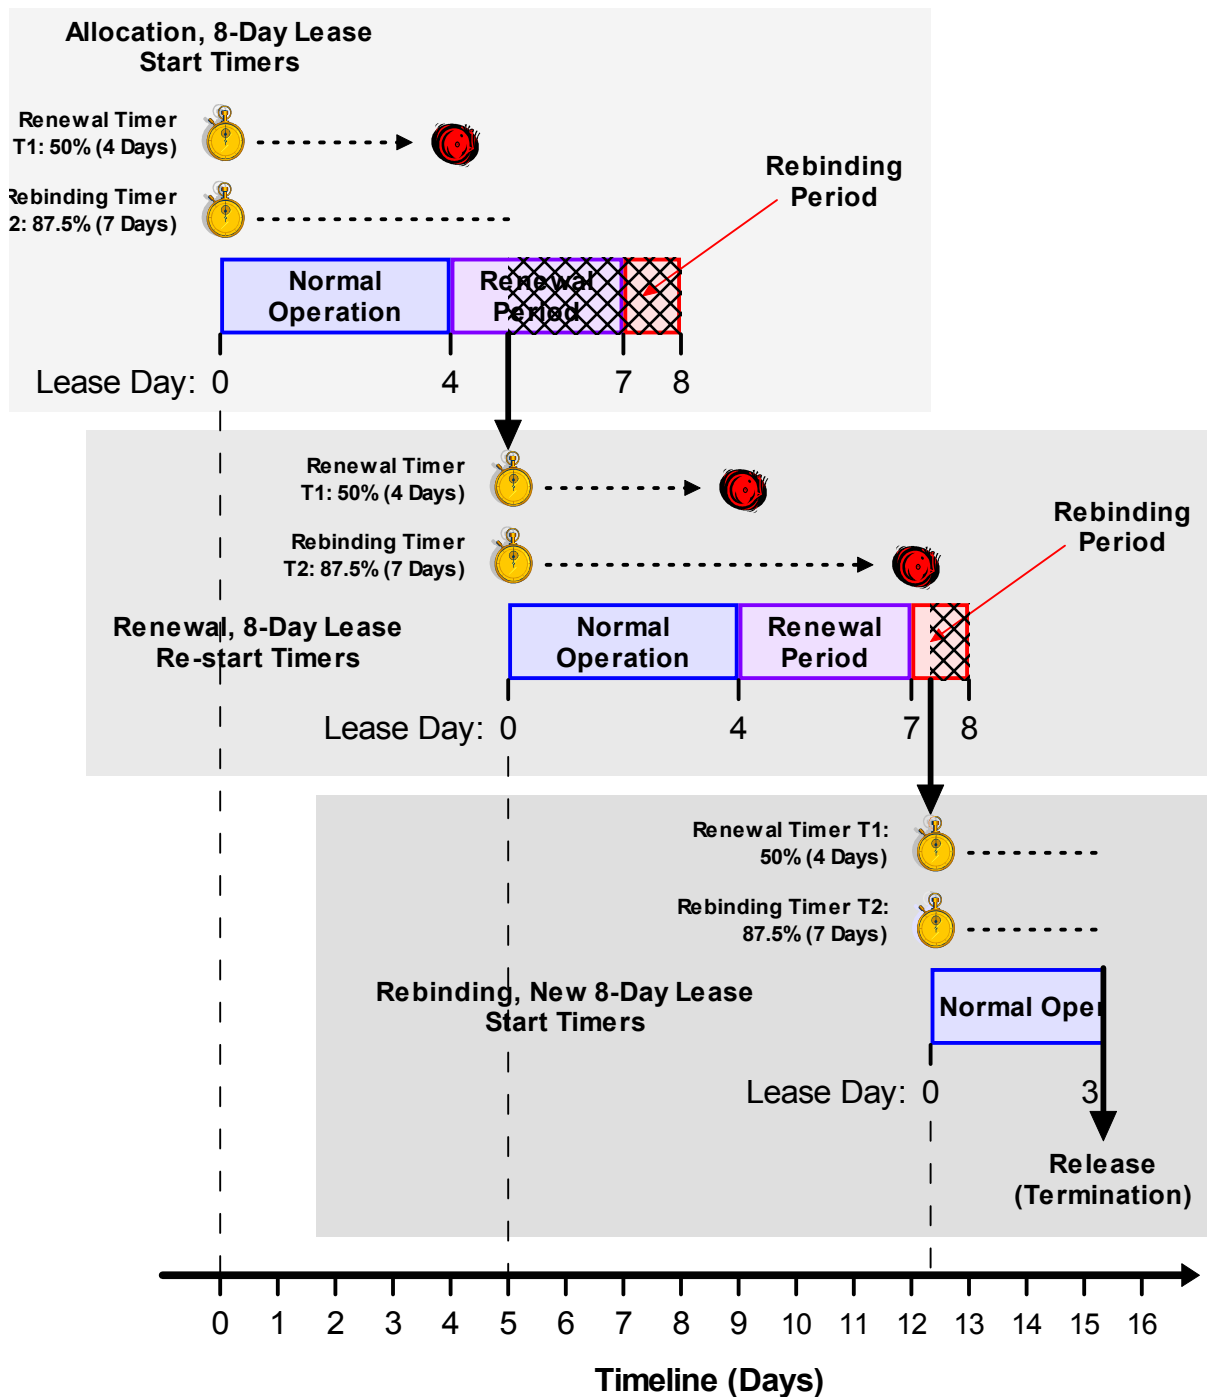

- ☉ **Renewal Timer (T1):** This timer is set by default to 50% of the lease period. When it expires, the client will begin the process of renewing the lease. It is simply called “T1” in the DHCP standards.
- ☉ **Rebinding Timer (T2):** This timer is set by default to 87.5% of the length of the lease. When it expires, the client will try to rebind, as described above. It is given the snappy name “T2” in the DHCP standards.

Naturally, if the client successfully renews the lease when the *T1* timer expires, this will result in a “fresh lease”, and both timers will be reset. *T2* only comes into play if the renewal is not successful. It is possible to change the amount of time to which these timers are set, but obviously *T1* must expire before *T2*, which must in turn expire before the lease itself ends. These usually are not changed from the default, but may be modified in certain circumstances.

**Key Concept:** DHCP leases follow a conceptual *life cycle*. The lease is first assigned to the client through a process of *allocation*; if the device later reboots it will *reallocate* the lease. After a period of time controlled by the *renewal timer (T1)*, the device will attempt to *renew* its lease with the server that allocated it. If this fails, the *rebinding timer (T2)* will go off and the device will attempt to *rebind* the lease with any available server. The client may also *release* its IP address if it no longer needs it.

---

**Figure 259: DHCP “Life Cycle” Example**

In this example, the initial lease has a duration of eight days and begins at Day 0. The T1 and T2 timers are set for 4 days and 7 days respectively. When the T1 timer expires the client enters the renewal period, and successfully renews at Day 5 with a new 8-day lease. When this second lease’s T1 timer expires, the client is unable to renew with the original server. It enters the rebinding period when its T2 timer goes off, and is granted a renewed 8-day lease with a different server. Three days into this lease it is moved to a different network and no longer needs its leased address, so it voluntarily releases it.

---

The lease life cycle is described in the DHCP standards in the form of states that the client moves through as it acquires a lease, uses it, and then either renews or ends it. The next [section on DHCP configuration](#) describes these states and the specific exchanges of messages between a client and server to accomplish different lease activities.

## **DHCP Lease Address Pools, Ranges (Scopes) and Address Management**

Simpler host configuration methods such as BOOTP (or DHCP manual allocation for that matter) associate a single IP address with each client machine. DHCP dynamic addressing removes this one-to-one correspondence, in favor of flexible address mapping to clients on an “as needed basis”. The clients no longer own the addresses but lease them from the true owner, the server. Obviously, then, a primary job of both a DHCP server and the administrator of that server is to maintain and manage these client addresses.

### ***Address Pool Size Selection***

The set of all addresses that a DHCP server has available for assignment is most often called the *address pool*. The first issue related to address management is ensuring that the address pool is large enough to serve all the clients that will be using the server. The number of addresses required depends on a number of factors:

- ☉ **Number Of Clients:** Obviously.
- ☉ **Stability and Frequency of Use Of Clients:** If most clients are left on and connected to the network all the time, you will probably need to plan on an address for each one. In contrast, if you are serving part-time employees, or consultants who frequently travel, you can get away with sharing a smaller number of addresses.
- ☉ **Consequences Of Over-Allocation:** If having certain clients be unable to get a free address is a problem, you need to more carefully manage the address pool to ensure that you don't run out. If having a client not get an address is **never** acceptable, make sure you have as many or more addresses as clients.

I'm sure you've probably noticed that these issues are similar to [those that I raised in discussing lease lengths](#) earlier in this section. In fact, the two matters are intimately related. Generally speaking, having more addresses gives the administrator the “luxury” of using longer leases. If you are short on addresses you probably need to use shorter leases to reduce the chances of any unused addresses continuing to be allocated to devices not needing them.

### ***Lease Address Ranges (Scopes)***

In its simplest form, the address pool takes the form of a list of all addresses that the DHCP server has reserved for dynamic client allocation. Along with each address, the server stores certain parameters, such as a default lease length for the address and other configuration information to be sent to the client when it is assigned that address (for example, a subnet mask and the address of a default router). All of this data is stored in a special database on the server.

---

Of course, many clients will request addresses from this pool. Most of these clients are “equals” as far as the DHCP server is concerned, and it doesn't matter which address each individual client gets. This means most of the information stored with each of the addresses in a pool may be the same except for the address number itself. Due to this similarity, it would be inefficient to have to specify each address and its parameters individually. Instead, a *range* of addresses is normally handled as a single group defined for a particular network or subnet. These are not given any particular name in the DHCP standards, but are commonly called *scopes*. This term has been popularized by Microsoft in its DHCP server implementations. Other operating systems sometimes just call these blocks of addresses *ranges*, but I prefer “scope” so that is what I am using here.

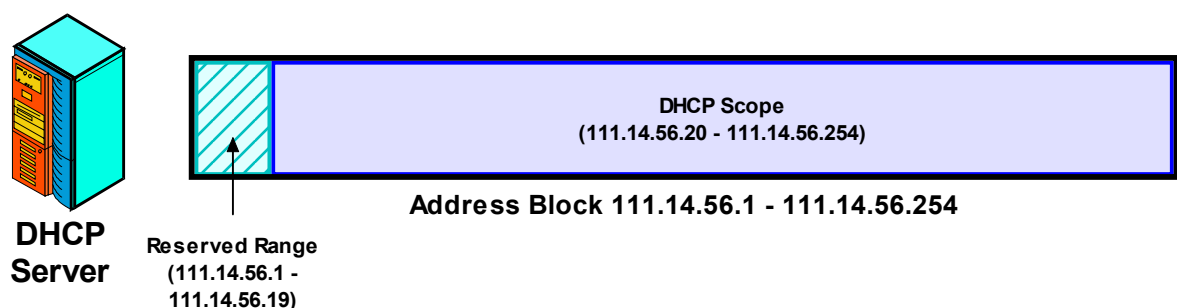

**Key Concept:** Each DHCP server maintains a set of IP addresses that it uses to allocate leases to clients. These are usually contiguous blocks of addresses assigned to the server by an administrator, called DHCP *address ranges* or *scopes*.

---

### ***Simple Address Assignment For a Single Scope***

The exact method for setting up scopes depends on the particular operating system and DHCP server software, and I am not going to get into that here. However, each scope definition typically begins by specifying a range of addresses using a starting and an ending IP address. For example, if a company was assigned the IP address block 111.14.56.0/24, the administrator might set up a scope encompassing addresses 111.14.56.20 through 111.14.56.254, as shown in [Figure 260](#). Then for that scope, the administrator can set up various parameters to be specified to each client assigned an address from the scope.

**Figure 260: DHCP Scope**

Why not start at 111.14.56.1? Usually we will want to set aside certain IP addresses for manual configuration of servers, routers and other devices requiring a fixed address. One easy way to do that is to simply reserve a block of addresses that aren't used by DHCP. Alternately, most DHCP server software will allow you to specify a range but *exclude* an address or set of addresses from the range. So we could specify 111.14.56.1 through 111.14.56.254 and individually mark as “not available” addresses we manually assign. Or specify that 111.14.56.1 through 111.14.56.19 are reserved.

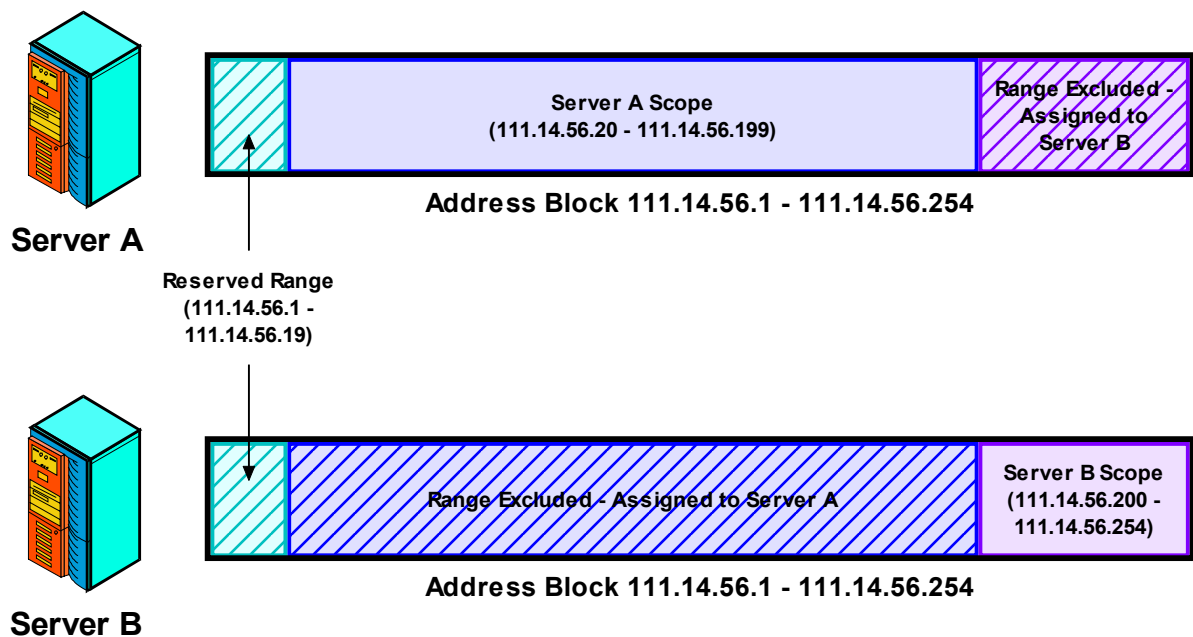

---

## Address Assignment With Multiple Scopes

Instead of putting all of its addresses (except excluded ones) in a single scope, a server may use multiple scopes. One common reason for the latter approach is to support more than one subnet on a server. Multiple scopes are also commonly used when multiple DHCP servers are used to serve the same clients. There are two ways to do this: either by having *overlapping* or *non-overlapping* scopes.

Overlapping scopes allows each server to assign any address from the same pool. However, the DHCP standard doesn't specify any way for servers to communicate with each other when they assign an address, so if both servers were told they could assign addresses from the same address pool, this could result in both servers trying to assign a particular address to two different devices.

**Figure 261: DHCP Multi-Server Non-Overlapping Scopes**

DHCP servers A and B have been assigned non-overlapping scopes to ensure that they do not conflict. This has been done by starting with the same scope definition for both. The common reserved range is excluded from each. Then, server A has server B's address range excluded (shaded purple at top) and B has A's range excluded (shaded blue, bottom).

As a result, if you are using two DHCP servers (as is often recommended for redundancy reasons), the administrator generally gives them different, non-overlapping scope assignments. Alternately, the same scope is given to each server, with each server told to exclude from use the addresses the other server is assigning.

For example, suppose we have two DHCP servers: A (the main server) and B (the backup). We want to assign most of the addresses to A and a few as backup to B. We could give both A and B the scope 111.14.56.1 through 111.14.56.254. We'd exclude 111.14.56.1 through 111.14.56.19 from both. Then we'd exclude from server A the range 111.14.56.200

---

through 111.14.56.254, and exclude from server *B* the range 111.14.20 through 111.14.56.199. [Figure 261](#) shows how this would work. The main advantage of this method is that if one server goes down, the administrator can quickly remove the exclusion and let the remaining server access all addresses. Also, if one server runs out of addresses while the other has plenty, the allocations can be easily shifted.

### ***Other Issues With Address Management***

There are many other issues related to address management, which start to get into the “guts” of DHCP server implementation. For example, as was the case with BOOTP, we may need to use relay agents when the DHCP server is responsible for addresses on a subnet different from its own. There are also special DHCP features that affect how addresses are managed. For example, [the DHCP conflict detection feature](#) can actually allow two servers to have overlapping scopes, despite what we said above. [The section on DHCP implementation and features](#) gets into these issues in more detail.

**Key Concept:** If a site has multiple DHCP servers, they can be set up with either *overlapping* or *non-overlapping* scopes. Overlapping scopes allow each server to assign from the same pool, providing flexibility, but raising the possibility of two clients being assigned the same address unless a feature such as *server conflict detection* is employed. Non-overlapping scopes are “safer” because each server has a dedicated set of addresses for its use, but this means one server could run out of addresses while the other still has plenty, and if a server goes down its addresses will be temporarily unallocatable.

---

---

## **DHCP Configuration and Operation**

The “big news” in DHCP is dynamic address allocation, and [the concept of address leasing](#). It is in fact this new functionality that makes DHCP significantly more complex than its predecessor. BOOTP is a simple request/reply protocol because a server only needs to look up a client's hardware address and send back the client's assigned IP address and other parameters. In contrast, DHCP clients and servers must do much more to carry out both parameter exchange and the many tasks needed to manage IP address leasing.

In this section I delve into the “nuts and bolts” of how DHCP operates. I begin with two background topics. The first provides an overview of the responsibilities of clients and servers in DHCP, and shows in general terms how they relate to each other. The second discusses DHCP configuration parameters and how they are stored and communicated.

The remaining five topics illustrate the operation of DHCP in detail. The first of the five describes the DHCP client *finite state machine*, which will give you a high-level look at the entire client lease “life cycle”, including address allocation, reallocation, renewal, rebinding and optionally, lease termination. This theoretical description is then used as the basis for several topics that explain the actual processes by which DHCP client lease activities occur. These show the specific actions taken by both client and server and when and how DHCP messages are created and sent. The last of the five topics describes the special mechanism by which a device not using DHCP for address allocation can request configuration parameters.

---

**Note:** If you are going to read this section, I strongly recommend reading the first three topics in sequence. Then, if you plan to read any of the following four “Process” topics, start with the first one on allocation, as it contains a number of important notes that apply also to the topics that follow it.

---

### **DHCP Overview of Client and Server Responsibilities**

DHCP is the newest and most current TCP/IP host configuration protocol. However, as we saw in its [overview](#), it wasn't built “from scratch”—it was designed as an extension of the Boot Protocol. In many ways, DHCP is like “BOOTP with more”, and this can be seen in the basic setup of the protocol and how it works.

Both BOOTP and DHCP are designed based on [the common TCP/IP model of client/server operation](#). In any interaction, one device plays the role of client and the other server. Each has specific responsibilities and must send and receive messages following the protocol described in the DHCP standard. The difference is that where BOOTP involves relatively little work for servers and clients and uses a simple single-message exchange for communication, DHCP requires that both servers and clients do more, and uses several types of message exchanges.

---

## DHCP Server Responsibilities

A DHCP server is a network device that has been programmed to provide DHCP services to clients. The server plays a central role in DHCP because DHCP's main function is host configuration, and the server is what configures hosts (clients) that communicate with it. On smaller networks there may be only a single server to support many clients, while larger networks may use multiple servers; regardless of the number of servers, each will usually service many clients.

The following are the key responsibilities of servers in making DHCP work:

- ① **Address Storage and Management:** DHCP servers are the owners of the addresses used by all DHCP clients. The server stores the addresses and manages their use, keeping track of which addresses have been allocated and which are still available.
- ② **Configuration Parameter Storage and Management:** DHCP servers also store and maintain other parameters that are intended to be sent to clients when requested. Many of these are important configuration values that specify in detail how a client is to operate.
- ③ **Lease Management:** As we saw in the previous section, DHCP servers use leases to dynamically allocate addresses to clients for a limited time. The DHCP server maintains information about each of the leases it has granted to clients, as well as policy information such as lease lengths.
- ④ **Responding To Client Requests:** DHCP servers respond to different types of requests from clients to implement the DHCP communication protocol. This includes assigning addresses, conveying configuration parameters and granting, renewing or terminating leases.
- ⑤ **Providing Administration Services:** To support all of the above, the DHCP server includes functionality to allow a human administrator to enter, view, change and analyze addresses, leases, parameters and all other information needed to run DHCP.

## DHCP Client Responsibilities

A DHCP client is any device that sends DHCP requests to a server to obtain an IP address or other configuration information. Due to the advantages of DHCP, most host computers on TCP/IP internetworks today include DHCP client software, making them **potential** DHCP clients if their administrator chooses to enable the function. The main responsibilities of a DHCP client are:

- ① **Configuration Initiation:** The client takes the *active* role by initiating the communication exchange that results in it being given an IP address and other parameters. The server, in contrast, is *passive* and will not really do anything for the client until the client makes contact.
- ② **Configuration Parameter Management:** The client maintains parameters that pertain to its configuration, some or all of which may be obtained from a DHCP server.
- ③ **Lease Management:** Assuming its address is dynamically allocated, the client keeps track of the status of its own lease. It is responsible for renewing the lease at the appropriate time, rebinding if renewal is not possible, and terminating the lease early if the address is no longer needed.

- 
- ☛ **Message Retransmission:** Since DHCP uses the unreliable [User Datagram Protocol](#) for messaging, clients are responsible for detecting message loss and retransmitting requests if need be.

### **DHCP Device Roles and Interaction**

The DHCP server and client obviously play complementary roles. The server maintains configuration parameters for all clients; each client maintains its own parameters, as discussed in the next topic. IP address assignment and lease creation, renewal, rebinding and termination are accomplished through specific exchanges using a set of eight DHCP message types, which we will see later in this section. To accomplish this messaging, special rules are followed to generate, address and transport messages, which are [explained in a topic in the section on DHCP messaging](#).

Like BOOTP, DHCP also supports a third type of device, the *relay agent*. Relay agents are neither clients nor servers, but rather intermediaries that facilitate cross-network communication between servers and clients. They are described in more detail in [the section on DHCP implementation and features](#) (where you can also find more of the implementation details of servers and clients.)

**Key Concept:** *DHCP servers* are devices programmed to provide DHCP services to clients. They manage address information and other parameters and respond to client configuration requests. *DHCP clients* are TCP/IP devices that have been set to use DHCP to determine their configuration. They send requests and read responses, and are responsible for managing their own leases, including renewing or rebinding a lease when necessary.

---

### **DHCP Configuration Parameters, Storage and Communication**

One of the more important oversights in DHCP's predecessor, BOOTP, is that the original protocol allowed a server to tell a client only three pieces of information: its IP address, the name of the server it could use to download a boot file, and the name of the boot file to use. This was a result of BOOTP's legacy as a protocol created primarily to let diskless workstations be bootstrapped.

Obviously, the IP address is a very important parameter, but in modern networks it isn't the only one that a client needs to be given for it to function properly. A typical host needs to be given other essential information to allow it to know how it should operate on its local network and interact with other devices. For example, it needs to know the address of a default local router, the subnet mask for the subnet it is on, parameters for creating outgoing IP datagrams, and much more.

---

## Configuration Parameter Management

The inability to specify additional configuration parameters in BOOTP was resolved by using the special [BOOTP Vendor-Specific Area](#) for vendor-independent *vendor information fields*, as first defined in RFC 1048. In DHCP, this idea has been extended further, and more important, formalized, as part of the effort to make DHCP a more general-purpose configuration tool. Configuration parameter storage, maintenance and communication is no longer an optional feature, but an essential part of the host configuration process.

Just as DHCP servers are the “bosses” that own and manage IP addresses, they also act as the repository for other configuration parameters that belong to DHCP clients. This centralization of parameter storage provides many of the same benefits that centralizing IP addresses in DHCP does: parameters can be checked and adjusted in a single place rather than having to go to each client machine.

Each DHCP server is programmed with parameters that are to be communicated to clients in addition to an IP address when an address is assigned. Alternately, a client that has already been assigned an address using some other mechanism [may still query the DHCP server to get parameter information](#), using the *DHCPINFORM* message type. (This was actually added to the protocol in RFC 2131; it was not in the original DHCP standard.)

The exact method of storage of client parameters is to some extent implementation-dependent. Typically, there will be some parameters that apply to all clients. For example, on a small network with only one router, that router will probably be the default router for every DHCP client regardless of address.

### Client-Specific Parameters and Client Identifiers

The DHCP server will also have certain parameters that are client-specific; the IP address itself is an obvious example, but there are other parameters that may apply to only certain clients on a network. These parameters are stored in some sort of a database, and indexed using a particular *client identifier*.

The default identifier consists of the client's IP subnet number and its hardware address. Thus, when a server gets a request from a particular subnet it can use the client's hardware address in the request to look up client-specific parameters and return them. The client identifier can be changed if a different identification scheme is desired.

### Client Parameter Storage

Clients are also responsible for parameter storage, but of course, only their own parameters. Many of these will be obtained from the DHCP server, though some may be supplied in other ways. The specific implementation of the client determines which parameters it considers important and how they are discovered.

---

## Configuration Parameter Communication

Communication of configuration parameters between DHCP clients and servers is accomplished using *DHCP options*, which replace BOOTP vendor information fields. A number of options were defined when DHCP was first created, and additional new ones have been created over the years. There are today several dozen of these options. Obviously, the ability to have so many different parameters automatically delivered to a client provides a great deal of host configuration flexibility to administrators. [DHCP options are described further in the section on DHCP message formats.](#)

## **DHCP General Operation and Client Finite State Machine**

Dynamic address allocation is probably the most important new capability introduced by DHCP. In [the last section](#) I discussed in detail the significance of the change from IP address *ownership* to IP address *leasing*. I also provided a high-level look of the activities involved in leasing, by providing an overview of [the DHCP lease “life cycle”](#).

An overview of this sort is useful to get a general handle on how leases work, but to really understand the mechanics of DHCP address assignment and client/server communication, we need more detail on how the devices behave and what messages they send. One tool often employed by networking engineers to describe a protocol is a theoretical model called a *finite state machine (FSM)*. In this technique, the protocol's specific behavior is illustrated by showing the different *states* a device can be in, what possible *transitions* exist from one state to another, what *events* cause transitions to occur, and what *actions* are performed in response to an event. The [TCP operational overview](#) contains more general background information on finite state machines.

The DHCP standard uses an FSM to describe the lease life cycle from the perspective of a DHCP client. The client begins in an initial *INIT* state where it has no lease, and then transitions through various states as it acquires, renews, rebinds and/or releases its IP address. The FSM also indicates what message exchanges occurs between the server and client at various stages.

Some people think finite state machines are a little “dense” and hard to understand, and I can see why. You can skip this topic of course, but I think the FSM provides a useful way of illustrating in a comprehensive way most of the behavior of a DHCP client. [Table 189](#) describes each of the DHCP client states, and summarizes the messages sent and received by the client in each, as well as showing the state transitions that occur in

response. The FSM's states, events and transitions are easier to envision in [Figure 262](#), which also incorporates a color coding scheme so you can see which states are associated with each of the main DHCP processes.

**Table 189: DHCP Client Finite State Machine (Page 1 of 3)**

State	State Description	Event and Transition
<b>INIT</b>	This is the initialization state, where a client begins the process of acquiring a lease. It also returns here when a lease ends, or when a lease negotiation fails.	<b>Client Sends <i>DHCPDISCOVER</i>:</b> The client creates a <i>DHCPDISCOVER</i> message and broadcasts it to try to find a DHCP server. It transitions to the <i>SELECTING</i> state.
<b>SELECTING</b>	The client is waiting to receive <i>DHCPOFFER</i> messages from one or more DHCP servers, so it can choose one.	<b>Client Receives Offers, Selects Preferred Offer, Sends <i>DHCPREQUEST</i>:</b> The client chooses one of the offers it has been sent, and broadcasts a <i>DHCPREQUEST</i> message to tell DHCP servers what its choice was. It transitions to the <i>REQUESTING</i> state.
<b>REQUESTING</b>	The client is waiting to hear back from the server to which it sent its request.	<b>Client Receives <i>DHCPACK</i>, Successfully Checks That IP Address Is Free:</b> The client receives a <i>DHCPACK</i> message from its chosen server, confirming that it can have the lease that was offered. It checks to ensure that address is not already used, and assuming it is not, records the parameters the server sent it, sets the lease timers <i>T1</i> and <i>T2</i> , and transitions to the <i>BOUND</i> state.
		<b>Client Receives <i>DHCPACK</i>, But IP Address Is In Use:</b> The client receives a <i>DHCPACK</i> message from its chosen server, confirming that it can have the lease that was offered. However, it checks and finds the address already in use. It sends a <i>DHCPDECLINE</i> message back to the server, and returns to the <i>INIT</i> state.
		<b>Client Receives <i>DHCPNAK</i>:</b> The client receives a <i>DHCPNAK</i> message from its chosen server, which means the server has withdrawn its offer. The client returns to the <i>INIT</i> state.
<b>INIT-REBOOT</b>	When a client that already has a valid lease starts up after a power-down or reboot, it starts here instead of the <i>INIT</i> state.	<b>Client Sends <i>DHCPREQUEST</i>:</b> The client sends a <i>DHCPREQUEST</i> message to attempt to verify its lease and re-obtain its configuration parameters. It then transitions to the <i>REBOOTING</i> state to wait for a response.

**Table 189: DHCP Client Finite State Machine (Page 2 of 3)**

State	State Description	Event and Transition
<b>REBOOTING</b>	A client that has rebooted with an assigned address is waiting for a confirming reply from a server.	<b>Client Receives <i>DHCPACK</i>, Successfully Checks That IP Address Is Free:</b> The client receives a <i>DHCPACK</i> message from the server that has its lease information, confirming that the lease is still valid. To be safe, the client checks anyway to ensure that the address is not already in use by some other device. Assuming it is not, the client records the parameters the server sent it and transitions to the <i>BOUND</i> state.
		<b>Client Receives <i>DHCPACK</i>, But IP Address Is In Use:</b> The client receives a <i>DHCPACK</i> message from the server that had its lease, confirming that the lease is still valid. However, the client checks and finds that while the client was offline, some other device has grabbed its leased IP address. The client sends a <i>DHCPDECLINE</i> message back to the server, and returns to the <i>INIT</i> state to obtain a new lease.
		<b>Client Receives <i>DHCPNAK</i>:</b> The client receives a <i>DHCPNAK</i> message from a server. This tells it that its current lease is no longer valid; for example, the client may have moved to a new network where it can no longer use the address in its present lease. The client returns to the <i>INIT</i> state.
<b>BOUND</b>	Client has a valid lease and is in its normal operating state.	<b>Renewal Timer (<i>T1</i>) Expires:</b> The client transitions to the <i>RENEWING</i> state.
		<b>Client Terminates Lease, Sends <i>DHCPRELEASE</i>:</b> The client decides to terminate the lease (due to user command, for example.) It sends a <i>DHCPRELEASE</i> message and returns to the <i>INIT</i> state.
<b>RENEWING</b>	Client is trying to renew its lease. It regularly sends <i>DHCPREQUEST</i> messages with the server that gave it its current lease specified, and waits for a reply.	<b>Client Receives <i>DHCPACK</i>:</b> The client receives a <i>DHCPACK</i> reply to its <i>DHCPREQUEST</i> . Its lease is renewed, it restarts the <i>T1</i> and <i>T2</i> timers, and returns to the <i>BOUND</i> state.
		<b>Client Receives <i>DHCPNAK</i>:</b> The server has refused to renew the client's lease. The client goes to the <i>INIT</i> state to get a new lease.
		<b>Rebinding Timer (<i>T2</i>) Expires:</b> While attempting to renew its lease, the <i>T2</i> timer expires, indicating that the renewal period has ended. The client transitions to the <i>REBINDING</i> state.

**Table 189: DHCP Client Finite State Machine (Page 3 of 3)**

State	State Description	Event and Transition
<b>REBINDING</b>	The client has failed to renew its lease with the server that originally granted it, and now seeks a lease extension with any server that can hear it. It periodically sends <i>DHCPREQUEST</i> messages with no server specified until it gets a reply or the lease ends.	<b>Client Receives <i>DHCPACK</i>:</b> Some server on the network has renewed the client's lease. The client binds to the new server granting the lease, restarts the <i>T1</i> and <i>T2</i> timers, and returns to the <i>BOUND</i> state.
		<b>Client Receives <i>DHCPNAK</i>:</b> A server on the network is specifically telling the client it needs to restart the leasing process. This may be the case if a new server is willing to grant the client a lease, but only with terms different than the client's current lease. The client goes to the <i>INIT</i> state.
		<b>Lease Expires:</b> The client receives no reply prior to the expiration of the lease. It goes back to the <i>INIT</i> state.

This is just a summary of the finite state machine, and does not show every possible event and transition, since it is complex enough already. For example, if a client that received two offers in the *SELECTING* state receives a *DHCPNAK* from its chosen server in the *REQUESTING* state, it may choose to send a new *DHCPREQUEST* to its “second choice” instead of starting over from scratch. Also, the client must have logic that lets it “time out” if it receives no reply to sent messages in various states, such as not receiving any offers in the *SELECTING* state. The next few topics discuss these matters in more detail.

Note also that the DHCP standard does not describe the DHCP **server's** behavior in the form of a finite state machine, only the client's. Here too, there is more information on what exactly DHCP servers do in the pages that follow.

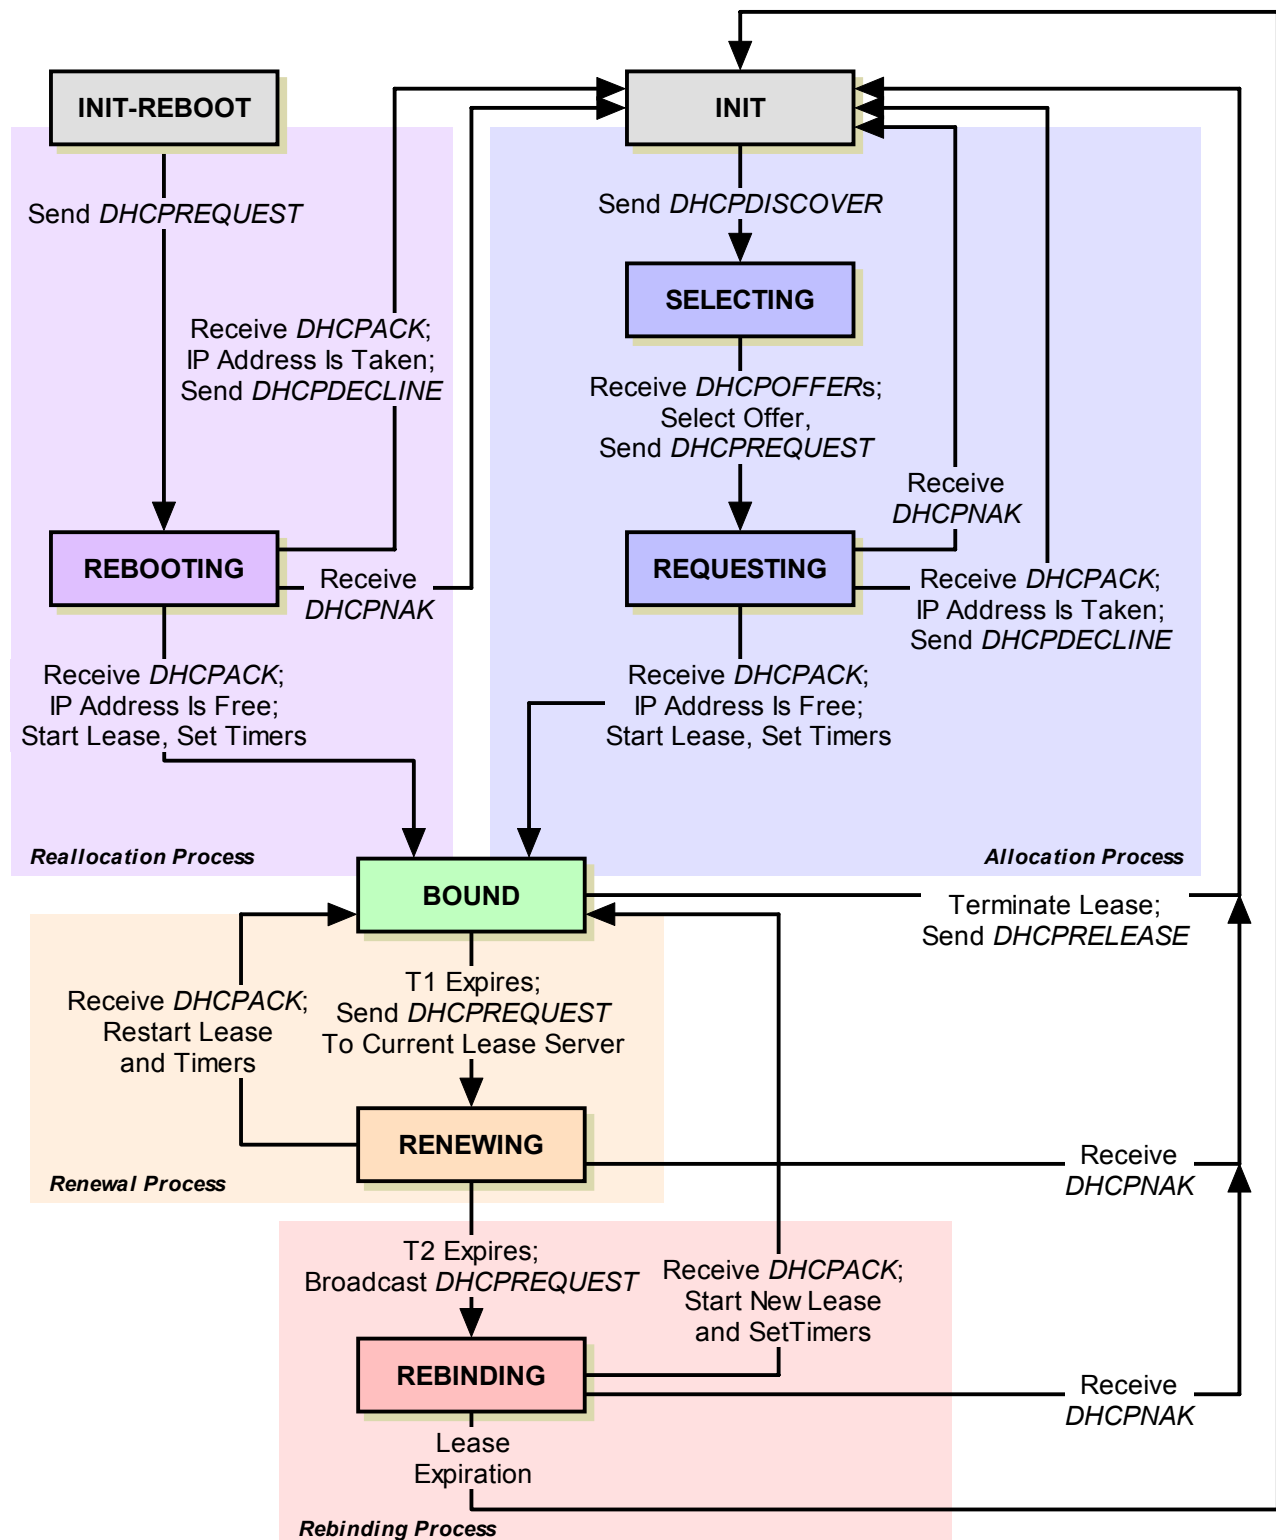

I should also point out explicitly that this finite state machine applies to dynamically-allocated clients; that is, ones with conventional leases. A device configured using “automatic” allocation will go through the same basic allocation process, but does not need to renew its lease. The process for manual allocation is somewhat different.

## **DHCP Lease Allocation Process**

To implement DHCP, an administrator must first set up a DHCP server and provide it with configuration parameters and policy information: IP address ranges, lease length specifications, and configuration data that DHCP hosts will need to be delivered to them. Host devices can then have their DHCP client software enabled, but nothing will happen until the client initiates communication with the server. When a DHCP client starts up for the first time, or when it has no current DHCP lease, it will be in an initial state where it doesn't have an address and needs to acquire one. It will do so by initiating the process of *lease allocation*.

## ***Notes on Lease Communication Descriptions***

Before I begin, some notes about this description, which also apply to subsequent topics in this section on DHCP lease communications:

**Figure 262: DHCP Client Finite State Machine**

This diagram shows the finite state machine used by DHCP clients. The colored background areas show the transitions taken by a DHCP client as it moves through the four primary DHCP processes: allocation, reallocation, renewal and rebinding.

- 
- ☛ **Addressing:** DHCP assumes that clients will normally broadcast messages, since they don't know the address of servers when they initiate contact, but that servers will send replies back unicast to the client. This can be done even before the client has an IP address, by sending the message at the link layer. Some clients don't support this and require that messages to them be broadcast instead. The details of how messages are created and addressed are discussed in [the section on DHCP messaging](#).
  - ☛ **DHCP Message Fields and Options:** DHCP uses many of the same basic fields as BOOTP, but much of the extra information the protocol requires is carried in DHCP *options*. Obviously, some of these “options” aren't really optional, despite the name—they are needed for the basic function of DHCP. An obvious example would be the *DHCP Message Type* option, which is what specifies the message type itself. Again, you can find a full description of all DHCP fields and options in [the section on DHCP messaging](#).
  - ☛ **DHCP Relay Agents:** I have assumed that no relay agents are in use here; see [the topic on DHCP/BOOTP relay agents](#) for more on how they change the allocation process (and other processes).

### **Lease Allocation Process Steps**

Below I have described the steps that are followed by a DHCP client and server in the initial allocation of an IP address lease. This is a basic description, and I have not included all the details of what the client and server do, as that would make this description incredibly long. Instead, I have focused on the most important tasks each device performs, and also specified the message types exchanged and critical pieces of data included in each message, as well as client states and transitions. The process is also illustrated in [Figure 263](#).

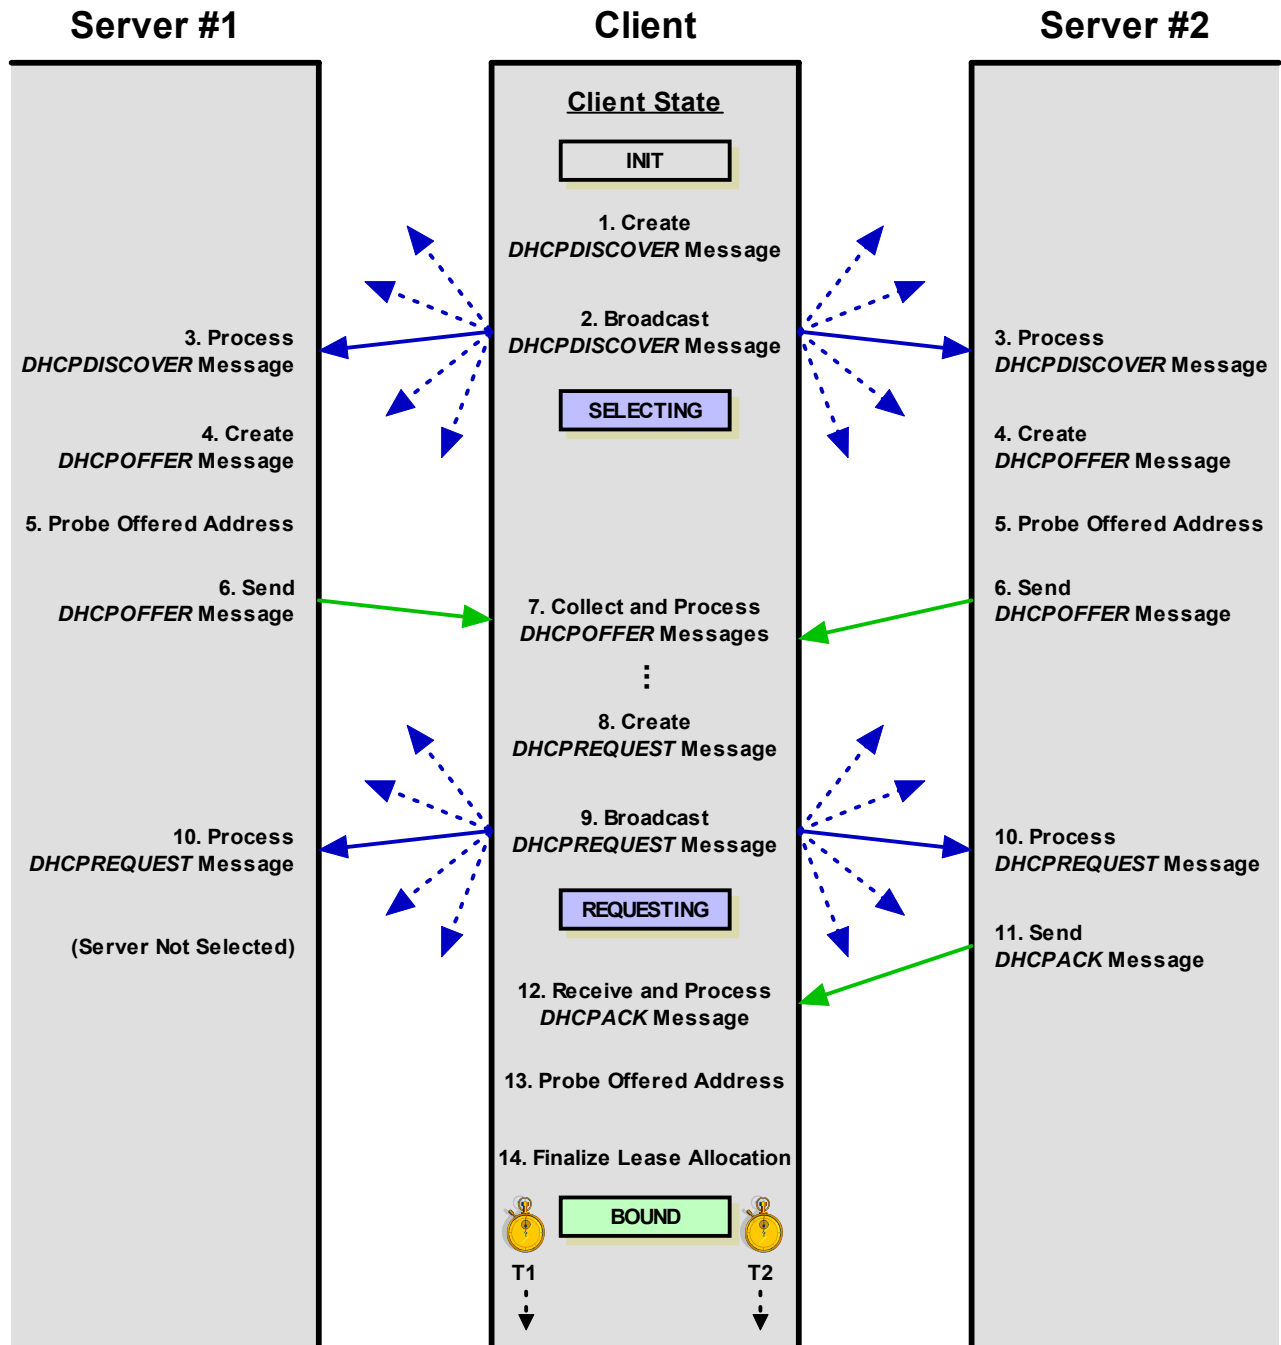

#### **1. Client Creates *DHCPDISCOVER* Message**

The client begins in the *INIT (initialization)* state. It has no IP address and doesn't even know whether or where a DHCP server may be on the network. To find one, it creates a *DHCPDISCOVER* message, including the following information:

- ☛ Its own hardware address in the *CHAddr* field of the message, to identify itself.
- ☛ A random transaction identifier, put into the *XID* field. This is used to identify later messages as being part of the same transaction.
- ☛ Optionally, the client may request a particular IP address using a *Requested IP Address* DHCP option, a particular lease length using an *IP Address Lease Time* option, and/or specific configuration parameters by including a *Parameter Request List* option in the message.

#### **2. Client Sends *DHCPDISCOVER* Message**

The client broadcasts the *DHCPDISCOVER* message on the local network. The client transitions to the *SELECTING* state, where it waits for replies to its message.

**Figure 263: DHCP Lease Allocation Process**

This diagram shows the steps involved in DHCP client lease allocation. This diagram is a bit different from most of the other client/server exchange diagrams in this Guide in that I have shown two servers instead of one. This shows how a client handles responses from multiple DHCP servers and how each servers react differently depending on whether or not its lease offer was chosen by the client.

---

### 3. Servers Receive and Process *DHCPDISCOVER* Message

Each DHCP server on the local network receives the client's *DHCPDISCOVER* message and examines it. The server looks up the client's hardware address in its database and determines if it is able to offer the client a lease, and what the terms of the lease will be. If the client has made requests for a particular IP address, lease length, or other parameters, the server will attempt to satisfy these requests, but is not required to do so. A server may decide not to offer a lease to a particular client if it has not been programmed to provide service for it, it has no remaining IP addresses or for other reasons.

### 4. Servers Create *DHCPOFFER* Messages

Each server that chooses to respond to the client creates a *DHCPOFFER* message including the following information:

- ☉ The IP address to be assigned to the client, in the *YIAddr* field. If the server previously had a lease for this client it will attempt to reuse the IP address it used last time. Failing that, it will try to use the client's requested address if present; otherwise, it will select any available address.
- ☉ The length of the lease being offered.
- ☉ Any client-specific configuration parameters either requested by the client or programmed into the server to be returned to the client.
- ☉ Any general configuration parameters to be returned to all clients or clients in this client's class.
- ☉ The server's identifier in the DHCP *Server Identifier* option.
- ☉ The same transaction ID (*XID*) used in the *DHCPDISCOVER* message.

### 5. Servers Probe And/Or Reserve Offered Address (Optional)

The DHCP standard specifies that before sending a *DHCPOFFER* to a client, the server “SHOULD” check to see that the IP address isn't already in use by sending an [ICMP Echo message](#) to that address. If the probe is made and the address is in use, the server will of course not offer it to the client. This may be disabled by an administrator. It is considered a key part of the [DHCP server conflict detection feature](#).

Whether or not it probes the address offered, the server may also *reserve* the address so that if the client decides to use it, it will be available. This isn't mandatory, because as we'll see below, the protocol handles the case where an offered lease is retracted. It is more efficient if servers do reserve addresses, but if IP addresses are in very short supply, such reservation may not be practical.

### 6. Servers Send *DHCPOFFER* Messages

Each server sends its *DHCPOFFER* message. They of course may not all be sent at exactly the same time. The messages are sent either unicast or broadcast, as mentioned earlier.

---

## 7. Client Collects and Processes *DHCPOFFER* Messages

The client waits for *DHCPOFFER* messages to arrive in response to its *DHCPDISCOVER*. The exact behavior of the client here is implementation-dependent. The client may decide to simply take the first offer it receives, for expediency. Alternately, it may choose to “shop around” by waiting for a period of time. It can then process each offer and take the one with the most favorable terms—for example, the one with the longest lease.

If no *DHCPOFFER* messages are received, the client will enter a retransmission mode and try sending the *DHCPDISCOVER* again for a period of time.

## 8. Client Creates *DHCPREQUEST* Message

The client creates a *DHCPREQUEST* message for the server offer it has selected. This message serves two purposes: it tells the server whose offer the client has accepted “yes, I accept your offer, assuming it is still available” and also tells the other servers “sorry, your offer was rejected”. (Well, except for the “sorry” part; servers are pretty thick-skinned about rejection. ☺) In this message, the client includes the following information:

- ☉ The identifier of the “chosen” server in the *DHCP Server Identifier* option, so everyone knows “who won”.
- ☉ The IP address that the DHCP server assigned the client in the *DHCPOFFER* message, which the client puts in the *Requested IP Address* DHCP option as a confirmation.
- ☉ Any additional configuration parameters it wants in a *Parameter Request List* option in the message.

## 9. Client Sends *DHCPREQUEST* Message

The client sends the *DHCPREQUEST* message. Since it is intended for not just the selected DHCP server but all servers, it is broadcast. After doing this, the client transitions to the *REQUESTING* state, where it waits for a reply from the chosen server.

## 10. Servers Receive and Process *DHCPREQUEST* Message

Each of the servers receives and processes the client's request message. The servers not chosen will take the message as a rejection. However, note that a client may select one offer, attempt to request the lease and have the transaction not complete successfully. The client may then come back and try its “second choice” offer by sending a *DHCPREQUEST* containing a different *Server Identifier*. This means that if Server *A* receives a single *DHCPREQUEST* with a *Server Identifier* of Server *B*, that doesn't necessarily mean that Server *A* is done with the transaction. For this reason, “rejected” servers will wait for a while before offering a previously-offered lease to another client.

## 11. Server Sends *DHCPACK* or *DHCPNAK* Message

The chosen server will see that its lease has been selected. If it did not previously reserve the IP address that was offered to the client, it must check to make sure it is still available. If it is not, the server sends back a *DHCPNAK* (*negative acknowledgment*) message, which

---

essentially means “never mind, that lease is no longer available”. Usually, however, the server will still have that lease. It will create a *binding* for that client, and send back a *DHCPACK* (*acknowledgment*) message that confirms the lease and contains all the pertinent configuration parameters for the client.

## 12. Client Receives and Processes *DHCPACK* or *DHCPNAK* Message

The client receives either a positive or negative acknowledgment for its request. If the message is a *DHCPNAK*, the client transitions back to the *INIT* state and starts over: back to square one (step #1). If it is a *DHCPACK*, the client reads the IP address from the *YIAddr* field, and records the lease length and other parameters from the various message fields and DHCP options.

If the client receives neither message, it may retransmit the *DHCPREQUEST* message one or more times. If it continues to hear nothing then it must conclude that the server flaked out and go back to step #1.

## 13. Client Checks That Address Is Not In Use

The client device should perform a final check to ensure that the new address isn't already in use before it concludes the leasing process. This is typically done by generating an [Address Resolution Protocol \(ARP\)](#) request on the local network, to see if any other device thinks it already has the IP address this client was just leased. If another device responds, the client sends a *DHCPDECLINE* message back to the server, which basically means “hey server, you screwed up, someone's already using that address”. The client then, you guessed it, goes back to step #1 and starts over.

## 14. Client Finalizes Lease Allocation

Assuming that the address is not already in use, the client finalizes the lease and transitions to the *BOUND* state. It also sets its two lease timers, *T1* and *T2*. It is now ready for normal operation.

## *Dealing With Lost Messages or Failure of the Allocation Process*

You can see in this description that there are a number of situations that may occur that require a client to retransmit messages. This is because [DHCP uses UDP](#) which is unreliable and can cause messages to be lost. If retransmissions don't fix a problem such as not receiving a *DHCPOFFER* or a *DHCPACK* from a server, the client may have to start the allocation process over from scratch. The client must include enough “intelligence” to prevent it from simply trying forever to get a lease when there may not be a point—for example, if there are no DHCP servers on the network, no number of retransmissions will help.

Thus, after a number of retries the client will give up and the allocation process will fail. If the client is configured to use the [Automatic Private IP Addressing](#) feature, this is where it would be used to give the client a default address. Otherwise, the client will be, well, “dead in the water”.

**Key Concept:** The most important configuration process in DHCP is the *lease allocation process*, used by clients to acquire a lease. The client broadcasts a request to determine if any DHCP servers can hear it. Each DHCP server that is willing to grant the client a lease sends it an offer. The client selects the lease it prefers and sends a response to all servers telling them its choice. The selected server then sends the client its lease information.

---

## **DHCP Lease Reallocation Process**

When a DHCP client starts up for the first time and has no lease, it begins in the *INIT* (*initialize*) state and goes through [the allocation process described in the preceding topic](#) to acquire a lease. The same process is used when a lease ends, if a lease renewal fails, or some error or other happening causes a client to need a new lease.

### ***Situations Where Reallocation Is Performed***

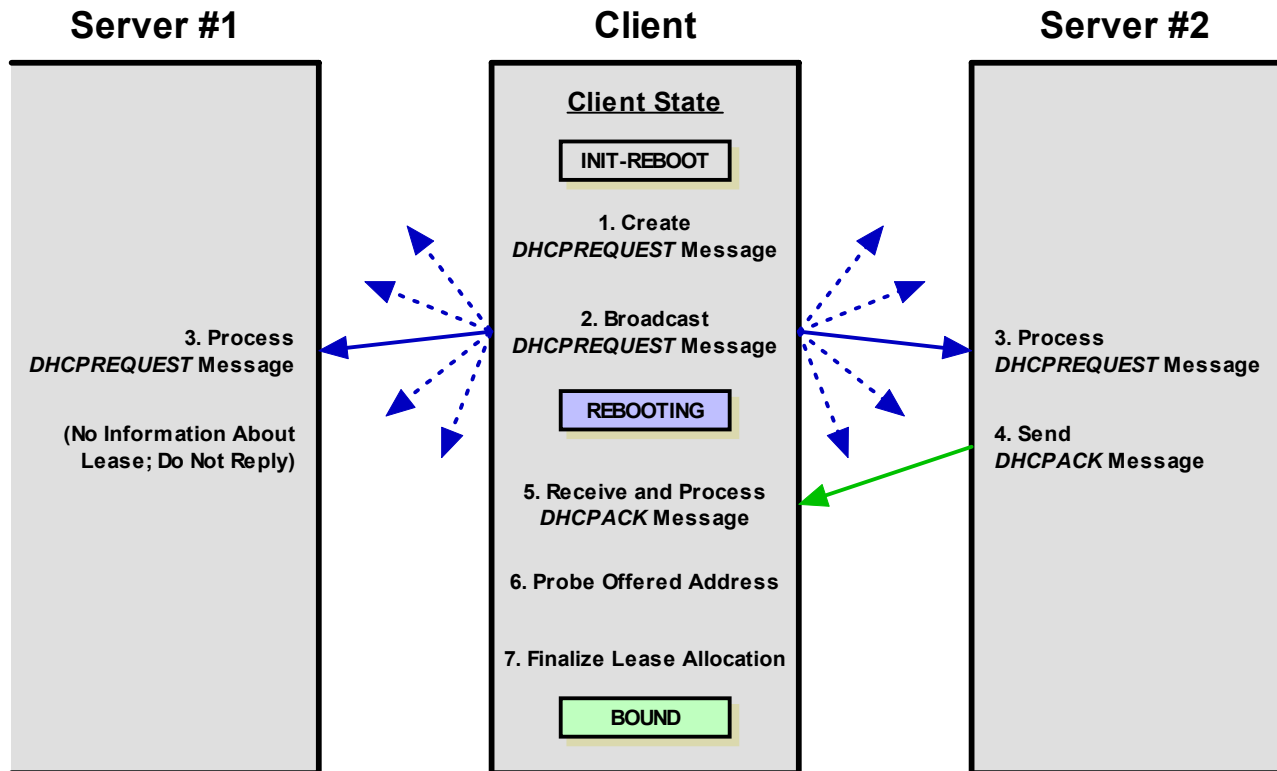

There are certain situations in which a client starts up while it still has a lease already in place. In this situation, the client does not need to go through the entire process of getting an IP address allocation and a new lease setup. Instead, it simply tries to re-establish its existing lease, through a process that I call *reallocation*.

There are two primary circumstances under which a client performs reallocation rather than allocation:

- ☉ **Power On With Existing Lease:** The length of time that a client lease lasts can range from minutes to years; it is entirely a matter of the [lease length policy](#) set for the network and client by the administrator. Many, if not most client machines are not left connected to the network 24 hours a day; they are turned on during the day and then shut down at night, and also shut down on weekends. A client with a very short lease that is shut down and then later started again will probably find that its lease has expired, and will have to get a new one. However, if a lease is longer than a few days, it will still probably be in effect when the client starts up again.
- ☉ **Reboot:** Clients are also sometimes rebooted, to install new software or correct a problem. In this case even when the lease length is very short, the restarting client will still have a valid lease when it starts up.

### ***Lease Reallocation Process Steps***

The reallocation process is essentially an abbreviated version of the allocation process described in the previous topic. There is no need for the client to go through the whole “yoo-hoo, any servers out there want to give me a lease” routine. Instead, the client attempts to find the server that gave it the lease in the first place, seeking a confirmation that the lease is still valid and that it may resume using its previously-allocated IP address. It also receives confirmation of the parameters it should use.

**Figure 264: DHCP Lease Reallocation Process**

The lease reallocation process consists of seven steps that correspond approximately to steps 8 through 14 of the full lease allocation process shown in [Figure 263](#). In this example, the server that originally granted the lease to the client is Server #2, so it is normally the only one that responds.

The following steps summarize the reallocation process, which is also shown in [Figure 264](#). (Note that the same notes about addressing fields, relay agents and such that I mentioned in [the discussion of lease allocation](#) apply here as well):

#### 1. Client Creates *DHCPREQUEST* Message

The client begins in the *INIT-REBOOT* state instead of the *INIT* state. It creates a *DHCPREQUEST* message to attempt to find a server with information about its current lease. Note that this may or may not be the server that originally granted the lease; the server responsible for a lease could, theoretically, have changed in the time since the client obtained the lease. Thus, unlike the *DHCPREQUEST* message in step #8 in the allocation process, the client does **not** include a *DHCP Server Identifier* option. It does include the following information:

- ☛ Its own hardware address in the *CHAddr* field of the message, to identify itself.
- ☛ The IP address of its existing lease, in the *Requested IP Address* DHCP option. Note that this address is **not** put into the *CIAddr* field.
- ☛ A random transaction identifier, put into the *XID* field. This is used to identify later messages as being part of the same transaction.

- 
- ④ Any additional configuration parameters it wants, in a *Parameter Request List* option in the message.

## 2. Client Sends *DHCPREQUEST* Message

The client broadcasts the *DHCPREQUEST* message. It then transitions to the *REBOOTING* state, where it waits for a reply from a server.

## 3. Servers Receive and Process *DHCPREQUEST* Message and Generate Replies

Each server on the network receives and processes the client's request. The server looks up the client in its database, attempting to find information about the lease. Each server then decides how to reply to the client:

- ④ **Server Has Valid Client Lease Information:** The server has information about the client's lease. It sends a *DHCPACK* message to confirm the lease. It will also reiterate any parameters the client should be using.
- ④ **Server Determines Client Lease Is Invalid:** The server determines that the client's lease is no longer valid. Common reasons for this happening are the client trying to confirm a lease after it has moved to a different network, or after the lease has in fact already expired. In such a case the server sends a *DHCPNAK* message to negate the lease request.
- ④ **Server Has No Definitive Information About Client Lease:** A server that has no information about the lease does not respond. A server is also required not to respond unless its information is guaranteed to be accurate. So, for example, if a server has knowledge of an old expired lease, it cannot assume that the lease is no longer valid and send a *DHCPNAK*, unless it also has certain knowledge that no other server has a newer, valid lease for that client.

## 4. Servers Send Replies

Servers that are going to respond to the client's *DHCPREQUEST* send their *DHCPACK* or *DHCPNAK* messages.

## 5. Client Receives and Processes *DHCPACK* or *DHCPNAK* Message

The client waits for a period of time to get a reply to its request. Again, there are three possibilities that match the three in the previous step:

- ④ **Positive Acknowledgment:** The client receives a *DHCPACK* message; this confirms the validity of the lease. The client will prepare to begin using the lease again, and continue with the next step below.
- ④ **Negative Acknowledgment:** The message is a *DHCPNAK*, which tells the client that its lease is no longer valid. The client transitions back to the *INIT* state to get a new lease—step #1 in the allocation process.
- ④ **No Reply:** If the client receives no reply at all, it may retransmit the *DHCPREQUEST* message. If no reply is received after a period of time, it will conclude that no server has information about its lease and will return to the *INIT* state to try to get a new lease.

---

## 6. Client Checks That Address Is Not In Use

Before resuming use of its lease, the client device should perform a final check to ensure that the new address isn't already in use. Even though this should not be the case when a lease already exists, it's done anyway, as a "safety measure" of sorts. The check is the same as described in step #13 of the allocation process: an ARP request is issued on the local network, to see if any other device thinks it already has the IP address this client was just leased. If another device responds, the client sends a *DHCPDECLINE* message back to the server, which tells it that the lease is no good because some other device is using the address. The client then goes back to the *INIT* state to get a new lease.

## 7. Client Finalizes Lease Allocation

Assuming that the address is not already in use, the client finalizes the lease and transitions to the *BOUND* state. It is now ready for normal operation.

**Key Concept:** If a client starts up and already has a lease, it need not go through the full lease allocation process; instead, it can use the shorter *reallocation process*. The client broadcasts a request to find the server that has the current information on its lease; that server responds back to confirm that the client's lease is still valid.

---

## DHCP Lease Renewal and Rebinding Processes

Once a DHCP client completes the allocation or reallocation process, it enters the *BOUND* state. The client is now in its regular operating mode, with a valid IP address and other configuration parameters it received from the DHCP server, and can be used like any regular TCP/IP host.

While the client is in the *BOUND* state, DHCP essentially lies dormant. As long as the client stays on and functioning normally, no real DHCP activity will occur while in this state. The most common occurrence that causes DHCP to "wake up" and come active again is arrival of the time when the lease is to be *renewed*. Renewal ensures that a lease is perpetuated so it can be used for a prolonged period of time, and involves its own message exchange procedure. (The other way that a client can leave the *BOUND* state is when it [terminates the lease early](#).)

If DHCP's [automatic allocation](#) is used, or if [dynamic allocation](#) is used with an infinite lease period, the client's lease will never expire, so it never needs to be renewed. Short of early termination, the device will remain in the *BOUND* state forever, or at least until it is rebooted. However, as we've already discussed, most leases are finite in nature. A client must take action to ensure that its lease is extended and normal operation continues.

To manage the lease extension process, two timers are set at the time that a lease is allocated. The *renewal timer* (*T1*) goes off to tell the client it is time to try to renew the lease with the server that initially granted it. The *rebinding timer* (*T2*) goes off if the client is not

---

successful in renewing with that server, and tells it to try any server to have the lease extended. If the lease is renewed or rebound, the client goes back to normal operation. If it cannot be rebound, it will expire and the client will need to seek a new lease.

### ***Lease Renewal/Rebinding Process Steps***

The following steps summarize the renewal/rebinding process. Obviously, the exact sequence of operations taken by a client depends on what happens in its attempts to contact a server; for example, if it is successful with renewal, it will never need to attempt rebinding. An example renewal and rebinding is illustrated in [Figure 265](#). Note also that the same notes about addressing fields, relay agents and such that I mentioned in [the allocation process topic](#) apply here as well.

#### **1. Renewal Timer (*T1*) Expires**

The renewal timer, *T1*, is set by default to 50% of the length of the lease. When the timer goes off, the client transitions from the *BOUND* state to the *RENEWING* state.

Note that a client *may* initiate lease renewal prior to *T1* timer expiration if it desires.

#### **2. Client Sends *DHCPREQUEST* Renewal Message**

The client creates a *DHCPREQUEST* message that identifies itself and its lease. It then transmits the message directly to the server that initially granted the lease, unicast. Note that this is different from the *DHCPREQUEST* messages used in the allocation/reallocation processes, where the *DHCPREQUEST* is broadcast. The client may request a particular new lease length, just as it may request a lease length in its requests during allocation, but as always, the server makes the final call on lease length.

#### **3. Server Receives and Processes *DHCPREQUEST* Message and Creates Reply**

Assuming the server is reachable, it will receive and process the client's renewal request. There are two possible responses:

- ① **Server Agrees To Renew Client Lease:** The server decides that the client's lease can be renewed. It prepares to send to the client a *DHCPACK* message to confirm the lease's renewal, indicating the new lease length and any parameters that may have changed since the lease was created or last renewed.
- ② **Server Refuses To Renew Client Lease:** The server decides for whatever reason not to renew the client's lease. It will create a *DHCPNAK* message.

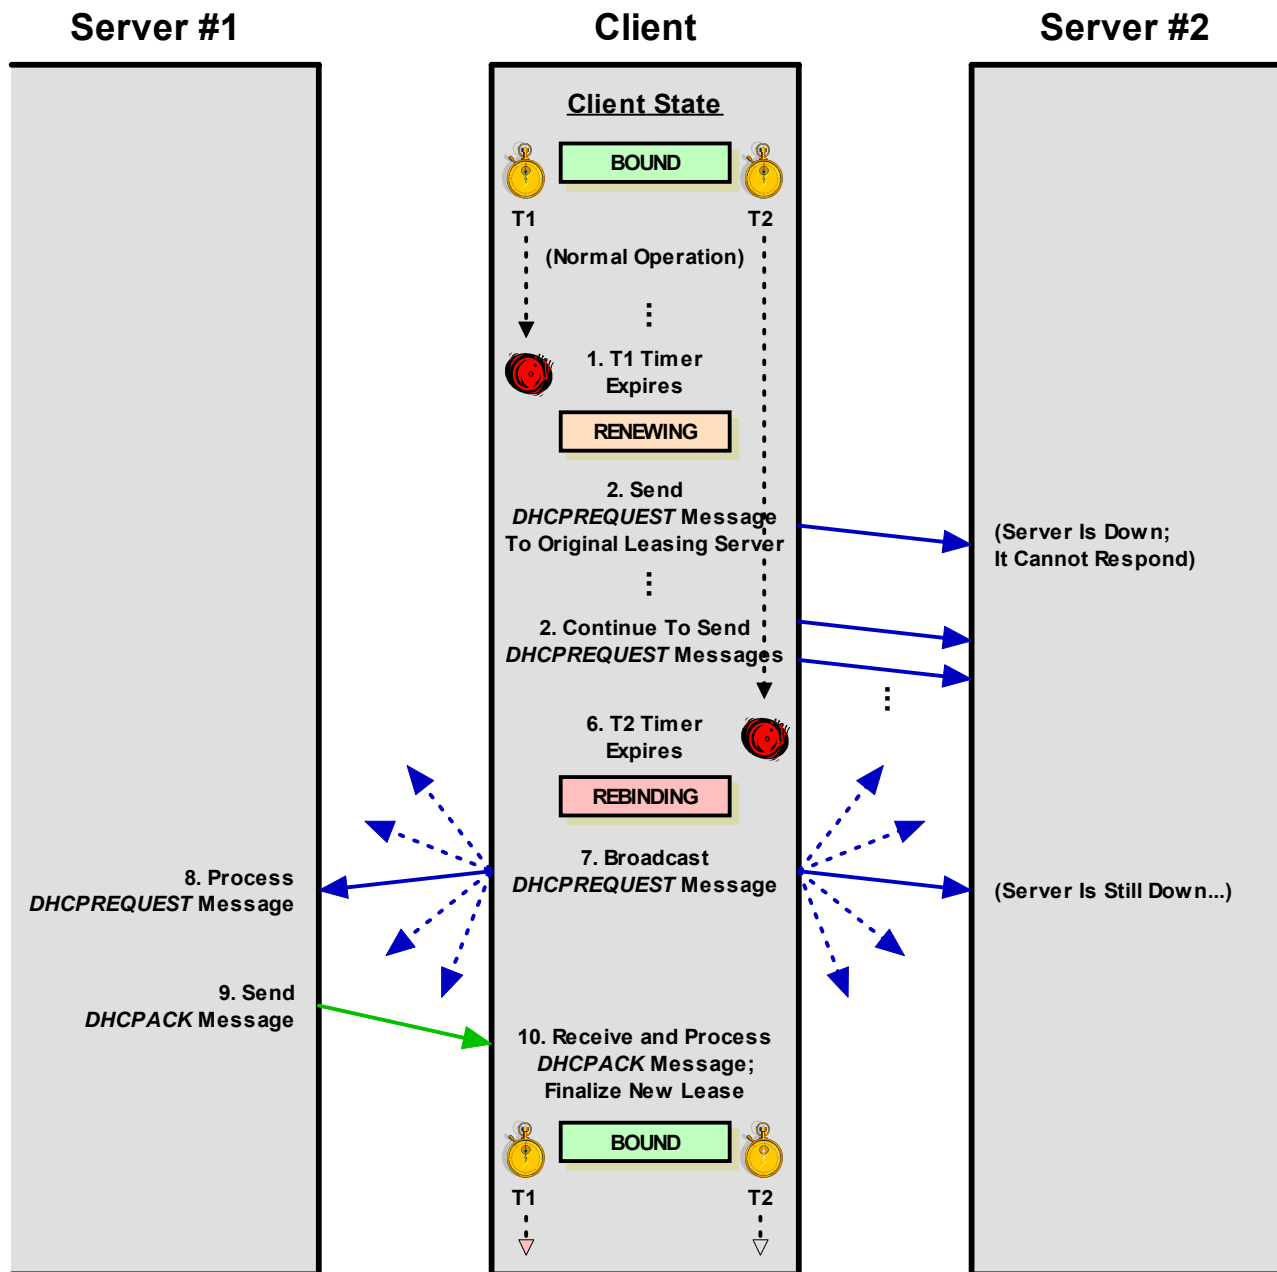

#### **4. Server Sends Reply**

The server sends the *DHCPACK* or *DHCPNAK* message back to the client.

#### **5. Client Receives and Processes Server Reply**

The client takes the appropriate action in response to the server's reply:

**Figure 265: DHCP Lease Renewal and Rebinding Processes**

This diagram shows the example of a client that presently holding a lease with Server #2 attempting to contact it to renew the lease. However, in this case, Server #2 is down for maintenance. The server is unable to respond and the client remains stuck at Step #2 in the renewal/rebinding process. It keeps sending *DHCPREQUEST* messages to Server #2 until its T2 timer expires. It then enters the rebinding state and broadcasts a *DHCPREQUEST* message, which is heard by Server #1, which in this case agrees to extend its current lease.

- ☉ **Positive Acknowledgment:** The client receives a *DHCPACK* message, renewing the lease. The client makes note of the new lease expiration time and any changed parameters sent by the server, resets the T1 and T2 timers, and transitions back to the *BOUND* state. Note that the client does *not* need to do an ARP IP address check when it is renewing.

- 
- ② **Negative Acknowledgment:** The message is a *DHCPNAK*, which tells the client that its lease renewal request has been denied. The client will immediately transition to the *INIT* state to get a new lease—step #1 in the allocation process.

## 6. Rebinding Timer (*T2*) Expires

If the client receives no reply from the server, it will remain in the *RENEWING* state, and will regularly retransmit the unicast *DHCPREQUEST* to the server. During this period of time, the client is still operating normally, from the perspective of its user. If no response from the server is received, eventually the rebinding timer (*T2*) expires. This will cause the client to transition to the *REBINDING* state. Recall that by default, the *T2* timer is set to 87.5% (7/8ths) of the length of the lease.

## 7. Client Sends *DHCPREQUEST* Rebinding Message

Having received no response from the server that initially granted the lease, the client “gives up” on that server and tries to contact any server that may be able to extend its existing lease. It creates a *DHCPREQUEST* message and puts its IP address in the *CIAddr* field, indicating clearly that it presently owns that address. It then broadcasts the request on the local network.

## 8. Servers Receives and Processes *DHCPREQUEST* Message and Send Reply

Each server receives the request, and responds according to the information it has for the client (a server that has no information about the lease or may have outdated information does not respond):

- ② **Server Agrees To Rebind Client Lease:** A server has information about the client's lease and agrees to extend it. It prepares for the client a *DHCPACK* message to confirm the lease's renewal, indicating any parameters that may have changed since the lease was created or last renewed.
- ② **Server Decides Client Cannot Extend Its Current Lease:** A server determines that for whatever reason, this client's lease should not be extended. It gets ready to send back to the client a *DHCPNAK* message.

## 9. Server Sends Reply

Each server that is responding to the client sends its *DHCPACK* or *DHCPNAK* message.

## 10. Client Receives Server Reply

The client takes the appropriate action in response to the two possibilities in the preceding step:

- ② **Positive Acknowledgment:** The client receives a *DHCPACK* message, rebinding the lease. The client makes note of the server that is now in charge of this lease, the new lease expiration time, and any changed parameters sent by the server. It resets the *T1* and *T2* timers, and transitions back to the *BOUND* state. (It may also probe the new address as it does during regular lease allocation.)

- 
- 🔊 **Negative Acknowledgment:** The message is a *DHCPNAK*, which tells the client that some server has determined that the lease should not be extended. The client immediately transitions to the *INIT* state to get a new lease—step #1 in the [allocation process](#).

## 11. Lease Expires

If the client receives no response to its broadcast rebinding request, it will, as in the *RENEWING* state, retransmit the request regularly. If no response is received by the time the lease expires, it transitions to the *INIT* state to get a new lease.

### *The Purpose of the Two-Step Rebinding/Renewal Process*

One valid question is: why bother with a two-step process, rebinding and renewal? The reason is that this provides the best blend of efficiency and flexibility. We first try to contact the server that granted the lease using a unicast request, to avoid taking up the time of other DHCP servers and disrupting the network as a whole with broadcast traffic. Usually this will work, because DHCP servers don't change that often and are usually left on continuously. If that fails, we then fall back on the broadcast, giving other servers a chance to take over the client's existing lease.

**Key Concept:** Each client's lease has associated with it a *renewal timer* (*T1*), normally set to 50% of the length of the lease, and a *rebinding timer* (*T2*), usually 87.5% of the lease length. When the *T1* timer goes off the client will try to renew its lease by contacting the server that originally granted it. If the client cannot renew the lease by the time the *T2* timer expires, it will broadcast a rebinding request to any available server. If the lease is not renewed or rebound by the time the lease expires, the client must start the lease allocation process over again.

---

## DHCP Early Lease Termination (Release) Process

A TCP/IP host can't really do much without an IP address; it's a fundamental component of the Internet Protocol, upon which all TCP/IP protocols and applications run. When a host has either a manual IP address assignment or an "infinite" lease, it obviously never has to worry about losing its IP address. When a host has a finite DHCP lease, it will use the [renewal/rebinding process](#) to try to "hang on" to its existing IP address as long as possible.

So, under normal circumstances, a client will continue trying to extend its existing lease indefinitely. In certain cases, however, a host may decide to terminate its lease. This usually will not be something the client just decides to do spontaneously; it will occur in response to a specific request from the user to end the lease. A user may terminate a lease for a number of reasons, including the following:

- 🔊 The client is being moved to a different network;
- 🔊 The network is having its IP addresses renumbered;
- 🔊 The user wants the host to negotiate a new lease with a different server;

- 
- ☉ The user wants to reset the lease to fix some sort of a problem.

In any of these cases, the user can end the lease through a process called *early lease termination* or *lease release*. This is a very simple, unidirectional communication. The client sends a special *DHCPRELEASE* message unicast to the server that holds its current lease, to tell it that the lease is no longer required. The server then records the lease as having been ended. It does not need to reply back to the client.

The reason that the client can just assume that the lease termination has been successful is that this is not a mandatory part of the DHCP protocol. Having clients send *DHCPRELEASE* to end a lease is considered a courtesy, rather than a requirement. It is more efficient to have clients inform servers when they no longer need a lease, and this also allows the IP address in the terminated lease to be reused more quickly. However, DHCP servers are designed to handle the case where a client “disappears” without formally ending an existing lease.

### **DHCP Parameter Configuration Process For Clients With Non-DHCP Addresses**

The majority of DHCP clients make use of the protocol to obtain both an IP address and other configuration parameters. This is the reason why so much of DHCP is oriented around address assignment and leasing. A conventional DHCP client obtains all its configuration parameters at the same time it gets an IP address, using the message exchanges and processes we have seen in the preceding topics of this section.

#### ***The Motivation for a Distinct Parameter Configuration Process***

There are cases, however, where a device with an IP address assigned using a method other than DHCP still wants to use DHCP servers to obtain other configuration parameters. The main advantage of this is administrative convenience; it allows a device with a static IP address to still be able to automatically get other parameters the same way that regular DHCP clients do.

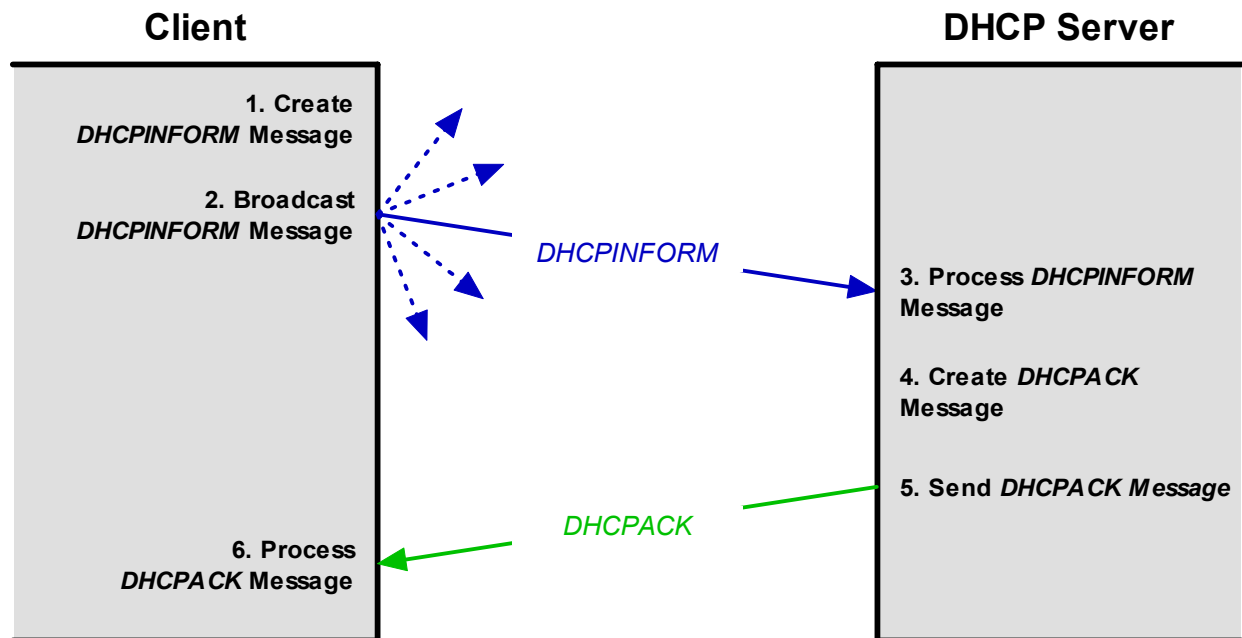

Ironically, one common case where this capability can be used is... configuring DHCP servers themselves! Administrators normally do not use DHCP to provide an IP address to a DHCP server, but they may want to use it to tell the server other parameters. In this case, the server requesting the parameters actually acts as a client for the purpose of the exchange with another server.

The original DHCP standard did not provide any mechanism for this sort of non-IP configuration to take place. RFC 2131 revised the protocol, adding a new message type (*DHCPINFORM*) that allows a device to request configuration parameters without going through the full leasing process. This message is used as part of a simple bidirectional communication that is separate from the leasing communications we have looked at so far. Since it doesn't involve IP address assignment, it is not part of the *lease “life cycle”*, nor is it part of the *DHCP client finite state machine*.

---

## Parameter Configuration Process Steps

The following steps show how a device with an externally-configured address uses DHCP to get other parameters (see [Figure 266](#) as well).

**Figure 266: DHCP Parameter Configuration Process**

A device that already has an IP address can use the simple request/reply exchange shown above to get other configuration parameters from a DHCP server. In this case I have shown the client broadcasting its request.

### 1. Client Creates *DHCPINFORM* Message

The client (which again, may be a DHCP server acting as a client) creates a *DHCPINFORM* message. It fills in its own IP address in the *CIAddr* field, since that IP address is current and valid. It may request specific parameters using the *Parameter Request List* option, or simply accept the defaults provided by the server.

### 2. Client Sends *DHCPINFORM* Message

The client sends the *DHCPINFORM* message unicast, if it knows the identity and address of a DHCP server, otherwise, it broadcasts it.

### 3. Server Receives and Processes *DHCPINFORM* Message

The message is received and processed by the DHCP server or servers (if there are multiple and the request was broadcast). Each server checks to see if it has the parameters needed by the client in its database.

---

#### 4. Server Creates *DHCPACK* Message

Each server that has the information the client needs creates a *DHCPACK* message, which includes the needed parameters in the appropriate DHCP [option fields](#). (Often this will be only a single server.)

#### 5. Server Sends *DHCPACK* Message

The server sends the message unicast back to the client.

#### 6. Client Receives and Processes *DHCPACK* Message

The client receives the *DHCPACK* message sent by the server, processes it, and sets its parameters accordingly.

#### *Dealing with Failure of the Configuration Process*

If a client receives no reply to its *DHCPINFORM* message it will retransmit it periodically. After a retry period it will give up and use default configuration values. It will also typically generate an error report to inform an administrator or user of the problem.

**Key Concept:** Devices that are not using DHCP to acquire IP addresses can still utilize its other configuration capabilities. A client can broadcast a *DHCPINFORM* message to request that any available server send it parameters for how the network is to be used. DHCP servers respond with the requested parameters and/or default parameters, carried in DHCP options of a *DHCPACK* message.

---

---

## **DHCP Messaging, Message Types and Formats**

The [topics on DHCP configuration and operation](#) demonstrated how DHCP works by showing the processes by which various leasing and information-exchange activities are accomplished. All of these procedures rely heavily on the exchange of information between client and server, which are carried in DHCP *messages*. Like all protocols, DHCP uses a special message format, and a set of rules that govern how messages are created, addressed and transported.

In this section I provide the details of how DHCP creates and sends messages, and show the formats used for DHCP messages and options. I begin with a description of how DHCP creates, addresses and transports messages, and how it deals with message retransmission. I then outline the DHCP general message format, showing how it is similar to the BOOTP message format upon which it is based, and also where it differs. I describe DHCP options, the format used for them, and the special option “overloading” feature used for efficiency. I conclude the section with a complete list of DHCP options.

**Related Information:** DHCP is most closely related to BOOTP in the area of messaging, so you'll find lots of references to BOOTP in this section. Note especially that DHCP options are based closely on [BOOTP vendor extensions](#), and many of the specific DHCP option types are the same as BOOTP vendor information fields. To avoid duplication, the summary table in this section lists the options/extensions for both protocols, indicating which ones are used by both BOOTP and DHCP, and which are used only by DHCP.

---

## **DHCP Message Generation, Addressing, Transport and Retransmission**

In [the previous section](#), we examined extensively the operation of DHCP, and its client/server nature. Pretty much every aspect of the protocol's operation is oriented around the notion of a client device exchanging information with a server. We can also see this reflected in all of the major characteristics of DHCP messaging. This includes the format of DHCP messages, as well as the specifics of how DHCP messages are created, addressed and transmitted—and when necessary, *retransmitted*.

### ***Message Generation and General Formatting***

DHCP messaging is similar in many ways to that of BOOTP, the protocol upon which DHCP was based. BOOTP defined only two message types, a request and a reply. DHCP is of course much more complex, using some eight different types of messages, but these are still categorized as either request or reply messages, depending on who sends them and why. DHCP uses a special *DHCP Message Type option* to indicate the exact DHCP message type, but still treats a message from a client seeking information as a request, and a response from a server containing information as a reply.

---

A client generates a message using the [general DHCP message format](#), which is very similar to the [BOOTP message format](#). When a server replies to a client message it does not generate the reply as a completely new message, but rather copies the client request, changes fields as appropriate, and sends the reply back to the client. A special transaction identifier (*XID*) is placed in the request and maintained in the reply, which allows a client know which reply goes with a particular request.

### ***Message Transport***

DHCP uses [UDP](#) for transport just as BOOTP does, and for the same reasons: simplicity and support for broadcasts. It also has many of the same addressing concerns that we discussed in [the topic on BOOTP messaging and addressing](#). Clients usually will send requests by broadcast on the local network, to allow them to contact any available DHCP server. The exception to this is when a client is trying to renew a lease with a server that it already knows. For compatibility with BOOTP, DHCP uses the same well-known (reserved) UDP port number, 67, for client requests to servers.

### ***Use of Broadcasts and Layer Two Message Delivery***

Some DHCP message exchanges require a server to respond back to a client that has a valid and active IP address. An example is a *DHCPACK* sent in reply to a *DHCPINFORM* request. In this situation, the server can always send a reply unicast back to the client. Other message exchanges, however, present the same “chicken and egg” conundrum that we saw with BOOTP: if a client is using DHCP to obtain an IP address, we can't assume that IP address is available for us to use to send a reply.

In BOOTP, there were two specified solution to this situation: first, the server could send back its reply using broadcast addressing as well; second, the server could send back a reply directly to the host at layer two. Due to the performance problems associated with broadcasts, DHCP tries to make the latter method the default for server replies. It assumes that a client's TCP/IP software will be capable of accepting and processing an IP datagram delivered at layer two, even before the IP stack is initialized.

As the standard itself puts it, “DHCP requires creative use of the client's TCP/IP software and liberal interpretation of RFC 1122”. RFC 1122 is a key standard describing the detailed implementation requirements of TCP/IP hosts. The DHCP standard, however, acknowledges the fact that not all devices may support this behavior. It allows a client to force servers to send back replies using broadcasts instead. This is done by the client setting the special *Broadcast (B)* flag to 1 in its request.

Since DHCP, like BOOTP, must use either layer two delivery or layer three broadcasts for server replies, it requires a separate well-known port number for servers to send to. Again, for compatibility with BOOTP, the same port number is used, 68. This port number is used whether a server reply is sent unicast or broadcast.

**Key Concept:** Requests from BOOTP clients are normally sent broadcast, to reach any available DHCP server. However, there are certain exceptions, such as in lease renewal, when a request is sent directly to a known server. DHCP servers can send their replies either broadcast to the special port number reserved for DHCP clients, or unicast using layer two. The DHCP standards specify that layer two delivery should be used when possible to avoid unnecessary broadcast traffic.

---

### ***Retransmission of Lost Messages***

Using UDP provides benefits such as simplicity and efficiency to DHCP, but since UDP is unreliable, there is no guarantee that messages will get to their destination. This can lead to potential confusion on the part of a client. Consider, for example, a client sending a *DHCPDISCOVER* message and waiting for *DHCPOFFER* messages in reply. If it gets no response, does this mean that there is no DHCP server willing to offer it service, or simply that its *DHCPDISCOVER* got “munched” somewhere on the network? The same applies to most other request/reply sequences, such as a client waiting for a *DHCPACK* or *DHCNACK* in reply to a *DHCPREQUEST* or *DHCPINFORM*.

The fact that messages can be lost means that DHCP itself must keep track of messages sent and if there is no response, retransmit them. Since there are so many message exchanges in DHCP, there is much more that can “go wrong”. As in BOOTP, DHCP puts responsibility for this squarely on the shoulders of the client. This makes sense, since the client initiates contact and can most easily keep track of messages sent and retransmit them when needed. A server can't know when a client's request is lost, but a client **can** react to a server's reply being lost.

In any request/reply message exchange, the client uses a retransmission timer that is set to a period of time that represents how long it is reasonable for it to wait for a response. If no reply is received by the time the timer expires, the client assumes that either its request or the response coming back was lost. The client then retransmits the request. If this request again elicits no reply, the client will continue retransmitting for a period of time.

To prevent large numbers of DHCP clients from retransmitting requests simultaneously (which would potentially clog the network), the client must use a randomized exponential backoff algorithm to determine when exactly a retransmission is made. As in BOOTP, this is similar to the technique used to recover from collisions in Ethernet. The DHCP standard specifies that the delay should be based on the speed of the underlying network between the client and the server. More specifically, it says that in a standard Ethernet network, the first retransmission should be delayed 4 seconds plus or minus a random value from 0 to 1 second—in other words, some value is chosen between 3 and 5 seconds. The delay is then doubled with each subsequent transmission (7 to 9 seconds, then 15 to 17 seconds and so forth) up to a maximum of 64 +/- 1 second.

---

To prevent it from retrying endlessly, the client normally has logic that limits the number of retries. The amount of time that retransmissions go on depends on the type of request being sent; that is, what process is being undertaken. If a client is forced to “give up” due to too many retries it will generally either take some sort of default action or generate an error message.

**Key Concept:** Like BOOTP, DHCP uses UDP for transport, which provide no reliability features. DHCP clients must detect when requests are sent and no response is received, and retransmit requests periodically. Special logic is used to prevent clients from sending excessive numbers of requests during difficult network conditions.

---

## **DHCP Message Format**

When DHCP was created, its developers had a bit of an issue related to how exactly they should structure DHCP messages. BOOTP was already widely used, and maintaining compatibility between DHCP and BOOTP was an important goal. This meant that DHCP's designers needed to continue using the existing BOOTP message format. However, DHCP has more functionality than BOOTP, and this means more information than can easily be held in the limited [BOOTP message format](#).

This apparent contradiction was resolved in two ways. First, the existing BOOTP message format was maintained for basic functionality, but DHCP clients and servers were programmed to use the BOOTP message fields in slightly different ways. Second, the BOOTP vendor extensions were formalized and became DHCP *options*, as we'll see in the next two topics. Despite the name “options”, some of these are in fact the additional fields needed for basic DHCP functionality, and are quite mandatory. 😊

With this dual approach, DHCP devices have access to the extra information they need. Meanwhile, the basic field format is unchanged, which allows DHCP servers to communicate with older BOOTP clients, which ignore the extra DHCP information that doesn't relate to them. [See the topic on BOOTP/DHCP interoperability for more.](#)

[Table 190](#) describes the format of DHCP messages, which is also shown in [Figure 267](#). In the table, I have specifically indicated which fields are used in DHCP in a manner similar to how they are used in BOOTP, and which are significantly different.

**Table 190: DHCP Message Format (Page 1 of 3)**

Field Name	Size (bytes)	Description																										
Op	1	<p><b>Operation Code:</b> Specifies the general type of message. A value of 1 indicates a request message, while a value of 2 is a reply message.</p> <p>This code represents the general category of the DHCP message; a client sending a request to a server uses an <i>Op</i> code of 1, while a server replying uses a code of 2. So, for example, a <i>DHCPREQUEST</i> would be a request, while a <i>DHCPACK</i> or <i>DHCPNAK</i> is a reply. The actual specific type of DHCP message is encoded using the <a href="#">DHCP Message Type option</a>.</p>																										
HType	1	<p><b>Hardware Type:</b> This field specifies the type of hardware used for the local network, and is used in exactly the same way as the equivalent field (<i>HRD</i>) in the <a href="#">Address Resolution Protocol (ARP) message format</a>. Some of the most common values for this field:</p> <table><tr><th>HType Field Value</th><th>Hardware Type</th></tr><tr><td>1</td><td>Ethernet (10 Mb)</td></tr><tr><td>6</td><td>IEEE 802 Networks</td></tr><tr><td>7</td><td>ARCNET</td></tr><tr><td>11</td><td>LocalTalk</td></tr><tr><td>12</td><td>LocalNet (IBM PCNet or SYTEK LocalNET)</td></tr><tr><td>14</td><td>SMDS</td></tr><tr><td>15</td><td>Frame Relay</td></tr><tr><td>16</td><td>Asynchronous Transfer Mode (ATM)</td></tr><tr><td>17</td><td>HDLC</td></tr><tr><td>18</td><td>Fibre Channel</td></tr><tr><td>19</td><td>Asynchronous Transfer Mode (ATM)</td></tr><tr><td>20</td><td>Serial Line</td></tr></table>	HType Field Value	Hardware Type	1	Ethernet (10 Mb)	6	IEEE 802 Networks	7	ARCNET	11	LocalTalk	12	LocalNet (IBM PCNet or SYTEK LocalNET)	14	SMDS	15	Frame Relay	16	Asynchronous Transfer Mode (ATM)	17	HDLC	18	Fibre Channel	19	Asynchronous Transfer Mode (ATM)	20	Serial Line
HType Field Value	Hardware Type																											
1	Ethernet (10 Mb)																											
6	IEEE 802 Networks																											
7	ARCNET																											
11	LocalTalk																											
12	LocalNet (IBM PCNet or SYTEK LocalNET)																											
14	SMDS																											
15	Frame Relay																											
16	Asynchronous Transfer Mode (ATM)																											
17	HDLC																											
18	Fibre Channel																											
19	Asynchronous Transfer Mode (ATM)																											
20	Serial Line																											
HLen	1	<p><b>Hardware Address Length:</b> Specifies how long hardware addresses are in this message. For Ethernet or other networks using IEEE 802 MAC addresses, the value is 6. This is also the same as a field in the <a href="#">ARP field format</a>, <i>HLN</i>.</p>																										
Hops	1	<p><b>Hops:</b> Set to 0 by a client before transmitting a request and used by <a href="#">relay agents</a> to control the forwarding of BOOTP and/or DHCP messages.</p>																										
XID	4	<p><b>Transaction Identifier:</b> A 32-bit identification field generated by the client, to allow it to match up the request with replies received from DHCP servers.</p>																										
Secs	2	<p><b>Seconds:</b> In BOOTP this field was vaguely defined and not always used. For DHCP, it is defined as the number of seconds elapsed since a client began an attempt to acquire or renew a lease. This may be used by a busy DHCP server to prioritize replies when multiple client requests are outstanding.</p>																										

**Table 190: DHCP Message Format (Page 2 of 3)**

Field Name	Size (bytes)	Description									
<b>Flags</b>	2	<p><b>Flags:</b> This corresponds to the formerly empty two-byte field in the BOOTP message format defined by RFC 951, which was redefined as a <i>Flags</i> field in RFC 1542. The field presently contains just one flag subfield, as follows:</p> <table> <tr> <th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr> <tr> <td><b>B</b></td><td>1/8 (1 bit)</td><td><b>Broadcast Flag:</b> A client that doesn't know its own IP address at the time it sends its request sets this flag to 1. This serves as an immediate indicator to the DHCP server or relay agent that receives the request that it should send its reply back by broadcast.</td></tr> <tr> <td><b>Reserved</b></td><td>1 7/8 (15 bits)</td><td><b>Reserved:</b> Set to zero and not used.</td></tr> </table>	Subfield Name	Size (bytes)	Description	<b>B</b>	1/8 (1 bit)	<b>Broadcast Flag:</b> A client that doesn't know its own IP address at the time it sends its request sets this flag to 1. This serves as an immediate indicator to the DHCP server or relay agent that receives the request that it should send its reply back by broadcast.	<b>Reserved</b>	1 7/8 (15 bits)	<b>Reserved:</b> Set to zero and not used.
Subfield Name	Size (bytes)	Description									
<b>B</b>	1/8 (1 bit)	<b>Broadcast Flag:</b> A client that doesn't know its own IP address at the time it sends its request sets this flag to 1. This serves as an immediate indicator to the DHCP server or relay agent that receives the request that it should send its reply back by broadcast.									
<b>Reserved</b>	1 7/8 (15 bits)	<b>Reserved:</b> Set to zero and not used.									
<b>CIAddr</b>	4	<p><b>Client IP Address:</b> The client puts its own current IP address in this field if and only if it has a valid IP address while in the <i>BOUND</i>, <i>RENEWING</i> or <i>REBINDING</i> states; otherwise, it sets the field to 0. The client can only use this field when its address is actually valid and usable, not during the process of acquiring an address. Specifically, the client does not use this field to request a particular IP address in a lease; it uses the <i>Requested IP Address</i> DHCP option.</p>									
<b>YIAddr</b>	4	<p><b>"Your" IP Address:</b> The IP address that the server is assigning to the client.</p>									
<b>SIAddr</b>	4	<p><b>Server IP Address:</b> The meaning of this field is slightly changed in DHCP. In BOOTP, it is the IP address of the BOOTP server sending a <i>BOOTREPLY</i> message. In DHCP, it is the address of the server that the client should use for the next step in the bootstrap process, which may or may not be the server sending this reply.</p> <p>The sending server always includes its own IP address in the <i>Server Identifier</i> DHCP option.</p>									
<b>GIAddr</b>	4	<p><b>Gateway IP Address:</b> This field is used just as it is in BOOTP, to route BOOTP messages when BOOTP relay agents are involved to facilitate the communication of BOOTP requests and replies between a client and a server on different subnets or networks. <a href="#">See the topic on DHCP relaying</a>. As with BOOTP, this field is not used by clients and does not represent the server giving the client the address of a default router (that's done using the <i>Router</i> DHCP option).</p>									
<b>CHAddr</b>	16	<p><b>Client Hardware Address:</b> The hardware (layer two) address of the client, which is used for identification and communication.</p>									

**Table 190: DHCP Message Format (Page 3 of 3)**

Field Name	Size (bytes)	Description
<b>SName</b>	64	<p><b>Server Name:</b> The server sending a <i>DHCPOFFER</i> or <i>DHCPACK</i> message may optionally put its name in this field. This can be a simple text “nickname” or a <a href="#">fully-qualified DNS domain name</a> (such as “myserver.organization.org”).</p> <p>This field may also be used to carry DHCP options, using the “<a href="#">option overload</a>” feature, indicated by the value of the DHCP <i>Option Overload</i> option.</p>
<b>File</b>	128	<p><b>Boot Filename:</b> Optionally used by a client to request a particular type of boot file in a <i>DHCPDISCOVER</i> message. Used by a server in a <i>DHCPOFFER</i> to fully specify a boot file directory path and filename.</p> <p>This field may also be used to carry DHCP options, using the “<a href="#">option overload</a>” feature, indicated by the value of the DHCP <i>Option Overload</i> option.</p>
<b>Options</b>	Variable	<p><b>Options:</b> Holds <a href="#">DHCP options</a>, including several parameters required for basic DHCP operation. Note that this field was fixed at 64 bytes in length in BOOTP but is variable in length in DHCP. See the next two topics for more information. This field may be used by both client and server.</p>

The DHCP standard does not specify the details of how DHCP messages are encapsulated within UDP. I would assume that due to the other similarities to BOOTP, DHCP maintains BOOTP's optional use of message checksums. It also most likely assumes that messages will not be fragmented (sent with the *Do Not Fragment* bit set to 1 in the [IP datagram](#)). This is to allow BOOTP clients to avoid the complexity of [reassembling fragmented messages](#).

I should point out, however, that DHCP messages are variable in length, compared to BOOTP's fixed message size. This was done by changing BOOTP's 64-byte *Vend* field into the variable-length *Options* field. DHCP relies on options much more than BOOTP does, and a device must be capable of accepting a message with an *Options* field at least 312 bytes in length. The *SName* and *File* fields may also be used to carry options, as described in the next topic.

## **DHCP Options, Option Format and "Option Overloading"**

When BOOTP was first developed, its [message format](#) included a 64-byte *Vend* field, called the *Vendor-Specific Area*. The idea behind this field was to provide flexibility to the protocol. The BOOTP standard did not define any specific way of using this field. Instead, the field was left open for the creators of different types of hardware to use it to customize BOOTP to meet the needs of their clients and/or servers.

**Figure 267: DHCP Message Format**

---

Including this sort of “undefined” field is always a good idea because it makes a protocol easily *extensible*. That is, allows the protocol to be easily enhanced in the future through the definition of new fields while not disturbing any existing fields. The problem with the BOOTP *Vendor-Specific Area*, however, is that the extensibility was in fact **vendor-specific**. It was useful only for special fields that were particular to a single vendor.

What was really needed was a way to define new fields for general purpose, vendor-independent parameter communication, but there was no field in the BOOTP message format that would let this happen. The solution came in the form of RFC 1048, which defined a technique called BOOTP *vendor information extensions*. This method redefines the vendor-specific area to allow it to carry general parameters between client and server. This idea was so successful that it [largely replaced the older vendor-specific use](#) of the *Vend* field.

### **Options and Option Format**

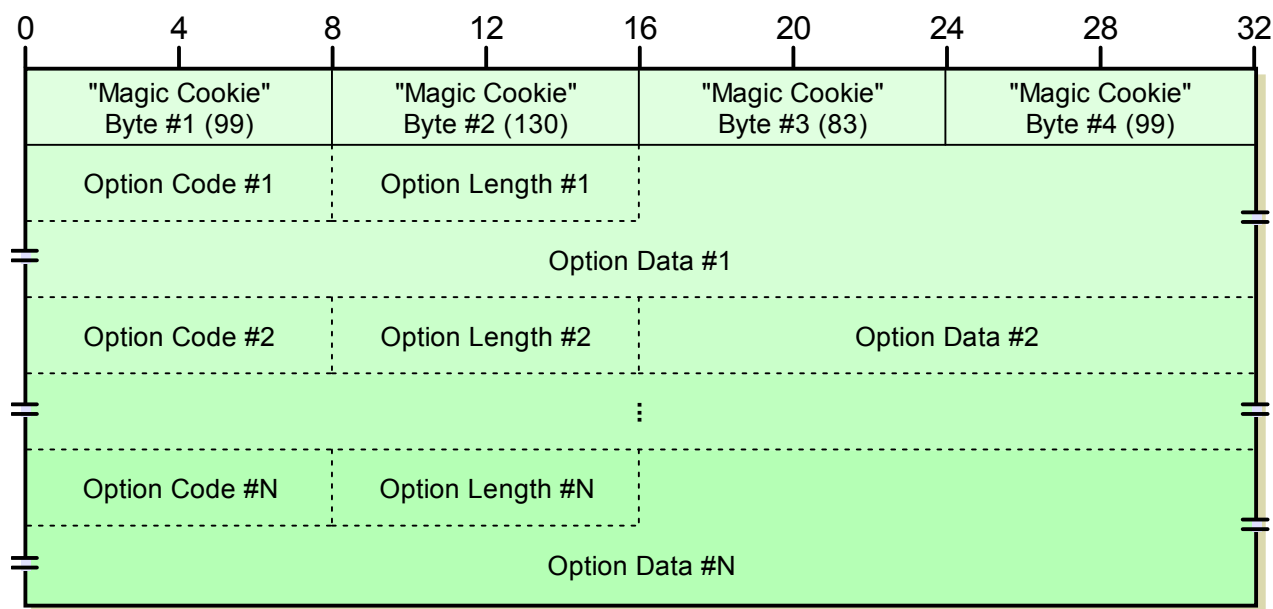

DHCP maintains, formalizes and further extends the idea of using the *Vend* field to carry general-purpose parameters. Instead of being called vendor information extensions, or vendor information fields, these fields are now called simply DHCP *options*. Similarly, the *Vend* field has been renamed the *Options* field, reflecting its new role as a way of conveying vendor-independent options between client and server.

Keeping with the desire to maintain compatibility between BOOTP and DHCP, the DHCP *Options* field is in most ways the same as the vendor-independent interpretation of the BOOTP *Vend* field introduced by RFC 1048. The first four bytes of the field still carry the “magic cookie” value “99.130.83.99” to identify the information as vendor-independent option fields. The rest of the *Option* field consists of one or more subfields, each of which has a “type, length, value” (*TLV-encoded*) substructure as in BOOTP. The main differences between BOOTP vendor information fields and DHCP options are the field names and the fact that the DHCP *Options* field is variable in length where the BOOTP *Vend* field is fixed at 64 bytes. The structure of the DHCP *Options* field as a whole is shown in [Figure 268](#); the subfield names of each option are described in [Table 191](#).

**Table 191: DHCP Option Format**

Subfield Name	Size (bytes)	Description
<b>Code</b>	1	<b>Option Code:</b> A single octet that specifies the option type.
<b>Len</b>	1	<b>Option Length:</b> The number of bytes in this particular option. This does not include the two bytes for the <i>Code</i> and <i>Len</i> fields.
<b>Data</b>	Variable	<b>Option Data:</b> The data being sent, which has a length indicated by the <i>Len</i> subfield, and which is interpreted based on the <i>Code</i> subfield.

All of the DHCP options follow the format of [Table 191](#), except for two special cases, again the same as BOOTP. A *Code* value of 0 is used as a *pad*, when subfields need to be aligned on word boundaries; it contains no information. The value 255 is used to mark the end of the vendor information fields. Both of these codes contain no actual data, so to save

**Figure 268: DHCP *Options* Field Format**

The format of the DHCP *Options* field is, unsurprisingly, very similar to that of the BOOTP *Vendor-Specific Area*, as shown in [Figure 257](#). The *Options* field begins with the same four-byte “magic cookie” and then contains a number of variable-length option fields. Each option has the format described in [Table 191](#).

space, when either is used just the single *Code* value is included; the *Len* and *Data* fields are omitted. A device seeing a *Code* value of 0 just skips it as filler; a device seeing a *Code* value of 255 knows it has reached the end of the fields in this *Options* field.

### ***Option Categories***

Before DHCP was invented, a series of BOOTP standards was published defining the current list of BOOTP vendor information extensions. When DHCP was developed, a single standard was created that merged both BOOTP vendor information extensions and DHCP options, since again, they are basically the same. The most recent of these is RFC 2132, entitled (ta-da!) *DHCP Options and BOOTP Vendor Extensions*.

RFC 2132 lists several dozen fields that can be used either as DHCP options or BOOTP vendor information fields. For easier “digestion”, these are broken into several categories. In addition, there is also a set of fields that are used only in DHCP, not in BOOTP. Despite being called “options”, only some really are optional; others are necessary for the basic

---

operation of DHCP. They are carried as “option” fields for only one reason: to allow DHCP to keep using the same basic message format as BOOTP for compatibility. [Table 192](#) summarizes the categories used for DHCP options.

**Table 192: DHCP Option Categories**

Option Category	Description
<b><i>RFC 1497 Vendor Extensions</i></b>	The <a href="#">BOOTP vendor extensions</a> defined in RFC 1497, the last RFC describing vendor extension fields that was BOOTP-specific (before DHCP was created). For easier reference, these were kept in a single group when DHCP options were created, even though some of the functions they represent might better belong in other categories.
<b><i>IP Layer Parameters Per Host</i></b>	Parameters that control the operation of the Internet Protocol on a host, which affect the host as a whole and are not interface-specific.
<b><i>IP Layer Parameters Per Interface</i></b>	Parameters that affect the operation of the Internet Protocol for a particular interface of a host. (Some devices have only one interface, of course, while others have more.)
<b><i>Link Layer Parameters Per Interface</i></b>	Parameters that affect the <a href="#">data link layer</a> operation of a host, on a per-interface basis.
<b><i>TCP Parameters</i></b>	Parameters that impact the operation of the <a href="#">TCP</a> layer; specified on a per-interface basis.
<b><i>Application and Service Parameters</i></b>	Parameters used to configure or control the operation of various miscellaneous applications or services.
<b><i>DHCP Extensions</i></b>	Parameters that are DHCP-specific, and used to control the operation of the DHCP protocol itself.

The [next topic](#) provides a complete list of the DHCP options defined in RFC 2132. Due to the popularity of DHCP, several other options have been defined since that standard was published. Each time a new option is created, documenting it would have required a new successor to RFC 2132, which would be confusing and time-consuming. Instead, the maintenance of these options / extensions has been moved from the RFC process to a set of files maintained by the [IANA](#), just like so many other parameters. There is also a process by which a developer can request additional standard extensions to be added to DHCP. This is described in section 10 of RFC 2132.

**Key Concept:** DHCP takes BOOTP’s vendor information extensions and formalizes them into an official feature called *DHCP options*. The *BOOTP Vendor-Specific Area* field becomes the *DHCP Options* field, and can contain an arbitrary number of parameters to be sent from the server to the client. Some of these include pieces of data that are actually mandatory for the successful operation of DHCP. There are several dozen DHCP options, which are divided into functional categories.

---

---

## Option Overloading

Since DHCP relies so much more on the use of options than BOOTP did, the size of the *Options* field could theoretically grow quite large. However, since DHCP is using UDP for transport, the overall size of a message is limited. This could theoretically have led to a situation where a message might run out of room and be unable to carry all its options. Meanwhile, there are two “spacious” fields in the message format, *SName* and *File*, at 64 and 128 bytes respectively. These fields might not even be needed in some cases, because many devices use DHCP for getting a lease and parameters and not to download a boot image. Even if they *are* needed, they might be carrying much less information than their large fixed size allows.

To make better use of the total space in the message format, DHCP includes a special feature called *option overloading*, which allows these two fields to be used to carry more option fields instead of their conventional information. Use of this option is itself indicated through the use of a DHCP option, *Option Overload*, which tells a device receiving a message how to interpret the two fields. If option overload is used, the *SName* and/or *File* fields are read and interpreted in the same way as the *Options* field, after all options in the *Option* field are parsed. If the message actually does need to carry a server name or boot file, these are included as separate options (number 66 and number 67, respectively), which are variable-length and can therefore be made exactly the length needed. Again, [see the next topic for details](#).

**Key Concept:** Since DHCP messages can contain so many options, a special feature called *option overloading* was created. When enabled, overloading allows options to make use of the large *SName* and *File* fields in the DHCP message format for options.

---

## Combining Vendor-Independent and Vendor-Specific Information

Incidentally, the creators of DHCP did recognize that even though vendor-independent options are important, a vendor might want to be able to send vendor-specific information just as the original BOOTP defined. To this end, they created a DHCP option called *Vendor Specific Information*. This option allows a vendor to encapsulate a set of vendor-specific option fields within the normal DHCP option structure.

In essence, you can think of this as a way of nesting a conventional BOOTP *Vend* field (of variable length) within a single DHCP option. Other DHCP options can be carried simultaneously, subject to overall message length limits. Note that this supplements an already-existing BOOTP option that allows reference to be made to a file containing vendor-specific information.

---

## Summary Of DHCP Options / BOOTP Vendor Information Fields

BOOTP *vendor information fields* are used to carry additional vendor-independent configuration parameters. These were used as the basis for DHCP *options*, which extend the concept to include parameters used to manage the operation of DHCP as a whole, as described in [the preceding topic](#). Since BOOTP vendor information fields and DHCP options are essentially the same (except for the DHCP-specific fields), they are described in the same TCP/IP standard, and hence, in this single Guide topic.

Below I have included a number of tables, organized by the RFC 2132 option categories, that list each of the DHCP options / BOOTP vendor information fields. I have shown each option's *Code* value, and the length of the *Data* subfield for the option, in bytes. I have then provided the formal name of the option and a brief description of how it is used. For simplicity, in the tables below I say just “options”; please read “option” as “option / vendor information field”, since they are the same (except, again, the DHCP-specific options.)

There are a lot of options in these tables, and some of them define parameters that are used by somewhat obscure protocols that I may not cover in this Guide, so don't be put off if the brief description is not enough for you to completely understand how each and every option is used. Other options will seem quite familiar to you based on other discussions in this Guide. Note in particular that many of the original BOOTP vendor information fields that are used to communicate the addresses of certain types of servers are now archaic and may no longer be used.

### RFC 1497 Vendor Extensions

[Table 193](#) shows the DHCP/BOOTP options that were originally defined in RFC 1497.

**Table 193: DHCP/BOOTP Options: RFC 1497 Vendor Extensions (*Page 1 of 3*)**

Code Value	Data Length (bytes)	Name and Description
0	0	<b>Pad:</b> A single byte used as “filler” to align a subsequent field on a word (two-byte) boundary. Contains no information.  One of two options that is a single byte in length, having no <i>Data</i> subfield (the other being the <i>End</i> option below.)
1	4	<b>Subnet Mask:</b> A 32-bit <a href="#">subnet mask</a> being supplied for the client to use on the current network. Must appear in the option list before the <i>Router</i> option if both are present.
2	4	<b>Time Offset:</b> Specifies the time offset of the client's subnet in seconds from <i>Coordinated Universal Time</i> (UTC, formerly <i>Greenwich Mean Time</i> or GMT). Positive values represent areas east of the prime meridian (in the United Kingdom), negative values areas west. Essentially, this is used to indicate the time zone of the subnet.

**Table 193: DHCP/BOOTP Options: RFC 1497 Vendor Extensions (Page 2 of 3)**

Code Value	Data Length (bytes)	Name and Description
3	Variable (Multiple of 4)	<b>Router:</b> Specifies a list of 32-bit router addresses for the client to use on the local network. Routers are listed in the order of preference for the client to use.
4	Variable (Multiple of 4)	<b>Time Server:</b> Specifies a list of time server addresses ( <a href="#">per RFC 868</a> ) for the client to use on the local network. Servers are listed in the order of preference for the client to use.
5	Variable (Multiple of 4)	<b>IEN-116 Name Server:</b> Specifies a list of IEN-116 name server addresses for the client to use on the local network. Servers are listed in the order of preference for the client to use.  Note that this option is not used for DNS name servers; see below.
6	Variable (Multiple of 4)	<b>DNS Name Server:</b> Specifies a list of <a href="#">DNS</a> name server addresses for the client to use on the local network. Servers are listed in the order of preference for the client to use.
7	Variable (Multiple of 4)	<b>Log Server:</b> Specifies a list of MIT-LCS UDP log server addresses for the client to use on the local network. Servers are listed in the order of preference for the client to use.
8	Variable (Multiple of 4)	<b>Cookie Server:</b> Specifies a list of <a href="#">RFC 865</a> “cookie” server addresses for the client to use on the local network. Servers are listed in the order of preference for the client to use.
9	Variable (Multiple of 4)	<b>LPR Server:</b> Specifies a list of RFC 1179 line printer server addresses for the client to use on the local network. Servers are listed in the order of preference for the client to use.
10	Variable (Multiple of 4)	<b>Impress Server:</b> Specifies a list of Imagen Impress server addresses for the client to use on the local network. Servers are listed in the order of preference for the client to use.
11	Variable (Multiple of 4)	<b>Resource Location Server:</b> Specifies a list of RFC 887 resource location server addresses for the client to use on the local network. Servers are listed in the order of preference for the client to use.
12	Variable	<b>Host Name:</b> Specifies a host name for the client. This may or may not be a DNS host name; see option #15 below.
13	2	<b>Boot File Size:</b> Specifies the size of the default boot image file for the client, expressed in units of 512 bytes.
14	Variable	<b>Merit Dump File:</b> Specifies the path and filename of the file to which the client should dump its core image in the event that it crashes.
15	Variable	<b>Domain Name:</b> Specifies the DNS domain name for the client. Compare to option #12.
16	4	<b>Swap Server:</b> Specifies the address of the client's swap server.
17	Variable	<b>Root Path:</b> Specifies the path name of the client's root disk. This allows the client to access files it may need, using a protocol such as <a href="#">NFS</a> .

**Table 193: DHCP/BOOTP Options: RFC 1497 Vendor Extensions (Page 3 of 3)**

Code Value	Data Length (bytes)	Name and Description
18	Variable	<p><b>Extensions Path:</b> Specifies the name of a file that contains vendor-specific fields that the client can interpret in the same way as the <i>Options</i> or <i>Vend</i> field in a DHCP/BOOTP message. This was defined to allow a client and server to still exchange vendor-specific information even though the <i>Option/Vend</i> field is now used for the general-purpose fields described in this topic.</p> <p>Also see option #43 below.</p>
255	0	<p><b>End:</b> Placed after all other options to mark the end of the option list.</p> <p>One of two options that is a single byte in length, having no <i>Data</i> subfield (the other being the <i>Pad</i> option above.)</p>

### IP Layer Parameters Per Host

These are parameters that control the operation of IP on a host as a whole (not interface-specific) see [Table 194](#).

**Table 194: DHCP/BOOTP Options: IP Layer Parameters Per Host**

Code Value	Data Length (bytes)	Name and Description
19	1	<b>IP Forwarding Enable/Disable:</b> A value of 1 turns on IP forwarding (that is, routing) on a client that is capable of that function; a value of 0 turns it off.
20	1	<p><b>Non-Local Source Routing Enable/Disable Option:</b> A value of 1 tells a client capable of routing to allow forwarding of IP datagrams with non-local source routes. A value of 0 tells the client not to allow this.</p> <p>See the <a href="#">source routing IP datagram option</a> for a bit more information on this and option #21 below.</p>
21	Variable (Multiple of 8)	<b>Policy Filter:</b> A set of address/mask pairs used to filter non-local source-routed datagrams.
22	2	<b>Maximum Datagram Reassembly Size:</b> Tells the client the size of the largest datagram that the client should be prepared to reassemble. The minimum value is 576 bytes.
23	1	<b>Default IP Time-To-Live:</b> Specifies the default value that the client should use for the <i>Time To Live</i> field in creating <a href="#">IP datagrams</a> .
24	4	<b>Path MTU Aging Timeout:</b> Specifies the number of seconds the client should use in aging path MTU values determined using Path MTU discovery.
25	Variable (Multiple of 2)	<b>Path MTU Plateau Table:</b> Specifies a table of values to be used in performing path MTU discovery.

---

## IP Layer Parameters Per Interface

These parameters are specific to a particular host interface at the IP level ([Table 195](#))

**Table 195: DHCP/BOOTP Options: IP Layer Parameters Per Interface**

Code Value	Data Length (bytes)	Name and Description
26	2	<b>Interface MTU:</b> Specifies the <a href="#">maximum transmission unit (MTU)</a> to be used for IP datagrams on this interface. Minimum value is 68.
27	1	<b>All Subnets Are Local:</b> When set to 1, tells the client that it may assume that all subnets of the IP network it is on have the same MTU as its own subnet. When 0, the client must assume that some subnets may have smaller MTUs than the client's subnet.
28	4	<b>Broadcast Address:</b> Tells the client what address it should use for broadcasts on this interface.
29	1	<b>Perform Mask Discovery:</b> A value of 1 tells the client that it should use <a href="#">ICMP</a> to discover a subnet mask on the local subnet. A value of 0 tells the client not to perform this discovery.
30	1	<b>Mask Supplier:</b> Set to 1 to tell the client that it should respond to ICMP subnet mask requests on this interface.
31	1	<b>Perform Router Discovery:</b> A value of 1 tells the client to use the <a href="#">ICMP router discovery process</a> to solicit a local router. A value of 0 tells the client to not do so. Note that DHCP itself can be used to specify one or more local routers using option #3 above.
32	4	<b>Router Solicitation Address:</b> Tells the client the address to use as the destination for router solicitations.
33	Variable (Multiple of 8)	<b>Static Route:</b> Provides the client with a list of static routes it can put into its routing cache. The list consists of a set of IP address pairs; each pair defines a destination and a router to be used to reach the destination.

## Link Layer Parameters Per Interface

[Table 196](#) lists the DHCP/BOOTP options that are specific to a particular link layer (layer two) interface.

**Table 196: DHCP/BOOTP Options: Link Layer Parameters Per Interface (Page 1 of 2)**

Code Value	Data Length (bytes)	Name and Description
34	1	<b>Trailer Encapsulation:</b> When set to 1, tells the client to negotiate the use of trailers, as defined in RFC 893. A value of 0 tells the client not to use this feature.

---

**Table 196: DHCP/BOOTP Options: Link Layer Parameters Per Interface (Page 2 of 2)**

Code Value	Data Length (bytes)	Name and Description
35	4	<b>ARP Cache Timeout:</b> Specifies how long, in seconds, the client should hold entries in its <a href="#">ARP cache</a> .
36	1	<b>Ethernet Encapsulation:</b> Tells the client what type of encapsulation to use when transmitting over Ethernet at layer two. If the option value is 0, specifies that Ethernet II encapsulation should be used, per RFC 894; when the value is 1, tells the client to use IEEE 802.3 encapsulation, per RFC 1042.

### **TCP Parameters**

The options impacting the operation of TCP are shown in [Table 197](#).

**Table 197: DHCP/BOOTP Options: TCP Parameters**

Code Value	Data Length (bytes)	Name and Description
37	1	<b>Default TTL:</b> Specifies the default <i>Time To Live</i> the client should use when sending TCP segments.
38	4	<b>TCP Keepalive Interval:</b> Specifies how long (in seconds) the client should wait on an idle TCP connection before sending a “keepalive” message. A value of 0 instructs the client not to send such messages unless specifically instructed to do so by an application.
39	1	<b>TCP Keepalive Garbage:</b> When set to 1, tells a client it should send TCP keepalive messages that include an octet of “garbage” for compatibility with implementations that require this.

### **Application and Service Parameters**

These are miscellaneous options that control the operation of various applications and services ([Table 198](#)).

**Table 198: DHCP/BOOTP Options: Application and Service Parameters (Page 1 of 3)**

Code Value	Data Length (bytes)	Name and Description
40	Variable	<b>Network Information Service Domain:</b> Specifies the client’s NIS domain. Contrast to option #64.
41	Variable (Multiple of 4)	<b>Network Information Servers:</b> Specifies a list of IP addresses of NIS servers the client may use. Servers are listed in the order of preference for the client to use. Contrast to option #65.

**Table 198: DHCP/BOOTP Options: Application and Service Parameters (Page 2 of 3)**

Code Value	Data Length (bytes)	Name and Description																		
42	Variable (Multiple of 4)	<b>Network Time Protocol Servers:</b> Specifies a list of IP addresses of <a href="#">Network Time Protocol</a> servers the client may use. Servers are listed in the order of preference for the client to use.																		
43	Variable	<b>Vendor Specific Information:</b> Allows an arbitrary set of vendor-specific information to be included as a single option within a DHCP or BOOTP message. This information is structured using the same format as the Options or Vend field itself, except that it does not start with a “magic cookie”. See the end of <a href="#">the previous topic</a> for more details.																		
44	Variable (Multiple of 4)	<b>NetBIOS Over TCP/IP Name Servers:</b> Specifies a list of IP addresses of <a href="#">NetBIOS</a> name servers (per RFC 1001/1002) that the client may use. Servers are listed in the order of preference for the client to use.																		
45	Variable (Multiple of 4)	<b>NetBIOS Over TCP/IP Datagram Distribution Servers:</b> Specifies a list of IP addresses of NetBIOS datagram distribution servers (per RFC 1001/1002) that the client may use. Servers are listed in the order of preference for the client to use.																		
46	1	<p><b>NetBIOS Over TCP/IP Node Type:</b> Tells the client what sort of NetBIOS node type it should use. Four different bit values are used to define the possible node type combinations. The following table shows the substructure:</p> <table> <tr> <th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr> <tr> <td><b>Reserved</b></td><td>4/8 (4 bits)</td><td><b>Reserved:</b> Not used.</td></tr> <tr> <td><b>H-Node</b></td><td>1/8 (1 bit)</td><td><b>H-Node:</b> Set to 1 to tell the client to act as a NetBIOS H-node.</td></tr> <tr> <td><b>M-Node</b></td><td>1/8 (1 bit)</td><td><b>M-Node:</b> Set to 1 to tell the client to act as a NetBIOS M-node.</td></tr> <tr> <td><b>P-Node</b></td><td>1/8 (1 bit)</td><td><b>P-Node:</b> Set to 1 to tell the client to act as a NetBIOS P-node.</td></tr> <tr> <td><b>B-Node</b></td><td>1/8 (1 bit)</td><td><b>B-Node:</b> Set to 1 to tell the client to act as a NetBIOS B-node.</td></tr> </table>	Subfield Name	Size (bytes)	Description	<b>Reserved</b>	4/8 (4 bits)	<b>Reserved:</b> Not used.	<b>H-Node</b>	1/8 (1 bit)	<b>H-Node:</b> Set to 1 to tell the client to act as a NetBIOS H-node.	<b>M-Node</b>	1/8 (1 bit)	<b>M-Node:</b> Set to 1 to tell the client to act as a NetBIOS M-node.	<b>P-Node</b>	1/8 (1 bit)	<b>P-Node:</b> Set to 1 to tell the client to act as a NetBIOS P-node.	<b>B-Node</b>	1/8 (1 bit)	<b>B-Node:</b> Set to 1 to tell the client to act as a NetBIOS B-node.
Subfield Name	Size (bytes)	Description																		
<b>Reserved</b>	4/8 (4 bits)	<b>Reserved:</b> Not used.																		
<b>H-Node</b>	1/8 (1 bit)	<b>H-Node:</b> Set to 1 to tell the client to act as a NetBIOS H-node.																		
<b>M-Node</b>	1/8 (1 bit)	<b>M-Node:</b> Set to 1 to tell the client to act as a NetBIOS M-node.																		
<b>P-Node</b>	1/8 (1 bit)	<b>P-Node:</b> Set to 1 to tell the client to act as a NetBIOS P-node.																		
<b>B-Node</b>	1/8 (1 bit)	<b>B-Node:</b> Set to 1 to tell the client to act as a NetBIOS B-node.																		
47	Variable	<b>NetBIOS Over TCP/IP Scope:</b> Specifies the <a href="#">NetBIOS over TCP/IP</a> scope parameter for the client.																		
48	Variable (Multiple of 4)	<b>X Window System Font Servers:</b> Specifies a list of IP addresses of X Window System Font servers that the client may use. Servers are listed in the order of preference for the client to use.																		
49	Variable (Multiple of 4)	<b>X Window System Display Manager:</b> Specifies a list of IP addresses of systems running the X Window System Display Manager that the client may use. Addresses are listed in the order of preference for the client to use.																		
64	Variable	<b>Network Information Service+ Domain:</b> Specifies the client's NIS+ domain. Contrast to option #40.																		

**Table 198: DHCP/BOOTP Options: Application and Service Parameters (Page 3 of 3)**

Code Value	Data Length (bytes)	Name and Description
65	Variable (Multiple of 4)	<b>Network Information Service+ Servers:</b> Specifies a list of IP addresses of NIS+ servers the client may use. Servers are listed in the order of preference for the client to use. Contrast to option #41.
68	Variable (Multiple of 4)	<b>Mobile IP Home Agent:</b> Specifies a list of IP addresses of <a href="#">home agents</a> that the client can use in <a href="#">Mobile IP</a> . Agents are listed in the order of preference for the client to use; normally a single agent is specified.
69	Variable (Multiple of 4)	<b>Simple Mail Transport Protocol (SMTP) Servers:</b> Specifies a list of IP addresses of <a href="#">SMTP</a> servers the client may use. Servers are listed in the order of preference for the client to use.
70	Variable (Multiple of 4)	<b>Post Office Protocol (POP3) Servers:</b> Specifies a list of IP addresses of <a href="#">POP3</a> servers the client may use. Servers are listed in the order of preference for the client to use.
71	Variable (Multiple of 4)	<b>Network News Transfer Protocol (NNTP) Servers:</b> Specifies a list of IP addresses of <a href="#">NNTP</a> servers the client may use. Servers are listed in the order of preference for the client to use.
72	Variable (Multiple of 4)	<b>Default World Wide Web (WWW) Servers:</b> Specifies a list of IP addresses of <a href="#">World Wide Web (HTTP)</a> servers the client may use. Servers are listed in the order of preference for the client to use.
73	Variable (Multiple of 4)	<b>Default Finger Servers:</b> Specifies a list of IP addresses of Finger servers the client may use. Servers are listed in the order of preference for the client to use.
74	Variable (Multiple of 4)	<b>Default Internet Relay Chat (IRC) Servers:</b> Specifies a list of IP addresses of <a href="#">Internet Relay Chat (IRC)</a> servers the client may use. Servers are listed in the order of preference for the client to use.
75	Variable (Multiple of 4)	<b>StreetTalk Servers:</b> Specifies a list of IP addresses of StreetTalk servers the client may use. Servers are listed in the order of preference for the client to use.
76	Variable (Multiple of 4)	<b>StreetTalk Directory Assistance (STDA) Servers:</b> Specifies a list of IP addresses of STDA servers the client may use. Servers are listed in the order of preference for the client to use.

## DHCP Extensions

Last but certainly not least, [Table 199](#) describes the DHCP-only options that control the operation of the DHCP protocol.

**Table 199: DHCP Options: DHCP Extensions (Page 1 of 2)**

Code Value	Data Length (bytes)	Name and Description																		
50	4	<b>Requested IP Address:</b> Used in a client's <i>DHCPDISCOVER</i> message to request a particular IP address assignment.																		
51	4	<b>IP Address Lease Time:</b> Used in a client request to ask a server for a particular DHCP lease duration, or in a server reply to tell the client the offered lease time. It is specified in units of seconds.																		
52	1	<b>Option Overload:</b> Used to tell the recipient of a DHCP message that the message's <i>SName</i> and/or <i>File</i> fields are being used to carry options, instead having their normal meanings. This option implements the <a href="#">option overload feature</a> . There are three possible values for this single-byte option: <table><tr><th>Option Value</th><th>Option Overload Method</th></tr><tr><td>1</td><td>The <i>File</i> field is carrying option data.</td></tr><tr><td>2</td><td>The <i>SName</i> field is carrying option data.</td></tr><tr><td>3</td><td>Both fields are carrying option data.</td></tr></table>	Option Value	Option Overload Method	1	The <i>File</i> field is carrying option data.	2	The <i>SName</i> field is carrying option data.	3	Both fields are carrying option data.										
Option Value	Option Overload Method																			
1	The <i>File</i> field is carrying option data.																			
2	The <i>SName</i> field is carrying option data.																			
3	Both fields are carrying option data.																			
53	1	<b>DHCP Message Type:</b> Indicates the specific type of DHCP message: <table><tr><th>Option Value</th><th>DHCP Message Type</th></tr><tr><td>1</td><td><i>DHCPDISCOVER</i></td></tr><tr><td>2</td><td><i>DHCPOFFER</i></td></tr><tr><td>3</td><td><i>DHCPREQUEST</i></td></tr><tr><td>4</td><td><i>DHCPDECLINE</i></td></tr><tr><td>5</td><td><i>DHCPACK</i></td></tr><tr><td>6</td><td><i>DHCPNAK</i></td></tr><tr><td>7</td><td><i>DHCPRELEASE</i></td></tr><tr><td>8</td><td><i>DHCPINFORM</i></td></tr></table>	Option Value	DHCP Message Type	1	<i>DHCPDISCOVER</i>	2	<i>DHCPOFFER</i>	3	<i>DHCPREQUEST</i>	4	<i>DHCPDECLINE</i>	5	<i>DHCPACK</i>	6	<i>DHCPNAK</i>	7	<i>DHCPRELEASE</i>	8	<i>DHCPINFORM</i>
Option Value	DHCP Message Type																			
1	<i>DHCPDISCOVER</i>																			
2	<i>DHCPOFFER</i>																			
3	<i>DHCPREQUEST</i>																			
4	<i>DHCPDECLINE</i>																			
5	<i>DHCPACK</i>																			
6	<i>DHCPNAK</i>																			
7	<i>DHCPRELEASE</i>																			
8	<i>DHCPINFORM</i>																			
54	4	<b>Server Identifier:</b> The IP address of a particular DHCP server. This option is included in messages sent by DHCP servers to identify themselves as the source of the message. It is also used by a client in a <i>DHCPREQUEST</i> message to specify which server's lease it is accepting.																		
55	Variable	<b>Parameter Request List:</b> Used by a DHCP client to request a list of particular configuration parameter values from a DHCP server.																		
56	Variable	<b>Message:</b> Used by a server or client to indicate an error or other message.																		

Table 199: DHCP Options: DHCP Extensions (Page 2 of 2)

Code Value	Data Length (bytes)	Name and Description
57	2	<b>Maximum DHCP Message Size:</b> Used by a DHCP client or server to specify the maximum size of DHCP message it is willing to accept. The minimum legal value is 576 bytes.
58	4	<b>Renewal (T1) Time Value:</b> Tells the client the value to use for its <a href="#">renewal timer</a> .
59	4	<b>Rebinding (T2) Time Value:</b> Tells the client what value to use for its <a href="#">rebinding timer</a> .
60	Variable	<b>Vendor Class Identifier:</b> Included in a message sent by a DHCP client to specify its vendor and configuration. This may be used to prompt a server to send the correct vendor-specific information using option #43.
61	Variable	<b>Client Identifier:</b> Used optionally by a client to specify a unique client identification for itself that differs from the DHCP default. This identifier is expected by servers to be unique amongst all DHCP clients and is used to index the DHCP server's <a href="#">configuration parameter database</a> .
66	Variable	<b>TFTP Server Name:</b> When the DHCP message's <i>SName</i> field has been used for options using the <a href="#">option overload feature</a> , this option may be included to specify the TFTP server name that would normally appear in the <i>SName</i> field.
67	Variable	<b>Bootfile Name:</b> When the DHCP message's <i>File</i> field has been used for options using the <a href="#">option overload feature</a> , this option may be included to specify the bootfile name that would normally appear in the <i>File</i> field.

---

## **DHCP Client/Server Implementation, Features and Issues**

The three preceding sections describe the DHCP [address leasing system](#), [configuration processes](#) and [messaging](#). Between them, these sections provide an explanation of all the fundamentals of the operation of DHCP. With this foundation in place, we can now proceed to look into some of the more interesting details of how DHCP is implemented. We can also delve into some of the extra capabilities and special features that change the basic DHCP mechanisms we have already studied.

In this section, I discuss DHCP client/server implementation issues, special features that enhance the protocol, and some of the problems and issues related to making DHCP work. I begin with a discussion of DHCP server and client implementation and management issues. I discuss DHCP message relaying and how it is related to the relaying feature used for BOOTP. I describe the DHCP feature for providing automatic default addressing when a client cannot contact a server, and the conflict detection feature for multiple servers. I then cover some of the issues related to interoperability of DHCP and BOOTP, and provide an outline of some of the more important problems and issues related to DHCP security.

**Background Information:** This section assumes that you are already familiar with the basic operation of DHCP. In particular, you should be sure that you have read through and understood [the section on DHCP operation](#) before proceeding.

---

## **DHCP Server General Implementation and Management Issues**

DHCP is a client/server protocol, relying on both server and client to fulfill [certain responsibilities](#). Of the two device roles, the DHCP server is arguably the more important, because it is in the server that most of the functionality of DHCP is actually implemented. The server maintains the configuration database, keeps track of address ranges and manages leases. For this reason, DHCP servers are also typically much more **complex** than DHCP clients.

In essence, without a DHCP server, there really is no DHCP. Thus, deciding how to implement DHCP servers is a large part of implementing the protocol. This overall chapter is about describing the function of protocols like DHCP and not getting into details of how to implement them. However, I feel it is useful to look at some of the general issues related to how DHCP servers are set up and used, to help put into perspective how the protocol really works.

### ***DHCP Server Implementations***

A “classical” DHCP server consists of DHCP server software running on a server hardware platform of one sort or another. A DHCP server usually will not be a dedicated computer except on very large networks. It is more common for a hardware server to provide DHCP services along with performing other functions, such as acting as an application server,

---

general database server, providing [DNS](#) services and so forth. So, a DHCP server need not be a special computer; any device that can run a DHCP server implementation can act as a server.

In fact, the DHCP server may not even need to be a host computer at all. Today, many **routers** include DHCP functionality. Programming a router to act as a DHCP server allows clients that connect to the router to be automatically assigned IP addresses. This provides numerous potential advantages in an environment where a limited number of public IP addresses is shared amongst multiple clients, or where [IP Network Address Translation \(NAT\)](#) is used to dynamically share a small number of addresses. Since DHCP requires a database, a router that acts as a DHCP server requires some form of permanent storage. This is often implemented using flash memory on routers, while “true” servers of course use hard disk storage.

Virtually all modern operating systems include support for DHCP, including most variants of UNIX, Linux, newer versions of Microsoft Windows, Novell NetWare and others. In some cases, you may need to run the “server version” of the operating system to have a host act as a DHCP server. For example, while Microsoft Windows XP supports DHCP, I don't believe that a DHCP server comes in “Windows XP Home”, the “home user” version. (Of course, you could install one yourself!)

### ***DHCP Server Software Features***

In most networks you will choose the operating system based on a large number of factors. The choice of OS will then dictate what options you have for selecting DHCP server software. Most common operating systems have a number of options available for software. While all will implement the core DHCP protocol, they will differ in terms of the usual software attributes: cost, performance, ease of use and so. They may also differ in terms of their features, such as the following:

- ☉ How they allow [address ranges \(scopes\)](#) to be defined.
- ☉ How clients can be grouped and managed.
- ☉ The level of control an administrator has over parameters returned to a client.
- ☉ The level of control an administrator has over general operation of the protocol, such as specification of the [T1 and T2 timers](#) and other variables, and how leases are [allocated](#) and [renewals](#) handled.
- ☉ [Security features](#).
- ☉ Ability to interact with DNS to support dynamic device naming.
- ☉ Optional features such as [BOOTP support](#), [conflict detection](#), and [automatic private IP addressing](#).

### ***Choosing the Number of Servers***

In setting up DHCP for a network, there are a number of important factors to consider and decisions to be made. One of the most critical is the number of servers you want to have. In theory, each network requires only one DHCP server; in practice, this is often not a great

---

idea. Servers sometimes experience hardware or software failures, or have to be taken down for maintenance. If there is only one server and clients can't reach it, no DHCP clients will be able to get addresses. For this reason, two or more servers are often used.

If you do use more than one server, you have to carefully plan how you will configure each one. One of the first decisions you will need to make is which servers will be responsible for which addresses and clients. You have to determine whether you want the servers to have distinct or overlapping address pools, as discussed in [the topic on DHCP address ranges](#). Distinct pools ensure that addresses remain unique but result in unallocatable addresses if a server fails; overlapping addresses are more flexible, but risk address conflicts unless a feature like [conflict detection](#) is used.

### ***Server Placement, Setup and Maintenance***

Once you know how many servers you want, you have to determine on which part of the network you want to place them. If you have many physical networks, you may also need to use [DHCP relaying](#) to allow all clients to reach a server. Of course, the structure of the network may affect the number of servers you use, so many of these decisions are interrelated.

You must make policy decisions related to all the DHCP operating parameters we have seen earlier. The two biggies are deciding on the size and structure of the address pool, and making lease policy decisions such as [lease length](#) and the settings for the [T1 and T2 timers](#). You also must decide what clients will be dynamically allocated addresses and how [manually-configured clients](#) will be handled.

Finally, it's essential for the administrator to remember that an organization's DHCP server is a **database server** and must be treated accordingly. Like any database server, it must be maintained and managed carefully. Administrative policies must be put into place to ensure the security and efficient operation of the server. Also, unlike certain other types of database systems, the DHCP database is not automatically replicated; the server database should therefore be routinely backed up, and using RAID storage is also a good idea.

### **DHCP Client General Implementation and Management Issues**

I said in the previous topic that without DHCP servers, there would be no DHCP, which is true. DHCP servers are where most of the protocol is implemented, so they are the heart of the protocol. With servers you have DHCP, but without **clients**, there's nothing to actually use DHCP, so nobody would even care. Thus, even though they are less critical than servers when viewed strictly from the point of view of the protocol, DHCP clients are still quite important.

Just as a DHCP server consists of server software running on a server platform or hardware acting as a server, a DHCP client is simply DHCP client software running on a client device. Most often, a client device is a host computer connected to a TCP/IP internetwork. DHCP is today so widely accepted that virtually all hosts include DHCP client software. The DHCP client is usually integrated into graphical operating systems like Windows, or is implemented using a specific client daemon like *dhclient* or *dhcpcd* on UNIX/Linux.

---

Since the entire idea behind DHCP is to put the server in charge of parameter storage, configuration and address management, DHCP clients are relatively simple. The client implements the messaging protocol and communicates parameters received from the DHCP server to the rest of the TCP/IP software components as needed. It doesn't do a whole lot else.

In fact, there's not really much for an administrator to do to set up a client to use DHCP. In some operating systems, it's as simple as "throwing a switch", by enabling DHCP support within the client itself. This prompts the client to then stop using any manually-configured parameters and start searching for a DHCP server instead. The server then becomes responsible for the client's configuration and address assignment.

Since the client doesn't do a great deal in DHCP other than communicate with the server, not much is required in the way of user software for a DHCP client. In most cases, control over the DHCP client software is accomplished using a [TCP/IP configuration utility](#). Windows clients use the programs *ipconfig* or *winipcfg* to display the status of their current DHCP leases. These programs also allow the client to manually release the current lease or renew it.

Releasing the lease means [early lease termination](#) using the *DHCPRELEASE* message. This is usually the only way that a lease is terminated. Renewing the lease is a manual version of the automated renewal process. Releasing and renewing the lease may be done in sequence to reset a client that is in a confused state or is having some other type of DHCP or connectivity problem.

## **DHCP Message Relaying and BOOTP Relay Agents**

DHCP is the third-generation host configuration protocol for TCP/IP. We've already seen extensively how it was based directly on the [Boot Protocol](#); BOOTP was in turn an enhancement of the earlier [Reverse Address Resolution Protocol \(RARP\)](#). Even though each new protocol has made significant improvements over its predecessor, each iteration has retained certain limits that are actually common to all host configuration protocols.

One of the most important limitations with host configuration protocols is the reliance on broadcasts for communication. Whenever we are dealing with a situation where a client needs to communicate but doesn't know its IP address and doesn't know the address of a server that will provide it, the client needs to use [broadcast addressing](#). However, for performance reasons, broadcasts are normally only propagated on the local network. This means that the client and server would always need to be on the same physical network for host configuration to occur. Of course, we don't want this to be the case. It would require that a large internetwork have a different server on every network, greatly reducing the benefits of centralized configuration information, and creating numerous administrative hassles.

### ***Use of BOOTP Relay Agents for DHCP***

RARP didn't have any solution to the problem of clients and servers on different networks, which is one reason why it was so limited in usefulness. BOOTP did: it allows a client and server to be on different networks through the use of BOOTP *relay agents*. A relay agent is

---

a device that is not a BOOTP server, but which runs a special software module that allows it to act in the place of a server. A relay agent can be placed on networks where there are BOOTP clients but no BOOTP servers. The relay agent intercepts requests from clients and relays them to the server. The server then responds back to the agent, which forwards the response to the client. A full rationale and description of operation of BOOTP relay agents can be found in [the topic discussing them](#).

The designers of DHCP were satisfied with the basic concepts and operation behind BOOTP relay agents, which had already been in use for many years. For this reason, they made the specific decision to continue using BOOTP relay agent functionality in DHCP. In fact, this is one of the reasons why the decision was made to retain the BOOTP message format in DHCP, and also the basic two-message “request/reply” communication protocol. This allows BOOTP relay agents to handle DHCP messages as if they are BOOTP messages.

This is also why the mention of BOOTP in the title of this topic is not a typo—DHCP in fact uses BOOTP relay agents. Even the DHCP standard says that a “BOOTP relay agent is an Internet host or router that passes DHCP messages between DHCP clients and DHCP servers.” In practice, the agents are indeed sometimes called “DHCP relay agents”; you may also see the mixed terms “BOOTP/DHCP relay agent” and “DHCP/BOOTP relay agent”.

### ***DHCP Relaying Process***

Since DHCP was designed specifically to support BOOTP relay agents, the agents behave in DHCP much as they do in BOOTP. Of course DHCP has much more complex message exchanges, but as we've already seen, they are all still designed around the notion of a client request and server response. There are just more requests and responses. The BOOTP agent looks for broadcasts sent by the client and then forwards them to the server [just as described in the topic on BOOTP relay agent behavior](#), and then returns replies from the server. The additional information in the DHCP protocol is implemented using additions to the BOOTP message format in the form of DHCP options, which the relay agent doesn't look at. It just treats them as it does BOOTP requests and replies.

So, in summary, when a relay agent is used, here's what the various client requests and server replies in the DHCP operation section become:

- ④ **Client Request:** When a client broadcasts a request, the relay agent intercepts it on UDP port 67. It checks the *Hops* field, and discards the request if the value is greater than 16; otherwise it increments the field. The agent puts its own address into the *GIAddr* field unless another relay agent has already put its address in the field. It then forwards the client request to a DHCP server, either unicast or broadcast on another network.
- ④ **Server Reply:** The server sees a non-zero value in *GIAddr* and sends the reply to the relay agent whose IP address is in that field. The relay agent then sends the reply back to the client, using either unicast or broadcast as discussed in [the topic on DHCP addressing](#).

---

One difference between BOOTP and DHCP is that certain communications from the client to the server are unicast. The most noticeable instance of this is when a client tries to renew its lease with a specific DHCP server. Since it sends this request unicast, it can go to a DHCP server on a different network using conventional IP routing, and the relay agent does not need to be involved.

**Key Concept:** To permit DHCP clients and DHCP servers to reside on different physical networks, an intermediary device is required to facilitate message exchange between networks. DHCP uses the same mechanism for this as BOOTP: the deployment of *BOOTP relay agents*. The relay agent captures client requests, forwards them to the server, and then returns the server's responses back to the client.

---

## **DHCP Autoconfiguration / Automatic Private IP Addressing (APIPA)**

The IP address of a TCP/IP host is, in many ways, its identity. Every TCP/IP network requires that all hosts have unique addresses to facilitate communication. When a network is manually configured with a distinct IP address for each host, the hosts permanently know “who they are”. When hosts are made DHCP clients, they no longer have a permanent identity; they rely on a DHCP server to tell them “who they are”.

### ***Client Recovery From Failure to Obtain an IP Address***

The dependency of DHCP clients on servers is not a problem as long as DHCP is functioning normally and a host can get a lease, and in fact has many benefits that we have explored. Unfortunately, a number of circumstances can arise that result in one of the DHCP processes not resulting in a lease for the client. The client may not be able to obtain a lease, re-acquire one after reboot, or renew an existing lease. There are many possible reasons why this might happen:

- ☹ The DHCP server may have experienced a failure, or may be taken down for maintenance;
- ☹ The relay agent on the client's local network may have failed;
- ☹ Another hardware malfunction or power failure may make communication impossible;
- ☹ The network may have run out of allocatable addresses.

Without a lease, the host has no IP address, and without an address, the host is effectively dead in the water. The base DHCP specification doesn't really specify any recourse for the host in the event that it cannot successfully obtain a lease. It is essentially left up to the implementor to decide what to do, and when DHCP was first created, many host implementations would simply display an error message and leave the host unusable until an administrator or user took action.

---

Clearly this is far from an ideal situation. It would be better if we could just have a DHCP client that is unable to reach a server automatically configure itself. In fact, the IETF reserved a [special IP address block](#) for this purpose. This block, 169.254.0.1 through 169.254.255.254 (or 169.254.0.0/16 in classless notation) is reserved for autoconfiguration, as mentioned in RFC 3330:

“Hosts obtain these addresses by auto-configuration, such as when a DHCP server may not be found.”

Strangely, however, no TCP/IP standard has yet been defined to specify how such autoconfiguration works. To fill the void, Microsoft created an implementation that it calls *Automatic Private IP Addressing (APIPA)*. Due to Microsoft's market power, APIPA has been deployed on millions of machines, and has thus become a de facto standard in the industry.

### **APIPA Operation**

APIPA is really so simple that it's surprising it took so long for someone to come up with the idea. It takes over at the point where any DHCP lease process fails. Instead of just halting with an error message, APIPA randomly chooses an address within the aforementioned private addressing block. It then performs a test very similar to the one in step #13 in [the DHCP allocation process](#): it uses ARP to generate a request on the local network to see if any other client responds using the address it has chosen. If there is a reply, APIPA tries another random address and repeats the test. When the APIPA software finds an address that is not in use, it is given to the client as a default address. The client will then use default values for other configuration parameters that it would normally receive from the DHCP server. This process is illustrated in [Figure 269](#).

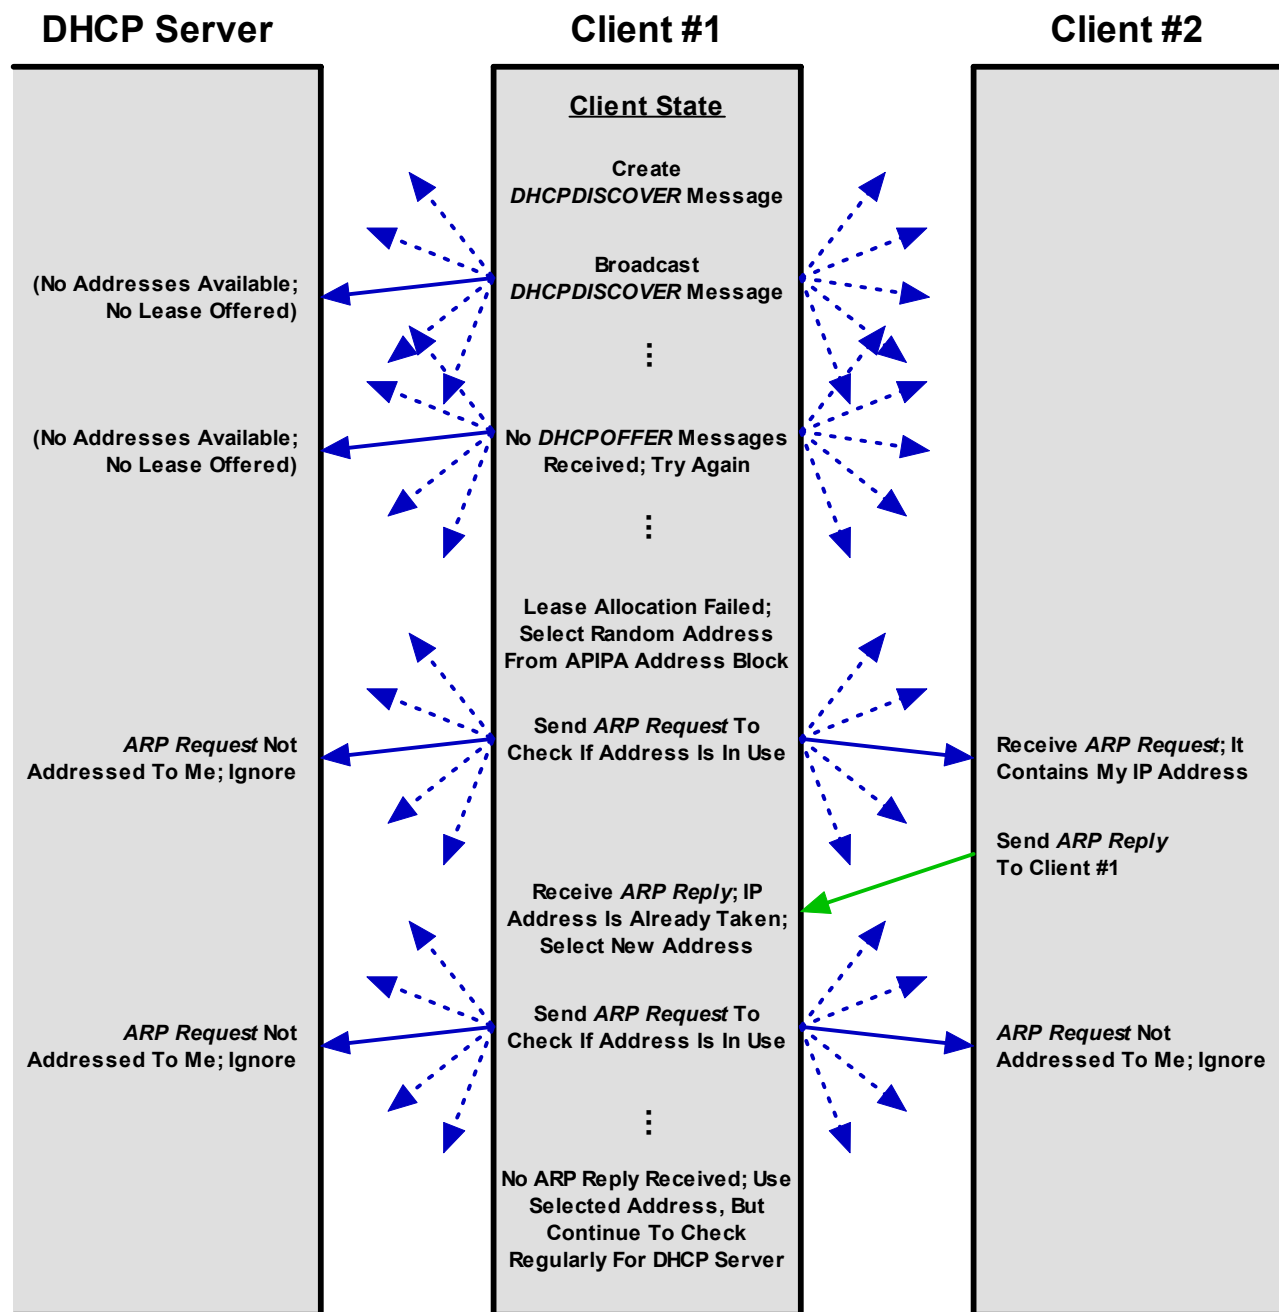

A client using an autoconfigured address will continue to try to contact a DHCP server periodically. By default, this check is performed every five minutes. If and when it finds one, it will obtain a lease and replace the autoconfigured address with the proper leased address.

APIPA is ideally suited to small networks, where all devices are on a single physical link. Conceivably, with 20 APIPA-enabled DHCP clients on a network with a single DHCP server, you could take the server down for maintenance and still have all the clients work properly, using 169.254.x.x addresses.

### **APIPA Limitations**

Bear in mind that APIPA is not a proper replacement for full DHCP. The 169.254.0.0/16 block is a private IP range and comes with all [the limitations of private IP addresses](#), including inability to use these addresses on the Internet. Also, APIPA cannot provide the other configuration parameters that a client may need to get from a DHCP server. Finally, APIPA will not work properly in conjunction with [proxy ARP](#), because the proxy will respond for any of the private addresses, so they will all appear to be used.

**Figure 269: DHCP Automatic Private IP Addressing (APIPA)**

In this example, Client #1 is trying to get an IP address from its DHCP server, but the server is out of addresses, so it does not respond to the client's requests. The client is configured to use APIPA, so it randomly selects an address from the APIPA address block. It sends an *ARP Request* on the local network to see if any other device is using that address; in this case, Usually there will be no conflict, but here Client #2 is in fact using the address, so it responds. Client #1 chooses a different address and this time gets no reply. It begins using that address, while continuing to check regularly for a DHCP server to come online.

Since it uses ARP to check for address conflicts, APIPA is not well-suited for large internetworks. To use it on an internetwork with multiple subnets, you would require software that allows each subnet to use a different portion of the full 169.254.0.0/16 blocks, to avoid

---

conflicts. In practice, APIPA is a solution for small networks; large internetworks deal with the problem of not being able to contact a DHCP server by making sure that a client can always contact a DHCP server. ☺

**Key Concept:** An optional DHCP feature called Automatic Private IP Addressing (APIPA) was developed to allow clients to still be able to communicate in the event that they are unable to obtain an IP address from a DHCP server. When enabled, the client chooses a random address from a special reserved block of private IP addresses, and checks to make sure the address is not already in use by another device. It continues to check for a DHCP server periodically until it is able to find one.

---

## **DHCP Server Conflict Detection**

As we saw in [the first topic of this section](#), one of the primary decisions any TCP/IP administrator using DHCP must make is how many DHCP servers to deploy. A single server has the advantage of simplicity, but provides no redundancy in the event of failure. It also means that whenever the DHCP server is down, clients can't get addresses. For these reasons, most larger networks use two or more servers.

### ***The Need to Prevent Duplicate Assignment of the Same Address***

When you have two servers or more—and let's just say two for sake of this discussion—you then have another decision to make: how do you divide the address pool between the servers? As I explored in detail in [the discussion of DHCP address pools](#), there are two options: either giving the servers overlapping addresses, or making them non-overlapping. Unfortunately, in classical DHCP, neither is really a great solution. Overlapping ranges mean both servers might try to assign the same address, since DHCP includes no provision for communication between servers. Non-overlapping ranges avoids this problem, but makes only some of the addresses available to each server.

It's strange that the DHCP standard didn't provide better support for cross-server coordination, even though there clearly was a need for it. However, certain DHCP implementations implement an optional feature to in fact allow two servers to have overlapping scopes without address clashes occurring. Again, this is a feature commonly found on Microsoft DHCP servers, and may also be present in other implementations. It is called *DHCP server conflict detection*.

### ***Conflict Detection Operation***

The idea behind conflict detection is very simple. Suppose a DHCP server receives a *DHCPDISCOVER* message from a client and decides to offer it a lease. Before sending the *DHCPOFFER* message, the server conducts a *probe* by sending [ICMP Echo \(ping\) messages](#) out to the address it plans to offer. It then waits a short period of time to hear if it receives any [ICMP Echo Reply messages](#) back. If it does, it knows the IP address is in use and chooses a different one.

---

If all DHCP servers are configured to do this before offering an address, then it is possible to give all of them the same, overlapping addresses for assignment. They won't have any way of coordinating with each other, but as long as they “ask first” by doing an ICMP check, there won't be any problems. This provides an administrator with the advantages of overlapping address ranges—simplicity and access to all addresses by all servers—without risk of address conflicts. The only small drawback is a little bit of extra network traffic to perform the check, and possibly a few milliseconds of server CPU time if a new address needs to be chosen.

If you were paying attention when you read about the DHCP allocation process, you may have noticed that what I am describing here sounds familiar. In fact, it's true: this feature really isn't anything new. The use of ICMP to check an address before offering it is actually mentioned in RFC 2131 as part of the standard DHCP allocation process, and you can find it mentioned as step #5 in [the allocation process](#) in this Guide.

So why was “conflict detection” required to be an extra feature? Simple: the use of ICMP wasn't mandatory because the standard says servers **SHOULD** do it and not that they **MUST** do it. That's why they capitalize those words in the standards. ☺ This choice was made to provide flexibility in implementing DHCP, but that flexibility comes at a cost. So, if you want to use this feature, you need to look for support for it in your server software.

**Key Concept:** Some DHCP implementations include a feature called *server conflict detection*. When this feature is activated, it causes each server to always check to make sure an address is not in use before granting it to a client. When conflict detection is used by all DHCP servers on a network, the servers can be given overlapping scopes, so each can assign any of the organization's IP addresses, while at the same time not needing to be concerned about two clients being assigned the same address by different servers.

---

## **DHCP and BOOTP Interoperability**

I've talked extensively about how DHCP was designed based on the [Boot Protocol](#), and how they use the same basic communication method and message format. This was done for several reasons, one of the most important of which was ensuring interoperability of the two protocols. Given this, you might expect that we could simply say that BOOTP and DHCP are compatible with each other, and that's that. Then again, given that you can see I have a whole topic on the subject, maybe you wouldn't think that at all...

It is in fact true that DHCP was intended to be compatible with BOOTP. RFC 2131 lists the following as one of DHCP's design goals: “DHCP must provide service to existing BOOTP clients.”. This seems pretty clear. The “reuse” of the [BOOTP message format](#) is one of the keys to DHCP and BOOTP compatibility. DHCP functionality is implemented not through new fields but rather through DHCP-specific options, such as the *DHCP Message Type* option that specifies the all important type of DHCP messages. DHCP devices can look for this extra information, while BOOTP devices can ignore it.

---

However, while DHCP and BOOTP are similar, they are not the same, and so there are some interoperability concerns that crop up when they are used together. The DHCP message format is structurally the same as the BOOTP format, but the interpretation of certain fields is slightly different. BOOTP clients don't understand DHCP, so when BOOTP and DHCP are used together, the DHCP client or server must sometimes behave slightly differently to compensate. Further complicating matters is the fact that not all implementations of DHCP and BOOTP are necessarily exactly the same, and the fact that certain specifications in the DHCP standard are not mandatory.

For these reasons, we cannot just assume that DHCP and BOOTP will work together. To address some of these issues, the IETF published RFC 1534, *Interoperation Between DHCP and BOOTP*, at the same time that DHCP was originally created. This document looks at how the protocols work together, focusing on the two distinct client/server interoperating combinations: a BOOTP client connecting to a DHCP server, and a DHCP client connecting to a BOOTP server. Let's consider each case one at a time.

### ***BOOTP Clients Connecting to a DHCP Server***

As indicated by the quote above from RFC 2131, DHCP was specifically intended to allow a DHCP server to handle requests from BOOTP clients. The protocol itself is set up to enable this, but it does require that the DHCP server be given certain intelligence to know how to deal with BOOTP clients. One of the most important issue is, of course, that BOOTP clients will follow the [BOOTP configuration process](#) and not the [DHCP leasing processes](#). The DHCP server must use BOOTP messages with the BOOTP meanings for fields when dealing with BOOTP clients. A server determines that a client is using BOOTP instead of DHCP by looking for the presence of the *DHCP Message Type option*, which must be present in all DHCP messages but of course is not used for BOOTP.

If a DHCP server detects that it is dealing with a BOOTP client, it can respond with configuration information for the client. The server can use either [manual or automatic allocation](#) for the client. Automatic allocation of course means the server chooses an address from its pool of unused addresses, but assigns it permanently. BOOTP clients are not capable of dynamic allocation since BOOTP is static in nature.

A DHCP server may include [BOOTP vendor information fields](#) in its response to a BOOTP client, including ones defined since BOOTP was created. However, it obviously must not send any DHCP-specific options.

### ***DHCP Clients Connecting to a BOOTP Server***

Now, for the other case. A DHCP client can obtain configuration information from a BOOTP server, because the server will respond to the client's initial *DHCPDISCOVER* message as if it were a BOOTP *BOOTREQUEST* message. The DHCP client can tell that a BOOTP reply has been received because there will be no *DHCP Message Type* option. A response from a BOOTP server should be treated as an infinite lease, since again, that's all that BOOTP supports. Note that if a DHCP client receives a response from both a BOOTP server and a DHCP server, it should use the DHCP response and not the BOOTP response (even if this means it gets a shorter lease).

---

## **DHCP Security Issues**

DHCP was designed in the early 1990s, when the number of organizations on the Internet was relatively small. Furthermore, it was based on BOOTP, which was created in the 1980s when the Internet as we know it today barely even existed. In those days, Internet security wasn't a big issue, because it was mostly a small group of research and educational organizations using TCP/IP on the Internet. As a result, DHCP, like many protocols of that era, doesn't do much to address security concerns.

Actually, this is a bit understated. Not only does DHCP run over IP and UDP, which are inherently insecure, the DHCP protocol itself has in fact *no* security provisions whatsoever. This is a fairly serious issue in modern networks, because of the sheer power of DHCP: the protocol deals with critical configuration information. There are two different classes of potential security problems related to DHCP:

- ☉ **Unauthorized DHCP Servers:** If a malicious person plants a “rogue” DHCP server, it is possible that this device could respond to client requests and supply them with spurious configuration information. This could be used to make clients unusable on the network, or worse, set them up for further abuse later on. For example, a hacker could exploit a bogus DHCP server to direct a DHCP client to use a router under the hacker's control, rather than the one the client is supposed to use.
- ☉ **Unauthorized DHCP Clients:** A client could be set up that masquerades as a legitimate DHCP client and thereby obtain configuration information intended for that client; this could then be used to compromise the network later on. Alternately, a “bad guy” could use software to generate lots of bogus DHCP client requests to use up all the IP addresses in a DHCP server's pool. More simply, this could be used by a thief to steal an IP address from an organization for his own use.

### ***Adding Security to DHCP***

These are obviously serious concerns. The normal recommended solutions to these risks generally involve providing security at lower layers. For example, one of the most important techniques for preventing unauthorized servers and clients is careful control over physical access to the network: layer one security. Security techniques implemented at layer two may also be of use, for example, in the case of wireless LANs. Since DHCP runs over UDP and IP, one could use [IPSec](#) at layer three to provide authentication.

### ***DHCP Authentication***

To try to address some of the more specific security concerns within DHCP itself, in June 2001 the IETF published RFC 3118, *[Authentication for DHCP Messages](#)*. This standard describes an enhancement that replaces the normal DHCP messages with authenticated ones. Clients and servers check the authentication information and reject messages that come from invalid sources. The technology involves the use of a new DHCP option type, the *Authentication* option, and operating changes to several of the leasing processes to use this option.

---

Unfortunately, 2001 was pretty late in the DHCP game, and there are millions of DHCP clients and servers around that don't support this new standard. Both client and server must be programmed to use authentication for this method to have value. A DHCP server that supports authentication could use it for clients that support the feature and skip it for those that do not. However, the fact that this option is not universal means that it is not widely deployed, and most networks must rely on more conventional security measures.

---

## DHCP For IP Version 6 (DHCPv6)

DHCP is currently the standard host configuration protocol for the TCP/IP protocol suite. TCP/IP is built upon version 4 of the Internet Protocol, also known sometimes as *IPv4*. However, development work has been underway since the early 1990s on a successor to IPv4: version 6 of the Internet Protocol, or *IPv6*. This new IP standard will be the future of TCP/IP; it is described in detail in [its own section of this Guide](#).

While most of the changes that IPv6 brings impact technologies at the lower layers of the TCP/IP architectural model, the significance of the modifications means that many other TCP/IP protocols are also affected. This is particularly true of protocols that work with addresses or configuration information, including DHCP. For this reason, a new version of DHCP is required for IPv6. Development has been underway for quite some time on *DHCP For IPv6*, also sometimes called *DHCPv6*. At the time that I write this topic, DHCPv6 has not yet been formally published—it is still an Internet draft under discussion. I will provide a summary of the protocol here, and may expand this into a larger section later.

**Note:** In discussions purely oriented around IPv6, DHCPv6 is sometimes just called “DHCP”, and the original DHCP is called “DHCPv4”, so watch out for that! For obvious reasons, I am not going to do that here.

---

### *Two Methods for Autoconfiguration in IPv6*

One of the many enhancements introduced in IPv6 is an overall strategy for easier administration of IP devices, including host configuration. There are two basic methods defined for autoconfiguration of IPv6 hosts:

- ☉ **Stateless Autoconfiguration:** A method defined to allow a host to configure itself without help from any other device.
- ☉ **“Stateful” Autoconfiguration:** A technique where configuration information is provided to a host by a server.

Which of these methods is used depends on the characteristics of the network. Stateless autoconfiguration is described in RFC 2462, and discussed in [a separate topic in the IPv6 section](#). “Stateful” autoconfiguration for IPv6 is provided by DHCPv6. As with regular DHCP, DHCPv6 may be used to obtain an IP address and other configuration parameters, or just to get configuration parameters when the client already has an IP address.

### *DHCPv6 Operation Overview*

The operation of DHCPv6 is similar to that of DHCPv4, but the protocol itself has been completely rewritten. It is not based on the older DHCP or on BOOTP, except in conceptual terms. It still uses UDP but uses new port numbers, a new message format, and restructured options. All of this means that the new protocol is not strictly compatible with DHCPv4 or BOOTP, though I believe work is underway on a method to allow DHCPv6 servers to work with IPv4 devices.

**Key Concept:** Since DHCP works with IP addresses and other configuration parameters, the change from IPv4 to IPv6 requires a new version of DHCP commonly called *DHCPv6*. This new DHCP represents a significant change from the original DHCP, and is still under development. DHCPv6 is used for IPv6 “*stateful*” *autoconfiguration*; the alternative is *stateless autoconfiguration*, a feature of IPv6 that allows a client to determine its IP address without need for a server.

---

DHCPv6 is also oriented around IPv6 methods of addressing, especially the use of [link-local scoped multicast addresses](#). This allows efficient communication even before a client has been assigned an IP address. Once a client has an address and knows the identity of a server it may communicate with the server directly using unicast addressing.

### ***DHCP Message Exchanges***

There are two basic client/server message exchanges that are used in DHCPv6: the *four-message exchange* and the *two-message exchange*. The former is used when a client needs to obtain an IPv6 address and other parameters. This process is similar to [the regular DHCP address allocation process](#); highly simplified, it involves these steps:

1. The client sends a multicast *Solicit* message to find a DHCPv6 server and ask for a lease.
2. Any server that can fulfill the client's request responds to it with an *Advertise* message.
3. The client chooses one of the servers and sends a *Request* message to it asking to confirm the offered address and other parameters.
4. The server responds with a *Reply* message to finalize the process.

There is also a shorter variation of the four-message process above, where a client sends a *Solicit* message and indicates that a server should respond back immediately with a *Reply* message.

If the client already has an IP address, either assigned manually or obtained in some other way, a simpler process can be undertaken, similar to [how in regular DHCP](#) the *DHCPINFORM* message is used:

1. The client multicasts an *Information-Request* message.
2. A server with configuration information for the client sends back a *Reply* message.

As in regular DHCP, a DHCPv6 client renews its lease after a period of time by sending a *Renew* message. DHCPv6 also supports [relay agent functionality](#) as in DHCPv4.

---

## TCP/IP Network Management Framework and Protocols (SNMP and RMON)

---

Modern networks and internetworks are larger, faster and more capable than their predecessors of years gone by. As we expand, speed up and enhance our networks, they become more complex, and as a result, more difficult to manage. Where years ago an administrator could get by with very simple tools to keep a network running, today this is simply insufficient. More sophisticated network management technologies are required to match the sophistication of our networks.

Some of the most important tools in the network manager's "toolbox" are now in fact software, not hardware. To manage a sprawling, heterogeneous and complex internetwork, software applications have been developed that allow information to be gathered and devices controlled using the internetwork itself. TCP/IP, being the most popular internet-working suite, of course has such software tools. One of the most important is a pair of protocols that have been implemented as part of an overall method of network management called the *TCP/IP Internet Standard Management Framework*.

In this section I describe in detail the TCP/IP Internet Standard Management Framework, looking at each of its architectural and protocol components and how they interoperate. The first subsection provides an overview of the network management framework itself and serves as an introduction to the sections that follow. The second subsection discusses the way that network management information is structured and arranged into information stores called Management Information Bases (MIBs). The third subsection describes the operation of the key protocol in TCP/IP network management, the Simple Network Management Protocol (SNMP). Finally, I round out the section with a brief look at Remote Network Monitoring (RMON), an enhancement of SNMP—sometimes called a protocol, even though it really isn't—that provides administrators with greater management and monitoring abilities on a TCP/IP internetwork.

**Note:** While you may be tempted to jump straight to the subsection on SNMP, what is written there will make a *lot* more sense if you read the subsections here in order.

---

---

## **TCP/IP Internet Standard Management Framework Overview, Architecture, Components and Concepts**

TCP/IP network management functions are most commonly associated with the key protocol responsible for implementing those functions: the *Simple Network Management Protocol (SNMP)*. Many people have heard of SNMP, and it is common for SNMP to be considered “the” way that network management is performed in TCP/IP.

This is true to an extent, but is really an oversimplification. The actual SNMP protocol is only one part of a higher-level network management strategy called the *Internet Standard Management Framework*. In order to really understand how SNMP works, we need to first have some background on the way this network management is structured as a whole.

In this section I provide an introduction to TCP/IP network management by describing the concepts and components of the TCP/IP Internet Standard Management Framework. I begin with an overview and history of the framework, and discuss how it is related to the Simple Network Management Protocol (SNMP). I describe the TCP/IP network management model and the key components that comprise a network management system. I provide a summary of the architecture of the Internet Standard Management Framework. I then describe the three main versions of the Framework and SNMP, and how they are similar and different. I conclude with a discussion of the many standards used to describe this technology.

### **Overview and History of the TCP/IP Internet Standard Management Framework and Simple Network Management Protocol (SNMP)**

An adage from the world of professional sports says that a baseball umpire is doing a good job when you forget that he is there. In many ways, the same could be said of a network administrator. The administrator is doing a good job when the network is running so smoothly and efficiently that users forget that the administrator exists. Because as the administrator knows all too well, the second there is a problem, the users will all remember that he or she is there very quickly. ☺

This means that a primary job of a network administrator is to keep tabs on the network and ensure that it is operating normally. Information about the hardware and software on the network is a key to performing this task properly. When networks were small, an administrator could stay informed about the status of hardware and software using simple means, such as physically walking over to a computer and using it, or using a low-level link layer management protocol.

This is simply not possible with modern internetworks, which are large, geographically diverse, and often consist of many different lower-layer technologies. Usually, the only thing all the devices on the network have in common is an implementation of a particular internet-working protocol suite, such as TCP/IP. This makes the internetwork itself a logical way to facilitate the communication of network management information between devices and a network administrator.

---

## Early Development of SNMP

Many people recognized during the early days of the Internet that some sort of network management technology would be needed for TCP/IP. Unfortunately, at first there was no single standard—in the 1980s, several different technologies were developed by different working groups. There were three main contestants: the *High-level Entity Management System (HEMS)* / *High-level Entity Management Protocol (HEMP)* as defined by RFCs 1021 through 1024; the *Simple Gateway Monitoring Protocol (SGMP)*, defined by RFC 1028; and the *Common Management Information Protocol (CMIP)*, which is actually part of the OSI protocol suite.

The [Internet Engineering Task Force \(IETF\)](#) recognized the importance of having a unifying management standard for TCP/IP, and in 1988 published RFC 1052, *IAB Recommendations for the Development of Internet Network Management Standards*. This memo is not a standard, but more of a statement of intention and documentation of a meeting held on this subject. The conclusion of RFC 1052 was that SGMP be used as the basis of a new Internet standard to be called the *Simple Network Management Protocol (SNMP)*. This development was to be carried out by the *SNMP Working Group*.

### The Two Meanings of "SNMP"

The rationale of the middle two words in the name "Simple Network Management Protocol" is obvious, but the other two words are slightly more problematic. ☺ The word "Protocol" implies that SNMP is just a TCP/IP communication protocol, like other protocols such as [DHCP](#) or [FTP](#). Unfortunately, this is both true and untrue: the term "SNMP" is ambiguous.

At a lower level, SNMP does indeed refer specifically to the actual protocol that carries network management information between devices. This is in fact what most people think of when they talk about "SNMP". However, as defined by the SNMP working group, the TCP/IP network management solution as a whole consists of a number of different elements arranged in an architecture.

This architecture originally had no specific name, but is now called the *Internet Standard Management Framework*. Oddly, this higher-level framework is not abbreviated "ISMF" or anything like that; it is **also** called "SNMP", which means that context is important in understanding that term.

**Note:** To avoid confusion, I will often use the phrases "SNMP Framework" and "SNMP Protocol" to differentiate these two uses of the term "SNMP".

---

### Design Goals of SNMP

The word "Simple" in "Simple Network Management Protocol" is another sore spot for me; having researched and written about this technology, I now consider the presence of this term in the name "SNMP" to be almost a taunt. Let's put it this way: if a brain surgeon tells

---

you that something is a “simple procedure”, you probably know to take that with a grain of salt—well, the same applies here. Even in its first iteration it was only somewhat simple; the most current version of SNMP is fairly complicated indeed, with many different standards defining the SNMP Framework, the SNMP Protocol itself, and a number of supporting elements.

So why is it called “simple”? Well, as they say, everything's relative; SNMP is “simple” when compared to other protocols that are even more complex. Some of this can be seen by looking at the basic goals of the Internet Standard Management Framework and the SNMP protocol as a whole:

- ☉ SNMP defines a universal way that management information can be easily defined for any object and then exchanged between that object and a device designed to facilitate network management;
- ☉ SNMP separates the functions of defining and communicating management information from the applications that are used for network management;
- ☉ The actual SNMP protocol is fairly simple, consisting of only a few easy-to-understand protocol operations;
- ☉ The implementation of SNMP is relatively simple for the designers and manufacturers of products.

Since SNMP is a TCP/IP application layer protocol, it can theoretically run over a variety of transport mechanisms. It is most commonly implemented over IP, of course, but the most recent versions also define *transport mappings* that can allow SNMP information to be carried over other internetworking technologies. Again, my focus will continue to be almost exclusively on TCP/IP.

**Key Concept:** The *Simple Network Management Protocol (SNMP)* defines a set of technologies that allows network administrators to remotely monitor and manage TCP/IP network devices. The term “SNMP” refers both to a specific communication protocol (sometimes called the *SNMP Protocol*) and an overall framework for Internet management (the *SNMP Framework*).

---

### ***Further Development of SNMP and the Problem of SNMP Variations***

The description above provides the history of how the first version of SNMP was developed, leading to the publishing of the first Internet Standard Management Framework in 1988; this is now called *SNMP version 1 (SNMPv1)*. This initial version of SNMP achieved widespread acceptance, and it is still probably the most common version of SNMP.

Much of the history of SNMP since that time has been a rather confusing “standards nightmare”. SNMPv1 had a number of weaknesses, particularly in the area of security. For this reason, shortly after SNMPv1 was done, work began on a new version of SNMP. Unfor-

---

tunately, this effort became a quagmire, with many competing variations of SNMPv2 being created. After many years of confusion, none of the SNMPv2 variants achieved significant success.

Recently, a third version of the SNMP Framework and Protocol has been published, which adds new features and “reunites” SNMP back under a single universal protocol again. The topics on [SNMP versions](#) and [SNMP standards](#) later in this section further explore the history of SNMP since 1988; they can be considered a continuation of this topic, as they help clarify the very confusing story behind SNMP versions over the last decade and a half.

This overview may have put more questions in your mind about the Internet Standard Management Framework and SNMP than it answered. This is part of why I said this stuff isn't really that simple. ☺ The next two topics in this section provide more information about the Framework and its components, and what those components do, so you can understand better what the Framework is all about.

**Related Information:** More background on the SNMP protocol proper can be found in [the overview topic on the actual protocol itself](#).

---

## **TCP/IP SNMP Operational Model, Components and Terminology.**

So, it seems the “Simple” Network Management Protocol (SNMP) isn't quite so simple after all. There are many versions and standards and uses of SNMP, and so a lot we need to learn. I think a good place to start in understanding what SNMP does is to look at its *model of operation*, and examine the components that comprise a TCP/IP network management system and the terminology used to describe them.

### ***SNMP Device Types***

As we saw in the preceding [high-level overview topic](#), the overall idea behind SNMP is to allow the information needed for network management to be exchanged using TCP/IP. More specifically, the protocol allows a network administrator to make use of a special network device that interacts with other network devices to collect information from them, and modify how they operate. In the simplest sense, then, two different basic types of hardware devices are defined:

- ☉ **Managed Nodes:** Regular nodes on a network that have been equipped with software to allow them to be managed using SNMP. These are, generally speaking, conventional TCP/IP devices; they are also sometimes called *managed devices*.
- ☉ **Network Management Station (NMS):** A designated network device that runs special software to allow it to manage the regular managed nodes mentioned just above. One or more NMSes must be present on the network, as these devices are the ones that really “run” SNMP.

---

## SNMP Entities

Each device that participates in network management using SNMP runs a piece of software, generically called an *SNMP entity*. The SNMP entity is responsible for implementing all of the various functions of the SNMP protocol. Each entity consists of two primary software components. Which components comprise the SNMP entity on a device depends of course on whether the device is a managed node or a network management station.

### Managed Node Entities

An SNMP managed node can be pretty much any network device that can communicate using TCP/IP, as long as it is programmed with the proper SNMP entity software. SNMP is designed to allow regular hosts to be managed, as well as intelligent network interconnection devices such as routers, bridges, hubs and switches. Other “unconventional” devices can likewise be managed, as long as they connect to a TCP/IP internetwork: printers, scanners, consumer electronic devices, even specialty medical devices and more.

The SNMP entity on a managed node consists of the following software elements and constructs:

- 🕒 **SNMP Agent:** A software program that implements the SNMP protocol and allows a managed node to provide information to an NMS and accept instructions from it.
- 🕒 **SNMP Management Information Base (MIB):** Defines the types of information stored about the node that can be collected and used to control the managed node. Information exchanged using SNMP takes the form of objects from the MIB.

### Network Management Station Entities

On a larger network, a network management station may be a separate, high-powered TCP/IP computer dedicated to network management. However, it is really software that makes a device into an NMS, so the NMS may not be a separate hardware device. It may act as an NMS and also perform other functions on the network.

The SNMP entity on a network management station consists of:

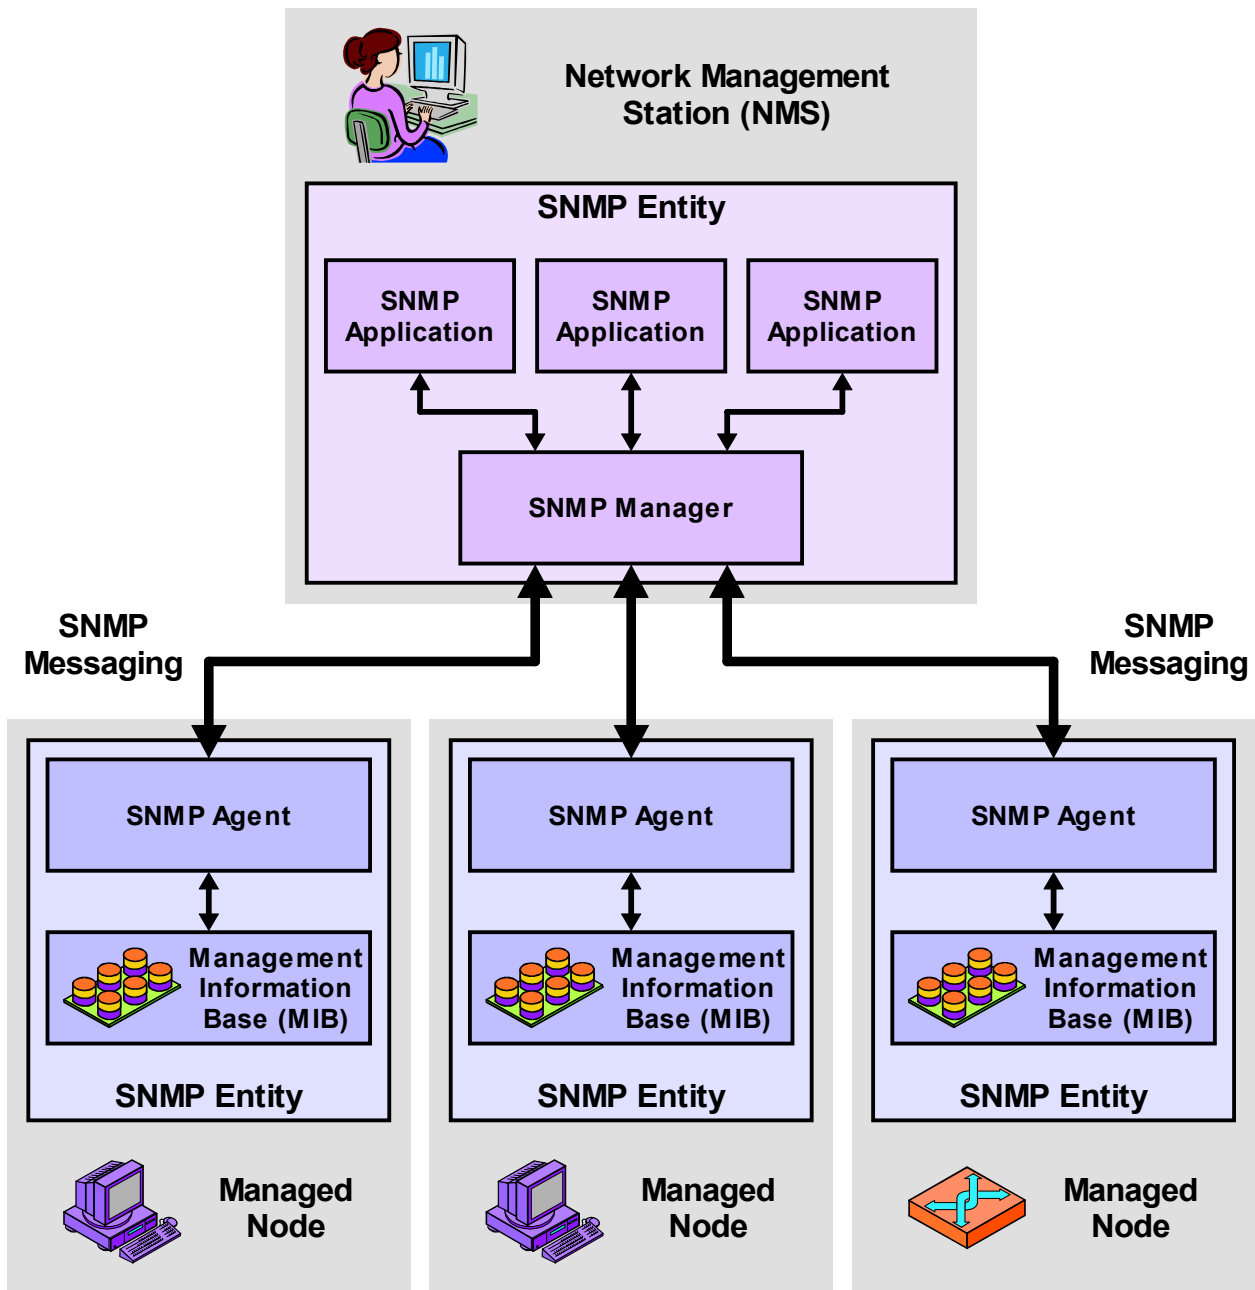

- 🕒 **SNMP Manager:** A software program that implements the SNMP protocol, allowing the NMS to collect information from managed nodes and to send instructions to them.
- 🕒 **SNMP Applications:** One or more software applications that allow a human network administrator to use SNMP to manage a network.

### SNMP Terminology Summary

So, to integrate and reiterate all of this, let's summarize. SNMP consists of a small number of network management stations (NMSes) that interact with regular TCP/IP devices that are called managed nodes. The SNMP manager on the NMS and the SNMP agents on the managed nodes implement the SNMP protocol and allows network management infor-

mation to be exchanged. SNMP applications run on the NMS and provide the interface to the human administrator, and allow information to be collected from the MIBs at each SNMP agent, as shown in [Figure 270](#). Simple! See, the name is good after all. ☺

**Figure 270: SNMP Operational Model**

This diagram shows a simplified implementation of SNMP, with one network management station used to maintain three managed nodes. Each device has an *SNMP Entity*, and they communicate using SNMP messages. The SNMP entity of the NMS consists of the *SNMP Manager* and one or more *SNMP Applications*; the managed nodes each run an *SNMP Agent* and maintain a *Management Information Base (MIB)*.

**Key Concept:** SNMP allows a network administrator using a *network management station (NMS)* to control a set of *managed nodes*. Each device incorporates an *SNMP entity* that implements the technology. In an NMS, the entity consists of an *SNMP manager* module and a set of *SNMP applications*; in a managed node, an *SNMP agent* and *management information base (MIB)*.

---

## TCP/IP Internet Standard Management Framework Architecture and Protocol Components

TCP/IP network management is based on the Simple Network Management Protocol, abbreviated SNMP. As we saw in [the overview topic](#), however, this term is ambiguous. While it is commonly used to refer to [the actual communication protocol](#) used to exchange network management information, the term also refers to the entire set of technologies that enable TCP/IP network management. The technical name for this larger architecture is the *Internet Standard Management Framework*. Again, even though it may seem strange, this term is actually abbreviated in the standards as “SNMP”. For simplicity, I abbreviate it as the “SNMP Framework”, to differentiate it from the SNMP protocol.

The Internet Standard Management Framework encompasses all of the technologies that comprise the TCP/IP network management solution. The SNMP Framework consists of a number of architectural components that define how management information is structured, how it is stored, and how it is exchanged using the SNMP protocol. The Framework also describes how the different components fit together, how SNMP is to be implemented in network devices, and how the devices interact.

### **SNMP Framework Components**

As we will explore in more detail later, the Internet Standard Management Framework is entirely *information-oriented*. It includes the following primary components (see [Figure 271](#)):

- ① **Structure of Management Information (SMI):** To ensure interoperability of various devices, we want to have a consistent way of describing the characteristics of devices to be managed using SNMP. In computer science, a *data description language (DDL)* is the tool for this job. The *Structure of Management Information (SMI)* is a standard that defines the structure, syntax and characteristics of management information in SNMP.
- ② **Management Information Bases (MIBs):** Each managed device contains a set of variables that is used to manage it. These variables represent information about the operation of the device that is sent to a network management station, and/or parameters sent to the managed device to control it. The *management information base (MIB)* is the full set of these variables that describe the management characteristics of a particular type of device.

Each variable in a MIB is called a *MIB object*, and is defined using the SMI data description language. A device may have many objects, corresponding to the different

---

hardware and software elements it contains. Initially, a single document defined the MIB for SNMP, but this model was inflexible. To allow new MIB objects to be more easily defined, groups of related MIB objects are now defined in separate RFC standards called *MIB modules*. Over 100 such MIB modules have been defined so far.

- **Simple Network Management Protocol (SNMP):** This is the actual SNMP protocol itself. It defines how information is exchanged between SNMP agents and network management stations. The SNMP *protocol operations* define the various SNMP messages and how they are created and used. SNMP *transport mappings* describe how SNMP can be used over various underlying internetworks, such as TCP/IP, IPX and others.
- **Security and Administration:** To the three main architectural components above, the SNMP Framework adds a number of supporting elements. These provide enhancements to the operation of the SNMP protocol for security, and address issues related to SNMP implementation, version transition and other administrative issues.

**Figure 271: Components of the TCP/IP Internet Standard Management Framework**

### ***SNMP Framework Architecture***

The creators of SNMP specifically designed the Framework to be modular because when SNMP was originally created, it was seen as only a temporary solution until a transition could be made to another network management protocol from the OSI protocol suite. The modular architecture separated definitional, data and functional (protocol) elements, to allow the SNMP protocol itself to be replaced without changing how network management information was defined and described.

This transition to the OSI protocol never occurred, but the architecture has still proven valuable in defining the entire scope of SNMP and in making its implementation much simpler. Each of the major components above, the SMI, MIBs and SNMP itself, are described in different standards. The modularity of the SNMP Framework has also allowed

---

changes to be made to these components relatively independently of each other, making the transition between SNMP versions easier than it would have been if one huge document defined everything.

**Key Concept:** The three main components of the Internet Standard Management Framework (SNMP Framework) are the Structure of Management Information (SMI), Management Information Bases (MIBs) and the SNMP Protocol itself. These are supported by SNMP security and administration elements.

---

## **TCP/IP Internet Standard Management Framework and SNMP Versions (SNMPv1, SNMPv2 Variants, SNMPv3)**

In the [Networking Fundamentals chapter](#) near the beginning of this Guide, I have a [section that discusses networking standards and their importance](#). I also explain the differences between [proprietary, de facto and open standards](#), and explain the many benefits of open standards. History is replete with examples of technologies that have succeeded because they used an open standard where a competing standard was proprietary.

TCP/IP and the Internet are often held up as a model for proper open standards development. Thousands of TCP/IP standards have been developed and published using the well-known “Request For Comments” (“RFC”) standardization process. The result has been the most successful set of internetworking protocols in computing history, accepted and used worldwide.

Nobody is perfect, however, and no process is perfect either. Some problems occurred in the introduction of SNMP version 2, leading to a virtual breakdown in the normally smooth protocol standardization method, and a proliferation of incompatible “variants” that we aren’t used to seeing in TCP/IP. The story behind this is a continuation of [the general SNMP overview and history](#) from earlier in this section, and explains the many SNMP standard names and numbers, so you can make sense of them. At the same time, the discussion serves as a vivid reminder of how important proper standard development is, and what the consequences are when there isn’t universal agreement on how a standard should evolve.

### **SNMPv1**

The first version of SNMP was developed in early 1988, and published in the form of three RFC standards in August 1988. This first version is now known as *SNMP version 1* or *SNMPv1*. The three SNMPv1 standards provided the initial description of the three main [Internet Standard Management Framework components](#): the Structure of Management Information (SMI), Management Information Bases (MIB) and the SNMP protocol itself. However, the term “Internet Standard Management Framework” was not actually used at that time.

---

SNMPv1 was generally accepted and widely deployed in many networks. SNMPv1 got the job done and became the standard for TCP/IP network management; it is still widely used today. It is the “Old Faithful” of SNMP versions. Slight revisions were made to the initial standards and more and more MIB modules were defined over time, but the technology remained the same for a number of years.

As with any technology, users of SNMPv1 identified weaknesses in it and opportunities for improvement, over time. One of the areas in which SNMPv1 was most criticized was the area of **security**. SNMP version 1 used only a “trivial” (as RFC 3410 puts it) authentication scheme using a password-like construct called a *community string*.

The issue of security turned out to be the bone of contention that eventually led to serious problems in the development of SNMP. Some people felt that community strings were sufficient security, but many others felt it was important that better security be put into SNMP. There were many different ways proposed to add security to SNMP, and no universal agreement on how to do it. The points raised about the security weaknesses in the original SNMPv1 had some validity, [as I explore in the SNMP protocol operations section](#).

## **SNMPsec**

The first attempt to add security to SNMP came in the form of three standards published in July 1992 that defined a new security mechanism using logical identifiers called *parties*. This is sometimes called *SNMP Security* or *SNMPsec*. This method was more secure than the original SNMPv1, but SNMPsec was never widely accepted, and is now considered “historic”.

## **SNMPv2**

While SNMPsec went away, the idea of party-based security it introduced never did. It was used as the basis of the definition of the first full revision of SNMP, when *SNMP Version 2* (*SNMPv2*) was published in RFCs 1441 through 1452 in April 1993. This new version incorporated the new security model, as well as making changes to the actual [SNMP protocol operations](#), changes to the [Structure of Management Information \(SMI\)](#) standard (defining version 2 of SMI, SMIv2), and formalizing the concept of the Internet Standard Management Framework.

Unfortunately, this new standard too was never universally accepted. Some people thought the whole new version was a great advance, but others took issue with the party-based security, claiming it was too complex. I am not familiar with all the details, but from what I understand, a great deal of debate and discussion took place over the next couple of years, as an attempt was made to get everyone “on board” with the new version.

---

## SNMPv2 Variants

Acceptance of SNMPv2 never happened. Instead, different “splinter groups” broke off and began work on *variants* of SNMPv2. To prevent confusion, the original SNMPv2 became known as either *SNMPv2 classic* (reminiscent of the name a particular soft drink) or *SNMPv2p*, with the “p” referring to “party-based” security. Things got very interesting (and confusing) when the following were proposed and/or developed:

- ☉ **SNMPv1.5:** I can tell immediately that an idea is probably going to be a problem when it proposes a version number lower than a number already standardized. SNMPv1.5 was an attempt to retain the “uncontroversial” elements in SNMPv2p—the enhancements to the SNMP protocol and SMI—while going back to community-based security as in SNMPv1. It never became a standard itself, but became the basis of...
- ☉ **Community-Based SNMPv2 (SNMPv2c):** This is SNMPv2p modified to use community strings instead of party-based security; in essence, the same idea as SNMPv1.5 but with a more “official-sounding” name and a few changes. Interestingly, the standard that defines this, RFC 1901, still has an “experimental” status, despite the fact that SNMPv2c actually achieved some degree of commercial success where the “standard” SNMPv2p did not.

SNMPv2c was defined by standards RFC 1902 through 1908, which incorporate other changes including a new version of SMI (SMIv2).

- ☉ **User-Based SNMPv2 (SNMPv2u):** This is an alternative security method for SNMPv2c, which is based on users rather than community strings. It is considered simpler than party-based but more secure than community-string security. It is defined by RFC 1909 and RFC 1910. It too is formally considered “experimental”.
- ☉ **SNMPv2\*:** As if all of the above was not enough, a well-known vendor decided to define another variant called *SNMPv2\** that combined elements of SNMPv2p and SNMPv2u. This was never formally standardized. (Yes, that's an asterisk in the name. No, there's no footnote at the bottom of this topic, so don't bother looking for one. Yes, putting an asterisk in a name is extremely confusing. No, I don't know how it is that marketing people get paid good money to come up with names like that. ☹)

Now, imagine that you were a network administrator in the mid-1990s and were faced with SNMPv2p, SNMPv2c, SNMPv2u and SNMPv2\*. Which one would you choose? Well, if you are like most people, you'd choose “none of the above”, saying “I think I'll stick with SNMPv1 until these version 2 folks get their act together”. And that's basically what happened. Some proponents of these variations promoted them, but there was never any agreement and the result was that the success of all of the various and sundry SNMPv2's was limited. As I said, a classic illustration of how important universal standardization is.

## SNMPv3

I would imagine that at some point, everyone realized that the situation was a mess, and decided “enough is enough”. In 1996 work began on a new approach to resolve the outstanding issues and return universality to SNMP. In 1998, *SNMP version 3 (SNMPv3)* was developed, which includes additional enhancements to SNMP and finally gets all the players back on the same team.

---

SNMPv3 is the most current version of SNMP and is still being actively revised. One of the important changes in SNMPv3 is a more formalized way of handling different security approaches to SNMP—obviously, a lesson learned from the SNMPv2 experience.

SNMPv3 uses SNMPv2 protocol operations and its PDU message format, and the SMIv2 standard from SNMPv2 as well. SNMPv3 allows a number of different security methods to be incorporated into its architecture, and includes standards describing user-based security as defined in SNMPv2u and SNMPv2\* as well as a new view-based access control model. It also includes additional tools to aid in the administration of SNMP.

## **TCP/IP Internet Standard Management Framework and SNMP Standards**

We've now seen that there are [three different versions of the Internet Standard Management Framework](#). Some of these versions have different variants. Each version or variant of the Framework includes multiple modular components. Each component has one or more documents that define it. Some of *these* have multiple revisions. Add to that dozens of individual [Management Information Bases \(MIBs\)](#) defined for SNMP and other support documents and what do you have? A boatload of TCP/IP standards, that's what. There are probably more RFCs defining parts of SNMP than any other single TCP/IP protocol or technology.

It is specifically because there are so many versions and components and documents associated with SNMP that I feel it is important to keep all the standards straight. To that end I have created a number of tables, which show the major SNMP standards for each of the versions and variants of the SNMP Framework. Each individual RFC defines one component of one version of the Framework.

The usual way that RFCs work is that when new versions of a standard are released that are direct replacements for older ones, the older ones are “obsoleted” by the new ones. With SNMP, due to the many versions and the controversy over the variants, this is a bit unclear. For example, the standards defining SNMPv2p are not considered by the IETF to obsolete the standards for SNMPv1, but the IETF says the standards for SNMPv2c and SNMPv2u **do** obsolete those of SNMPv2p.

To keep all of this distinct I have made the decision to show the standards for each version or variant separately. I only put the RFC numbers for obsolete RFCs where those RFCs are for the same SNMP version or variant. For example, RFC 3410 obsoletes 2570 because they both deal with SNMPv3 and 3410 is a direct replacement for 2570. Also, there are a few cases where the name of a standard changed slightly between RFC numbers; I have shown the current name.

Each of the six tables below shows the current and obsoleted standards for one of the SNMP versions or variants: SNMPv1 ([Table 200](#)); SNMPSec ([Table 201](#)); SNMPv2p ([Table 202](#)); SNMPv2c ([Table 203](#)); SNMPv2u ([Table 204](#)) and SNMPv3 ([Table 205](#)). (SNMPv2\* was not standardized using the regular RFC process.)

---

## **TCP/IP Structure of Management Information (SMI) and Management Information Bases (MIBs)**

The Internet Standard Management Framework defines three major components that describe how devices can be managed on a TCP/IP internetwork. One of these, the actual [Simple Network Management Protocol \(SNMP\)](#) is relatively well-known, but is only part of the overall picture. SNMP describes how information is exchanged between SNMP entities, but two other components are equally important because they describe the information itself.

In this section I describe these two important supporting elements of the TCP/IP Internet Standard Management Framework: the Management Information Base (MIB) standard that describes types of information that SNMP works with, and the Structure of Management Information (SMI) standard that specifies how MIB information is defined. Understanding these two parts of the SNMP Framework is an important initial step before we examine the actual SNMP protocol itself.

Since SMI and MIBs are so closely related, they are described in combination here. I begin with an overview description of the SMI data description language and how management information bases (MIBs) work. I discuss the MIB object name hierarchy and the notation used to refer to names. I also describe how MIB objects work, discussing the different object types and MIB object groups.

**Background Information:** If you have not yet already read [the section describing the SNMP Internet Standard Management Framework](#), you should do so before proceeding here.

---

**Note:** I describe here MIB concepts common to all of the versions of SNMP, and discuss both of the specific versions of SMI (SMIv1 and SMIv2) used in those SNMP versions.

---

## **TCP/IP Structure of Management Information (SMI) and Management Information Bases (MIBs) Overview**

The key to really understanding TCP/IP network management is to comprehend the *information-oriented* nature of the entire [Internet Standard Management Framework \(SNMP Framework\)](#). To see what I mean by this, let's step back for a moment and consider in general terms the problem of network management, and more specifically, the problem of managing devices on a network.

---

## Understanding SNMP's Information-Oriented Design

A network administrator needs to perform two basic types of actions: gather data about devices to learn how they are functioning, and give commands to devices to change how they are functioning. In the simplest terms, the first category can be considered like a “read” operation, and the second is comparable to a “write” operation.

A classical way of implementing this functionality is to define a communication protocol. Most such protocols are *command-oriented*—they consist of a specific set of commands to perform the “read” and “write” operations we mentioned above. For example, a network management protocol might have a read command such as “report on number of hours device has been in use”, and a write command such as “put this device into test mode”. The network manager would control the device by giving the appropriate commands.

A command-oriented management protocol has the advantage of simplicity: it's clear what the commands are for and how they are to be used. It can be reasonably well-suited for use in certain environments, but it doesn't work well on a large, heterogeneous TCP/IP inter-network. The main reason for this is that command-orientation inextricably ties the protocol to the devices being managed. Consider:

- ☉ Every type of device might require a distinct set of commands. For example, the commands given to a router might need to be different than those given to a host. This would lead either to a proliferation of commands in the protocol, or to inflexibility in allowing proper management of different device types.
- ☉ Every time a company created a new type of device, or made a unique version of a type of device, the network management protocol would have to be changed.
- ☉ Whenever the operation of a kind of device changed, due perhaps to a change in another protocol, the management protocol would need to be updated.
- ☉ The protocol itself could not be easily changed without affecting a lot of hardware.

The solution to the problems of command-oriented management protocols was to use an *information-oriented* model. Instead of defining specific commands that interrogate or control devices, the devices are defined in terms of units of information that are to be exchanged between the devices and a management station.

Instead of “read” commands and “write” commands, we have *variables* that can be “read” or “written”. Take the two examples mentioned earlier. Instead of a command like “report on a number of hours device has been in use”, the device keeps a variable called “number of hours in use” and the network management station can “read” this as one of many variables, with no need for a specific protocol command. Instead of a “write” command called “put this device into test mode”, the device has a variable called “current mode”. The network manager can change the mode of the device to “test” by changing the value of the variable.

This difference may seem subtle, but it in fact underlies every aspect of how SNMP works. I believe part of why the SNMP Framework is hard to understand is because insufficient emphasis is placed on looking at things in the “SNMP way”, which means thinking about information objects and not commands.

**Key Concept:** Unlike most protocols, which are command-oriented, SNMP is *information-oriented*. SNMP operations are implemented using objects called *variables* that are maintained in managed devices. Rather than issuing commands, a network management station checks the status of a device by reading variables, and controls the operation of the device by changing (writing) variables.

---

### ***The Management Information Base (MIB) and MIB Objects***

Given this backdrop, we can look at the SNMP Framework in a new light. The actual SNMP protocol itself, which we'll examine in the next section, has only a few, generic commands to accomplish “read” and “write” tasks as mentioned just above. It deals with only the methods by which network management information is exchanged between [SNMP agents](#) and [SNMP network management stations](#). The network management information is really the heart of TCP/IP network management.

So, instead of SNMP being defined in terms of commands used to control particular devices, it is defined in terms of management information variables, generally called *objects*. Each object describes a particular characteristic of a device. Some objects are fairly generic and are meaningful for any device on a TCP/IP network; for example, an object describing something related to the Internet Protocol itself, such as the device's IP address. Other objects might be particular to a specific type of device; for example, a router will have objects that a regular host's Ethernet network interface card would not.

A collection of objects used in SNMP is called a *management information base*, or *MIB*. (In fact, SNMP objects are often called *MIB objects*.) The first version of SNMP, SNMPv1, had a single standard that defined the entire MIB for SNMP. Newer versions however provide more flexibility by using different *MIB modules* that defines sets of variables particular to the hardware or software used by a device.

Defining objects using modules allows for significant flexibility in defining the variables that allow management of different types of devices. A device can incorporate all the MIB modules appropriate to the hardware and software it uses. For example, if you had a device using Ethernet, it would incorporate variables from the Ethernet MIB; one using Token Ring would use the Token Ring MIB. Both devices would also use the common SNMP MIB that is used by all TCP/IP devices. Other modules might also be included as needed. We'll see more of how this works later in this section.

**Key Concept:** The management data variables in a managed device are maintained in a logical collection called a *management information base (MIB)*. The objects in the MIB are often called *MIB objects*, and are typically collected into sets called *MIB modules*.

---

---

## Defining MIB Objects: the Structure of Management Information (SMI)

The use of MIB objects solves the problem of the network management protocol being tied to the network management information. However, we must be very particular about how we define these objects. Again, the reason is the wide variety of devices that TCP/IP allows to be connected together. Each device may represent information in a different way; for them all to communicate with each other, we need to ensure that management information is represented in a consistent manner.

The part of the SNMP Framework that ensures the universality of MIB objects is the *Structure of Management Information (SMI)* standard. SMI defines the rules for how MIB objects and MIB modules are constructed. In SMI, MIB objects are described using a precise set of definitions based on a data description language called the ISO *Abstract Syntax Notation 1 (ASN.1)* standard.

In essence then, we really have three “levels of abstraction” in SNMP. The actual SNMP protocol moves values that represent the state of management devices. The MIB defines what these variables are. And the SMI defines how the variables in the MIB are themselves defined.

There are two main SMI standards. The original, *SMIv1*, was part of the first SNMP Framework, SNMPv1, defined in RFC 1155. It sets out the basic rules for management information bases and MIB variables. The second, *SMIv2*, was defined as part of SNMPv2p in RFC 1442 and further updated in RFC 2578, part of SNMPv3. It is similar to the earlier version but defines more object types as well as the structure of MIB modules.

These SMI standards are responsible for defining the following important information elements in SNMP:

- ☉ The general characteristics associated with all MIB objects. SMI defines the standard way by which all MIB objects are described.
- ☉ The different types of MIB objects that can be created, such as integers, strings and more complex data types.
- ☉ A hierarchical structure for naming MIB objects, so they can be addressed in a consistent manner without names overlapping.
- ☉ The information associated with each MIB module.

**Key Concept:** The *Structure of Management Information (SMI)* standard is responsible for defining the rules for how MIB objects are structured, described and organized. SMI allows dissimilar devices to communicate by ensuring that they use a universal data representation for all management information.

---

---

In fact, the SMI and MIB standards are so closely related that it is hard to discuss one without the other. The rest of this section discusses SNMP management information structures making reference to both SNMP Framework components. We'll see how [MIB objects are defined and the characteristics of each](#), and look at MIB data types, [the structure used to organize MIB objects](#), and the way [MIB modules and object groups](#) work.

**Note:** Due to its name, the management information base is often called a “database”. This is, strictly speaking, inaccurate. The MIB is a description of objects. The actual MIB in a device *may* be implemented as a software database, but it need not be.

---

## **TCP/IP MIB Objects, Object Characteristics and Object Types**

The Internet Standard Management Framework (SNMP Framework) is designed to facilitate the exchange of management information. The *Management Information Base (MIB)* defines a device's management information. The MIB contains a number of variables called *MIB objects*; they are also called *managed objects*. These objects are defined according to the rules set out in the [Structure of Management Information \(SMI\)](#) standard.

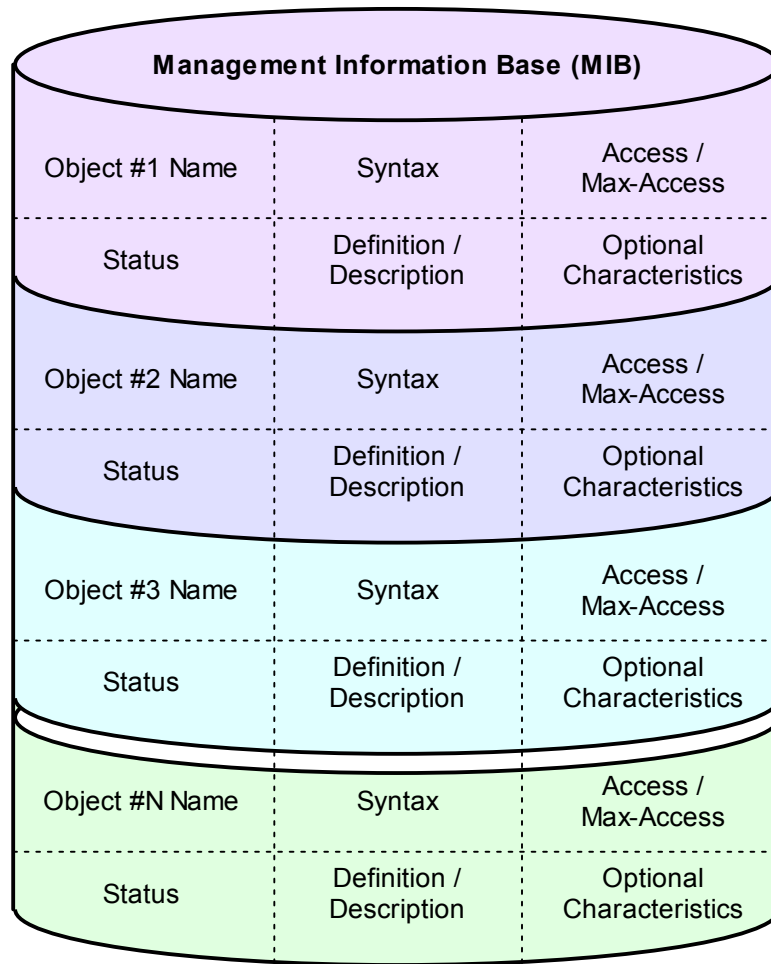

The best place to begin looking at MIB objects is by examining the SMI rules that define them. As I mentioned earlier in this section, two different versions of SMI have been created: SMIv1 as part of the original SNMP, and SMIv2 as part of SNMPv2 and SNMPv3. The two are similar in terms of how MIB objects are described, but SMIv2 allows more information to be associated with each object.

### ***MIB Object Mandatory Characteristics***

Just as a typical protocol uses a field format for specifying the content of messages sent between devices using the protocol, SMI uses a format that specifies the fundamental characteristics of each MIB object. The most basic of these are five mandatory characteristics defined in SMIv1. These are also used in SMIv2, but a couple of names were changed, and the possible values for some of the fields were modified as well. This is shown conceptually in [Figure 272](#).

#### ***Object Name***

Each object has a name that serves to uniquely identify it. Actually, that's not entirely true. Each object actually has *two* names: a textual name called an *Object Descriptor* and a numeric *Object Identifier* that indicates the object's place in the MIB object name hierarchy. I'm sure that made no sense to you, but that's why I included [the next topic discussing object naming](#) that hopefully will (make sense that is.)

**Figure 272: SNMP Management Information Base (MIB)**

This diagram shows an SNMP management information base containing “N” MIB objects. Each object has five mandatory characteristics and a variable number of optional characteristics.

### **Syntax**

An object’s *Syntax* defines its data type and the structure that describes it. This attribute of an MIB object is very important because it defines the data type of information that the object contains. There are two basic categories of data types allowed:

- ☉ **Regular Data Types:** These are single pieces of information, of the type we are used to dealing with on a regular basis; examples would be integers or strings. These are called *base types* in SMIv2. SMIv1 differentiates between *primitive types* like integers defined in ASN.1, and *defined types* that are special forms of primitive types that are still single pieces of information but with certain special meaning attached to how they are used. SMIv2 doesn’t use those two terms.

- 
- **Tabular Data:** A collection of multiple data elements. This may take the form of a list of base types or a table of base types. For example, a table of integers could be constructed to represent a set of values. In SMIv1 these are called *constructor types*; in SMIv2 they are *conceptual tables*. They can be accessed using special SNMP mechanisms designed for reading tables. See the topic on SNMP table traversal for more on tables.

### Access (*Max-Access* in SMIv2)

This field defines the ways that an SNMP application will normally use the object. In SMIv1, there are four different possible values: *read-only*, *read-write*, *write-only*, and *not-accessible*.

In SMIv2 there are five values, which are described as a hierarchy of sorts. SMIv2 calls this characteristic *Max-Access* (*maximum access*) to make it explicit that higher access levels include the lower levels as well. For example, an object with *read-create* access can also be used in any of the modes “below it”, such as *read-write*, but not vice versa. Table 206 shows the five SMIv2 access values, in decreasing order of access. Note that *write-only* has been removed in SMIv2:

**Table 206: SNMP SMI Version 2 *Max-Access* Values**

<i>Max-Access</i> Value	Description
<i>read-create</i>	Object can be read, written or created.
<i>read-write</i>	Object can be read or written.
<i>read-only</i>	Object can only be read.
<i>accessible-for-notify</i>	Object can be used only using SNMP notification (SNMP traps).
<i>not-accessible</i>	Used for special purposes.

### Status

Indicates the currency of the object definition. In SMIv1 there are three values: *mandatory*, *optional* and *obsolete*. In SMIv2, the first two are combined into simply *current*, meaning a current definition. The value *obsolete* is retained, and *deprecated* is added, meaning the definition is obsolete but maintained for compatibility.

### Definition (*Description* in SMIv2)

A textual description of the object.

**Key Concept:** Each management information variable, called a *MIB object*, has associated with it five key attributes: its name, syntax, maximum access, status and definition. It may also have a number of optional characteristics.

---

---

## SMIv2 MIB Object Optional Characteristics

SMIv2 adds the following optional characteristics that may appear in the definition of an object:

- ☉ **Units:** A text description of the units associated with the object.
- ☉ **Reference:** A text cross-reference to a related document or other information of relevance to the object.
- ☉ **Index:** A value used to define objects that are actually more complex “rows” of other objects.
- ☉ **Augments:** An alternative to the *Index* field.
- ☉ **DefVal:** Defines an acceptable default value for the object.

## SMI Regular Data Types

Table 207 shows the regular data types supported for objects in both SMIv1 and SMIv2. (The names with “32” in them are the ones used in SMIv2; they were changed to make the type’s bit size explicit.) The first five entries in the table are primitive types, the rest are defined types, using the SMIv1 terminology.

**Table 207: SNMP SMI Regular Data Types (Page 1 of 2)**

Data Type Code	Description	SMIv1?	SMIv2?
<b>Integer / Integer32</b>	A 32-bit signed integer in two's complement notation, capable of holding a value from -2,147,483,648 to +2,147,483,647. Can also be used to represent an enumerated type; for example, where 1 represents a particular constant, 2 represents a different one, and so on.	Yes	Yes
<b>Octet String</b>	A variable-length string of binary or text data.	Yes	Yes
<b>Null</b>	Nothing.	Yes	—
<b>Bits</b>	An enumeration of named bits. Used to allow a set of bit flags to be treated as a single data type.	—	Yes
<b>Unsigned</b>	A 32-bit unsigned integer, from 0 to 4,294,967,295.	—	Yes
<b>Network Address / IpAddress</b>	An IP address, encoded as a 4-byte octet string.	Yes	Yes
<b>Counter / Counter32</b>	A 32-bit unsigned integer, that begins at 0 and increases up to 4,294,967,295, then wraps back to 0.	Yes	Yes
<b>Gauge / Gauge32</b>	A 32-bit unsigned integer, that may have a value from 0 to 4,294,967,295 and may increase or decrease, like a gauge. A minimum and maximum value are associated with the gauge, indicating its normal range.	Yes	Yes
<b>TimeTicks</b>	A 32-bit unsigned integer that indicates the number of hundredths of seconds since some arbitrary start date. Used for timestamping and to compute elapsed time.	Yes	Yes

**Table 207: SNMP SMI Regular Data Types (Page 2 of 2)**

Data Type Code	Description	SMIv1?	SMIv2?
<b>Opaque</b>	Data using arbitrary ASN.1 syntax that is to be passed between devices without being interpreted. As in NFS's <a href="#">XDR</a> , the term “opaque” means that the data is treated like a “black box” whose internal details cannot be seen.	Yes	Yes
<b>Counter64</b>	A counter like Counter32 but 64 bits wide, allowing a value from 0 to 18,446,744,073,709,551,615.	—	Yes

### **SMIv2 Textual Conventions**

In addition to these types, other defined types are also created to again, indicate more specific semantics for a particular data type. These are called *textual conventions* and are described in RFC 2579 for SMIv2. For example, a type called *TimeStamp* is defined which is the same as *TimeTicks*. However, seeing an object using the former rather than the latter makes it more clear that the variable is representing a particular time stamp value. Another is called *TimeInterval*, which is also just an integer underneath its name, but conveys a different interpreted meaning.

### **Example SMIv2 Object Definition**

If all of the above seemed very confusing to you, note that this topic is in fact a significant simplification of SMI's object definitions. SNMP is so much fun! If an example will help, check out [Table 208](#), which shows an object definition from RFC 3418, using SMIv2.

**Table 208: Example SNMP SMIv2 Object Definition**

<pre> sysLocation OBJECT-TYPE     SYNTAX DisplayString (SIZE (0..255))     MAX-ACCESS read-write     STATUS current     DESCRIPTION "The physical location of this node (e.g., 'telephone closet, 3rd floor'). If the location is unknown, the value is the zero-length string."     ::= { system 6 } </pre>
--

Note that *DisplayString* is a textual convention for a displayed text string. The last part, “{ system 6 }”, will be explained in the next topic.

## **TCP/IP MIB Object Descriptors and Identifiers and the Object Name Hierarchy and Name Notation**

Of the many [MIB object characteristics](#), only one is sufficiently interesting that it really deserves its own exposition. Or perhaps I should say, only one is sufficiently **complicated** that it does. ☺ This is the object name, part of the larger naming system used for MIB objects.

---

As I said before, each MIB object actually has two names: an *object descriptor* and an *object identifier*. The object descriptor is a conventional text name that provides a “user-friendly handle” to refer to the object. The name is assigned based on the particular MIB object group in which the object is located. In the example definition I gave at the end of the prior topic, *sysLocation* is the object descriptor for that MIB object. I describe these names in greater detail in the next topic, on [MIB modules and object groups](#).

### ***The MIB Object Name Hierarchy***

Text names are convenient, but they are generally **unstructured**. There are at present over 10,000 different MIB objects, and even if each has a distinct text name, a huge collection of such names doesn’t help us to manage these objects and see how they are related. For this, we need a more structured approach to categorizing and naming objects.

This problem is similar to another problem that you may recall reading about: [the problem of how to assign names on the Internet](#). Originally names for hosts were simple, “flat” names, but this quickly grew unwieldy. The [Domain Name System \(DNS\)](#) formalized a structured hierarchy for domain names. The [DNS hierarchical name space](#) allows every device to be arranged into a single hierarchical tree structure. The name of the device can be formed by traversing the tree from the top down to the location of the device, listing the labels traversed separated by dots. For example, the Web server of The PC Guide is at “www.pcguide.com”.

This exact same concept is used to organize MIB objects in SNMP. A single universal hierarchy is used that contains all MIB objects. It is hierarchical in nature, and split into levels from the most general to the most specific. Each object has a particular place in the hierarchy. The names are formed by following the labels from the top of the tree down to the place where the object is located, and separating them with “dots”. (SNMP doesn’t reverse the order of the labels the way DNS does, however. They are listed top-down from left to right.)

There is another important difference between the MIB name hierarchy and the DNS one: the MIB name hierarchy is even more universal than the one for DNS. The entire subtree of all MIB objects is just one branch of the full, international object hierarchy maintained by ISO and ITU. This object identification hierarchy is so general that it can contain a name for every object or variable in use by any technology in the entire world. And possibly other planets. Or solar systems. ☺

The reason for my jocularly will become apparent in a moment. Suffice to say, this object tree is enormous. Each node in this tree is identified with both a label and an integer. The labels are for descriptive purposes; object (or subtree) identifiers are formed by listing the numbers in sequence from the top of the tree down to the node, separated by dots. (The text labels can be used for names too but are not because they would get very long due to how deep the tree structure is.)

**Key Concept:** SNMP MIB objects have two names. The first is a text *object descriptor*, which provides a means of addressing the object in a way that is familiar and easy for humans. The second is the *object identifier*, which consists of a sequence of integers that specifies the location of the object in the global object hierarchy maintained by the international standards bodies ISO and ITU.

---

### Structure of the MIB Object Name Hierarchy

Let's explore how the MIB object tree is structured, and more importantly, how SNMP MIB objects fit into it (you may find referring to [Figure 273](#) useful as you proceed here.) The tree's root has no label, and has three children:

- **ccitt(0):** For [ITU](#) (formerly the CCITT) standards. (Also seen as *itu(0)*).
- **iso(1):** For ISO standards.
- **joint-iso-ccitt(2):** For joint standards. (Also seen as *joint-iso-itu(2)*).

Following the *iso(1)* node, we see the following at the next several levels:

- Within *iso(1)*, the ISO has created a subtree for use by other organizations, called *org(3)*.
- Within *org(3)*, there is a subtree for the United States Department of Defense, which as you may recall was the originator of the Internet: *dod(6)*.
- Within *dod(6)*, there is a subtree called *internet(1)*.

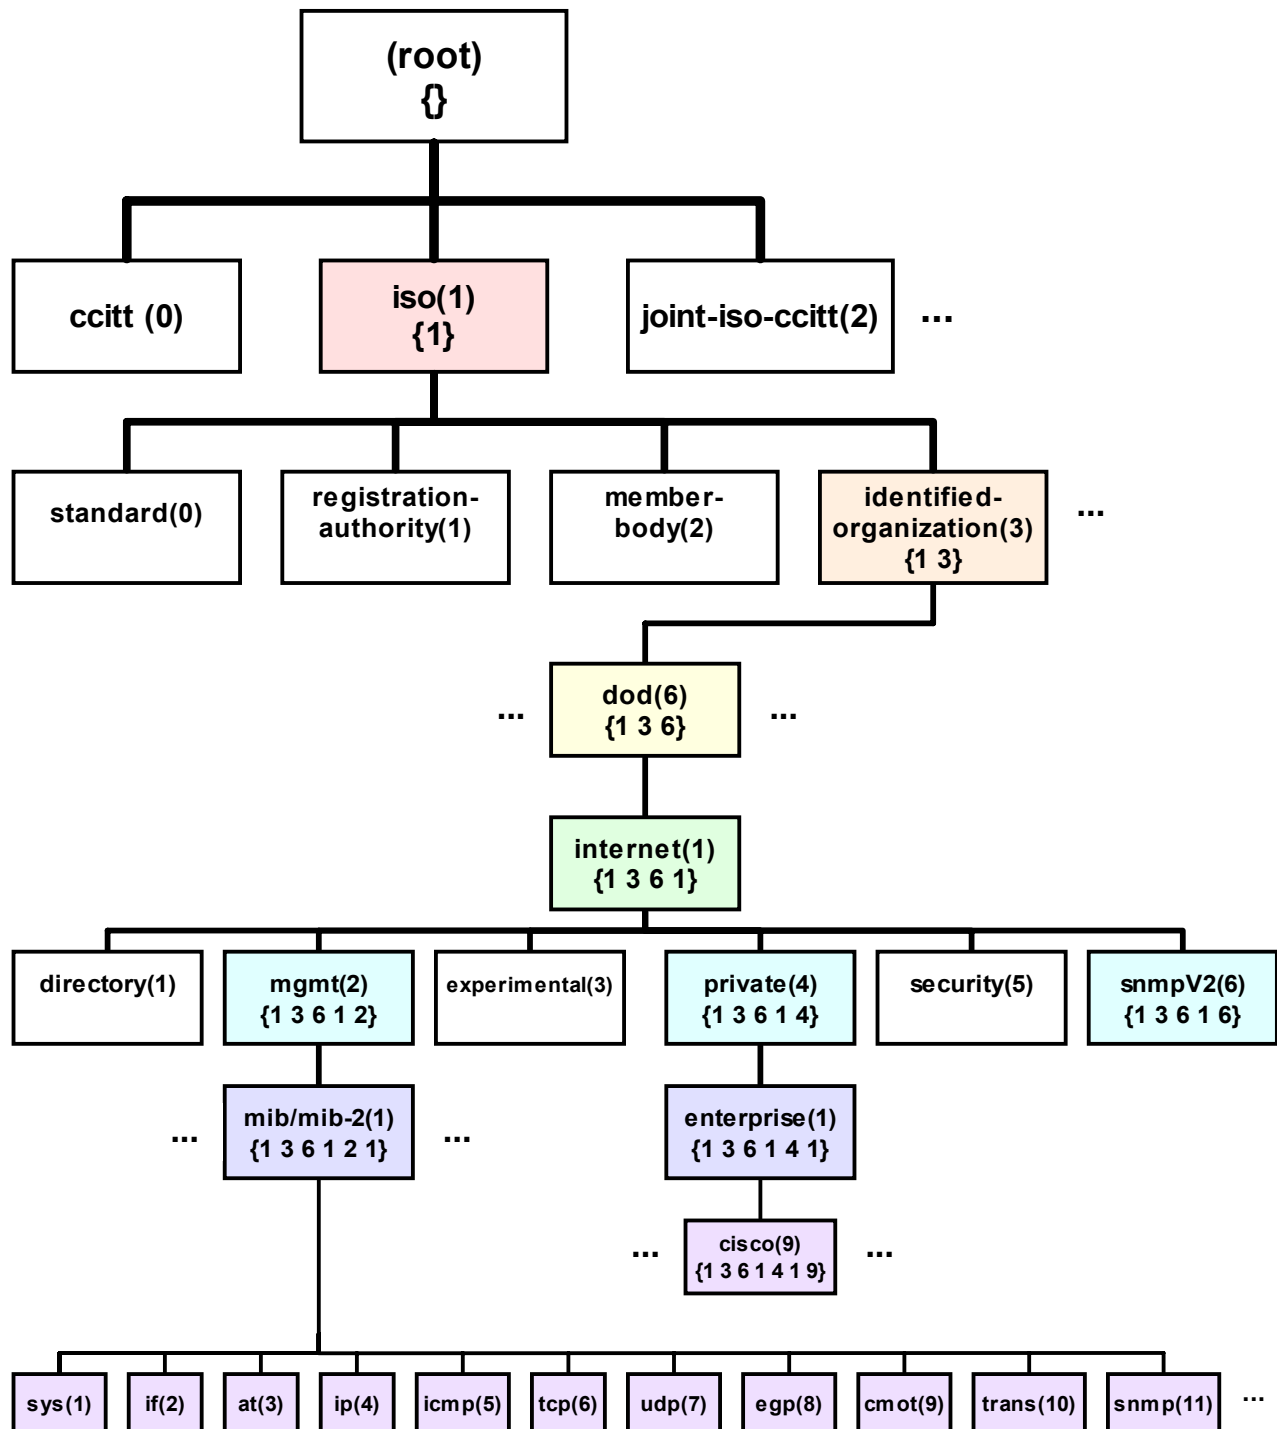

Everything we work with in SNMP is under this one very specific subtree: 1.3.6.1, which if we used the text labels would be "iso.org.dod.internet". Within this part of the name space, there are six subtrees below:

- **directory(1):** Reserved for future use by ISO.
- **mgmt(2):** The primary subtree where MIB objects are located. This is "1.3.6.1.2". It contains a subtree called *mib(1)*, which is 1.3.6.1.2.1. When MIB-II was created, a subtree called *mib-2(1)* was created using the same number, 1.3.6.1.2.1.
- **experimental(3):** Contains objects used for standards under development. This is "1.3.6.1.3".
- **private(4):** Used for objects defined by private companies. This node, 1.3.6.1.4, has a subtree called *enterprise(1)*, which is 1.3.6.1.4.1.
- **security(5):** Reserved for security use.
- **snmpV2(6):** Defines objects used specifically for SNMP version 2.

Phew. So, what's the bottom line of all this? Well, basically all MIB module objects are named within one of these two branches of the overall object tree:

- **Regular MIB Objects:** These are in the *mib(1)* subtree under *mgmt(2)*: 1.3.6.1.2.1.

**Figure 273: Global Object Name Hierarchy and SNMP MIB Hierarchies**

This diagram shows the object name hierarchy defined by ISO and CCITT (ITU) to allow all types of objects to be universally represented. The “path” within this larger tree to the tree branches relevant to SNMP can be found by following the colored boxes. The two subtrees used for SNMP are shown in light blue. Each contains its own substructure (some of which is illustrated by boxes in purple) defining thousands of different MIB objects. The branch on the left side is used for generic MIB objects and the one on the right for private ones. A separate hierarchy is also define for SNMP V2.

- 
- ☛ **Private MIB Objects:** These are in the *enterprise(1)* subtree under *private(4)*, which is 1.3.6.1.4.1. For example, within *enterprise(1)* there is an entry *cisco(9)* for Cisco Systems. So all Cisco-specific MIB objects start with 1.3.6.1.4.1.9.

Clear as mud, right? Why didn't they just make a separate hierarchy where “mib” was at the top instead of 6 levels deep? How dare you even suggest such a thing. Don't you understand the importance of global standards? ☺

All facetiousness aside, this name hierarchy is a bit cumbersome to deal with (okay, more than a bit) but it does allow us to keep MIB objects organized in a sensible way. Within the 1.3.6.1.2.1 subtree we find most of the regular MIB objects used in SNMP. Each subtree within 1.3.6.1.2.1 corresponds to one of the [regular SNMP object groups or a particular MIB module](#).

**Key Concept:** All MIB objects have object identifiers that fit within two branches of the global object hierarchy. Regular MIB objects (which are not vendor-specific) fit in the *mib(1)* subtree under *mgmt(2)*: 1.3.6.1.2.1. Private objects, which can be created by a hardware vendor to assist in managing that vendor's products, are in the *enterprise(1)* subtree under *private(4)*, which is 1.3.6.1.4.1

---

### ***Recursive Definition of MIB Object Identifiers***

An object is given a text object descriptor by putting its name at the start of the object as shown in [Table 208](#), but the definition of numeric object identifiers is, again, more complex. It is done by defining only the number of the object within its particular subtree. This means the object identifiers are defined **recursively** (one based on another) and are not explicitly stated for each object. Syntactically precise, but makes it hard to see at a glance what the number is for any particular object.

Consider again the example in [Table 208](#). For this object, *sysLocation* is the object descriptor, and “{ system 6 }” is the object identifier. This means it is object number 6 within the node *system*, which is in turn defined as “{ mib-2 1 }”—it is the first node within the *mib-2* subtree. Since *mib-2* is, as we said above, 1.3.6.1.2.1, this means *system* is 1.3.6.1.2.1.1 and *sysLocation* is 1.3.6.1.2.1.1.6.

### **TCP/IP MIB Modules and Object Groups**

The [Management Information Base \(MIB\)](#) contains the collection of MIB objects that describe the characteristics of a device using the [Internet Standard Management Framework \(SNMP Framework\)](#). When SNMP was first created, there were not that many objects in the MIB. Furthermore, they were mostly “generic” objects that applied fairly universally to TCP/IP devices as a whole. In fact, most of the MIB objects were variables related to the operation of TCP/IP protocols such as IP, TCP and ICMP.

---

For this reason, at first, a single document defined “the” Management Information Base (MIB) for SNMP. The first of these documents was RFC 1066, part of the initial SNMPv1 specification. It was then revised in RFC 1156. In RFC 1158, a second version of the MIB, *MIB II*, was defined, which was essentially the same but made a few changes.

### ***The Organization of MIB Objects into Object Groups***

The number of MIB objects defined in these standards was relatively small. However, there were still several dozen of them, and it was recognized from the start that more would be created in time. To help organize the objects in a logical way, they were arranged into *object groups*. These groups serve the purpose of separating the objects and defining how they should be given object identifiers in the overall [object name hierarchy](#).

Each group has associated with it three important pieces of information:

- ☉ **Group Name:** A name that is used as a text label in the object identification tree we saw in the previous topic. These objects are all located within the “iso.org.dod.internet.mgmt.mib” subtree. So for example, the group *system* would be “iso.org.dod.internet.mgmt.mib.system”.
- ☉ **Group Number:** A number corresponding to the group name used for making numeric identifiers from the object name tree. For example, the group *system* has the number 1, and so the group's object identifier is 1.3.6.1.2.1.1. All objects in that group will be under that tree; for example, *sysUpTime* is 1.3.6.1.2.1.1.3.
- ☉ **Group Code:** A text label that may be the same as the group name or may be an abbreviation. It is used as a prefix in making object descriptors (the text names of objects). For example, for the group *system* the code is *sys*, and so an object in this group is *sysUpTime*.

### ***Generic MIB Object Groups***

[Table 209](#) shows the eight generic SNMP groups defined in RFC 1158 along with their codes, names and numbers.

**Table 209: SNMP Generic MIB Object Groups (Page 1 of 2)**

Group Name	Group Code	Group Number	Full Group Identifier	Description
<i>system</i>	<i>sys</i>	1	1.3.6.1.2.1.1	General objects of relevance to all or most devices. For example, a general description of the device is an object in this group, as is the identifier of the object. Later MIB versions greatly expanded the number of variables in this group.
<i>Interfaces</i>	<i>if</i>	2	1.3.6.1.2.1.2	Objects related to the IP interfaces between this device and the internetwork; recall that <a href="#">a regular host normally has one interface while a router has two or more</a> .
<i>at (address translation)</i>	<i>at</i>	3	1.3.6.1.2.1.3	Objects used for IP address translation. (No longer used.)

**Table 209: SNMP Generic MIB Object Groups (Page 2 of 2)**

Group Name	Group Code	Group Number	Full Group Identifier	Description
<i>ip</i>	<i>ip</i>	4	1.3.6.1.2.1.4	Objects related to the <a href="#">IP layer</a> of the device as a whole (as opposed to interface-specific information in the <i>if</i> group.)
<i>icmp</i>	<i>icmp</i>	5	1.3.6.1.2.1.5	Objects related to the operation of the <a href="#">Internet Control Message Protocol</a> .
<i>tcp</i>	<i>tcp</i>	6	1.3.6.1.2.1.6	Objects related to the operation of the <a href="#">Transmission Control Protocol</a> .
<i>udp</i>	<i>udp</i>	7	1.3.6.1.2.1.7	Objects related to the operation of the <a href="#">User Datagram Protocol</a> .
<i>egp</i>	<i>egp</i>	8	1.3.6.1.2.1.8	Objects related to the operation of the <a href="#">Exterior Gateway Protocol</a> .
<i>cmot</i>	<i>cmot</i>	9	1.3.6.1.2.1.9	Objects related to running the CMIP protocol over TCP (historical, not used.)
<i>transmission</i>	<i>trans</i>	10	1.3.6.1.2.1.10	Objects related to the specific method of information transmission used by each interface on the system.
<i>snmp</i>	<i>snmp</i>	11	1.3.6.1.2.1.11	Objects used to manage SNMP itself.

All of the groups in this table are fairly generic, and with the exception of the one about EGP, apply to pretty much every TCP/IP system using SNMP. The first five groups and the last one are “mandatory” for all systems; the others are used only by devices that use the indicated protocols or functions. The mention of [EGP](#), a routing protocol now considered obsolete, shows the age of this list.

### **MIB Modules**

What's most conspicuous about [Table 209](#) are the groups that are *not* in it. There are no groups for most of the other TCP/IP protocols, nor any for variables that might be needed for specific hardware types. For example, most hosts will have a network card in them using a layer two protocol like Ethernet or Token Ring; how does a manager check or control the operation of this hardware? What about newer routing protocols like [OSPF](#) or [BGP](#)? How about objects related to running the [Domain Name System](#)?

Updating the MIB document constantly would have been impractical. Instead, in SNMPv2, the Management Information Base was changed from a single document to a group of documents. The basic organization into groups of objects was retained, but instead of all groups being in the same standard, they are divided into multiple standards. A method was also defined for how to create *MIB modules* that describe new groups of objects specific to a particular technology. A list of these modules is maintained by [IANA](#), the organization that maintains all of these sorts of numbers.

**On The Web:** The current list of SNMP MIB modules can be found here: <http://www.iana.org/assignments/smi-numbers>

The use of MIB modules makes putting SNMP support into a device somewhat like “going shopping”. The basic groups common to all devices are incorporated into each device, and then other modules/groups are used as needed. Table 210 provides a brief selection of MIB modules to give you an idea of what is out there, also showing the module's group number (within the 1.3.6.1.2.1 name subtree):

**Table 210: Some Common SNMP MIB Modules**

MIB Module Name	Group Number	Description
ospf	14	Objects related to the <a href="#">Open Shortest Path First</a> protocol.
bgp	15	Objects related to the <a href="#">Border Gateway Protocol</a> .
rmon	16	Objects used as part of <a href="#">Remote Network Monitoring (RMON)</a> , which we'll examine later in this chapter.
snmpDot3 RptrMgt	22	Objects related to IEEE 802.3 (Ethernet) repeaters.
rip-2	23	Objects used as part of version 2 of the <a href="#">Routing Information Protocol</a> .
snmpDot3 MauMgt	26	Objects related to IEEE 802.3 (Ethernet) medium attachment units.
etherMIB	35	Ethernet-like generic objects.
mipMIB	44	<a href="#">Mobile IP</a> objects.
ipMIB	48	Internet Protocol objects for SNMPv2.
tcpMIB	49	<a href="#">Transmission Control Protocol</a> objects for SNMPv2.
udpMIB	50	<a href="#">User Datagram Protocol</a> objects for SNMPv2.

There are of course, many, many more. The last three entries in the table above might seem a bit confusing, since there are already groups for IP, TCP and UDP in the first table above. The reason for these is that when the new modular architecture for MIB objects was created in SNMPv2, the definition of objects for the individual protocols that was part of the “one document” in SNMPv1 was separated out into individual MIB documents for consistency, and to allow them to be updated independently. In fact, the “base” SNMPv2 and SNMPv3 MIB documents now only define objects in the *system* and *snmp* groups.

**Key Concept:** MIB objects created early in SNMP's history were organized into *MIB object groups* that reside within *mib(1)* subtree, starting with identifier code 1.3.6.1.2.1. As the popularity of TCP/IP grew, it became impractical to centrally-define all MIB objects, so sets of objects particular to different hardware devices are now specified in *MIB modules*.

---

### ***MIB Module Format***

The format for MIB modules is described in the Structure of Management Information standard, version 2 (SMIv2). The document specifies how modules are to be defined in a way very similar to how objects themselves are defined, by listing a set of characteristics that must be included in each module description. The module fields are:

- ☉ **Module Name:** The name of the module. Remember that modules are really objects, syntactically, so like regular objects they have a textual object descriptor (like *tcpMIB*) and an object identifier (in the case of *tcpMIB*, the number 50).
- ☉ **Last Updated:** The date and time that the module was last revised.
- ☉ **Organization:** The name of the organization that is managing the development of the module.
- ☉ **Contact Information:** The name, address, telephone number and e-mail address of the "point person" for this module.
- ☉ **Description:** A description of the module.
- ☉ **Revision and Revision Description:** One *Revision* entry is placed for each revision of the module to show its history. Each entry has a description associated with it.

After the definition of the module itself, the objects in the module are described. For an example, see RFC 2012, which defines the SNMPv2 TCP MIB we've been discussing in this example.

---

## **TCP/IP Simple Network Management Protocol (SNMP) Protocol**

The overall network management solution for TCP/IP networks is the Internet Standard Management Framework. In the last two subsections we have taken a look at the framework as a whole, and also discussed the two components that define the management information transmitted between TCP/IP devices to accomplish network management. The third major part of the SNMP Framework is the actual *Simple Network Management Protocol*, *SNMP*, which is responsible for moving management information between devices.

In this section, I describe the concepts and operation of the actual SNMP protocol. I begin with a brief overview and history of the protocol, discussing it in general terms. I then have two subsections that describe SNMP's operation in detail. The first covers the different operations performed by the protocol and how they work. The second discusses protocol messaging and message formats.

**Background Information:** Please be sure that you have a solid understanding of [SNMP Management Information Bases \(MIBs\)](#) and [MIB objects](#) before proceeding in this section.

---

---

## **SNMP Protocol Overview, History and General Concepts**

I have described the [TCP/IP Internet Standard Management Framework \(SNMP Framework\)](#) as being *information-oriented*. A specific decision was made in the design of the SNMP Framework to decouple the management information conveyed between SNMP agents and SNMP managers from the protocol used to carry that information. This provides numerous benefits to the technology as a whole, chief among them flexibility and modularity.

In this model, the operation of the management protocol is not defined in terms of specific commands made to check the status of a device or change how it operates. Instead, the protocol is defined in terms of management information variables called *objects*, and a communication protocol that allows these objects to be either examined or changed by a network administrator. I describe this concept thoroughly in [the topic that overviews the SNMP Management Information Base \(MIB\) and the Structure of Management Information \(SMI\)](#).

The MIB and SMI spell out the rules for how MIB objects are created and described. These MIB objects describe the types of information that can be read from the device or written to the device. The last piece of the puzzle is the actual protocol that is responsible for these “read” and “write” operations. This is the *Simple Network Management Protocol* itself, which I give the somewhat redundant name *SNMP Protocol* to differentiate it from the SNMP Framework.

The result of the separation of the protocol from the management information it carries is that the protocol itself becomes significantly reduced in complexity. Instead of the SNMP Protocol having to define dozens or even hundreds of operations that specify particular network management functions, it only has to deal with the transmission of MIB object information between SNMP agents and managers. The SNMP Protocol does not itself pay attention to what is in these objects; it is merely concerned with moving them around. In some ways, the SNMP Protocol is the only really simple part of SNMP!

### ***Early Development of SNMPv1***

The history of the SNMP Protocol goes back to the predecessor of the SNMP Framework, the *Simple Gateway Monitoring Protocol (SGMP)*, which was defined in RFC 1028 in 1987. SGMP was designed as an interim solution for network management while larger issues were being explored as I explained in [the overview of the SNMP Framework](#). However, this standard is where many of the basic design concepts underlying the modern SNMP Protocol can be found.

The SGMP standard specified the basic design model used in SNMP, by describing the SGMP protocol in terms of only retrievals of, or alterations to, variables stored on an Internet gateway (router). The standard also outlines the small number of protocol operations that are still the basis for SNMP's operation today.

---

The first version of the SNMP Framework, SNMPv1, included the first formal definition of the SNMP Protocol, in RFC 1067 (later revised by RFCs 1098 and 1157). This standard refines the protocol operations given in the SGMP document. It makes the operation of the SNMP Protocol fit into the overall SNMP Framework, working with formally-defined MIB objects.

### ***SNMPv2 and the Division of SNMP into Protocol Operations and Transport Mappings***

When SNMPv2 was created, the single document describing the SNMP Protocol was split into two standards, to make the protocol more modular and better reflective of the layers used in internetworks. This division has been maintained in SNMPv3 as well. The two types of documents specify the following:

- ☛ **Protocol Operations:** The first document of the pair describes the actual mechanics by which MIB objects are moved between SNMP devices using particular SNMP message types. In SNMPv3 it is RFC 3416, *Version 2 of the Protocol Operations for the Simple Network Management Protocol (SNMP)*. When people talk about just “the SNMP standard”, this is the document they usually mean.
- ☛ **Transport Mappings:** The second document details how the SNMP protocol operations described in the first standard above can be transported over a variety of different protocol suites. By using the correct mapping, SNMP operations can be carried out using lower-layer technologies other than IP. This standard is represented in SNMPv3 by RFC 3417, *Transport Mappings for the Simple Network Management Protocol (SNMP)*.

I discuss transport mappings in a little more detail in [the topic on SNMP messaging](#), but since IP/UDP is by far the most common transport mechanism, there isn't a great deal to say about that aspect of the SNMP Protocol. The focus of most of our look at SNMP will concentrate on SNMP protocol operations: what messages are used, how they are structured and how they are exchanged. In examining these messages we will see the two main ways that information exchanges occur in SNMP (by polling and by interrupt) and also discover how the SNMP Protocol works with MIB objects.

**Key Concept:** The actual mechanism used to communicate management information between network management stations and managed devices is called the *Simple Network Management Protocol*, which may be called the *SNMP Protocol* to differentiate it from the SNMP Framework. It consists of a number of *protocol operations* that describe the actual message exchanges that take place between devices, and a set of *transport mappings* that define how these messages are carried over various types of internetworks. The Internet Protocol is the most common transport mapping used for SNMP.

---

---

## **SNMP Protocol Operations**

The Simple Network Management Protocol (SNMP) is the protocol responsible for allowing network management stations on a TCP/IP internetwork to perform management tasks with managed devices. The core of the protocol consists of a set of *protocol operations* that allow management information to be exchanged between SNMP agents and managers. Having previously examined the generalities of SNMP and what MIB objects are, we can now get down to the “nitty gritty” of how management information is actually communicated using SNMP. Yes, finally you get to actually see how SNMP “works”.

In this section I provide a detailed description of the operations performed by the SNMP Protocol. I begin with a general description of how SNMP operates and the two basic methods devices use to communicate; I also describe SNMP's message classes. I then provide topics that describe in detail each of the basic operations performed in SNMP and the messages used for those purposes: basic request/response, table traversal, object modification, and notification. I conclude with a discussion of SNMP security issues and a summary of the security methods in each of the SNMP versions.

Note that the number and types of protocol operations in SNMP changed between SNMPv1 and SNMPv2. The operations defined in SNMPv2 have been carried forward into the newest version, SNMPv3. Most of the discussion focuses on SNMPv3 as the newest implementation, while mentioning what differences there are between it and the original and still widely-used SNMPv1.

### **SNMP Protocol General Operation, Communication Methods and Message Classes**

The main function of the SNMP Protocol is to allow management information, in the form of Management Information Base (MIB) objects, to be communicated between SNMP-capable devices. The *protocol operations* of the SNMP Protocol are what describe how this communication is performed. Before looking at these operations individually in detail, it is instructive to take an overall look at information exchange methods used in SNMP.

#### ***SNMP Communication Methods***

For SNMP to be useful in enabling the management of a network, it must allow a network administrator using a [network management station \(NMS\)](#) to easily check the status of SNMP agents in managed devices. In data communications, there are two general techniques that are used in a situation where one entity needs to be kept informed about activity or occurrences on another:

- 🕒 **Poll-Driven:** This term refers to the general technique of having the one who wants the information ask for it; just like someone might conduct a political poll. In SNMP, the NMS would poll SNMP agents for information. A common “real life” example of polling is the model used by the regular mail service; every day you go to check your mailbox to see if you have any mail.

- 
- ☎ **Interrupt-Driven:** This term refers to having a device with information that another needs to know decide to send the information of its own “volition”. In SNMP, this would refer to an SNMP agent sending information to an NMS without being asked. This is the model used by that most famous of “interrupters”, the telephone.

Which is “better”? My quotation marks give me away again. The usual answer applies here: neither is better nor worse universally, which is why both options exist. Due to the obvious strengths and weaknesses of these models, The SNMP Protocol is designed to use both. Polling is used for the periodic gathering of routine information, such as checking the usage statistics and general status of a device. Interrupts are used in the form of *traps* that a network administrator can set on a managed device. These traps cause an SNMP agent to interrupt an NMS when an event of import occurs.

**Key Concept:** SNMP uses two basic methods for exchanging management information. Routine communication uses a *poll-driven* technique, where the network management station requests information from managed nodes. An *interrupt-driven* model is also supported: in situations where a managed device needs to tell a management station immediately about an occurrence, it can send a *trap* message without waiting for a request from the management station.

---

## **SNMP Messages and Protocol Data Units (PDUs)**

The actual communication of information in the SNMP Protocol is performed in a manner similar to most other protocols, through the exchange of SNMP messages. These messages are sometimes called *protocol data units* or *PDUs*. This is a term you may have heard used in other protocols, and is also part of [the formal definition of data encapsulation in the OSI Reference Model](#). A message is, of course, a “data unit” used by the “protocol”. SNMP messages all have “-PDU” at the ends of their names to identify them.

Some consider “protocol data unit” to be analogous to the military using “oblong metallic-headed manually-operated fastener acceleration device” to refer to a hammer. To be fair though, strictly speaking, in SMNP a PDU and a message are not exactly the same. The PDU is the higher-layer data that SNMP encapsulates, as described by the OSI model. The SNMP message format is a *wrapper* that encapsulates a PDU along with header fields, as I describe in [the section on SNMP messaging](#). However, the point of a message is to send a PDU, so the two are “close enough”, and the terms are sometimes used interchangeably.

## **SNMP PDU Classes**

SNMPv1 originally defined six PDUs. The number of PDUs was expanded and some changes made to their name and use in SNMPv2 and SNMPv3. The current SNMP Framework categorizes the PDUs into different *classes*. These classes describe both the function of each message type and the kind of communication they use to perform their task (polling versus interrupting).

---

[Table 211](#) shows the main SNMPv2/SNMPv3 PDU classes, describes them, and shows which PDUs are in each class in SNMPv2/SNMPv3. These classes were not used in SNMPv1 but for clarity I also show which messages from SNMPv1 fall into the classes conceptually:

**Table 211: SNMP PDU (Message) Classes**

SNMPv3 PDU Class	Description	SNMPv1 PDUs	SNMPv2/SNMPv3 PDUs
<b>Read</b>	Messages that read management information from a managed device using a polling mechanism.	<i>GetRequest-PDU</i> , <i>GetNextRequest-PDU</i>	<i>GetRequest-PDU</i> , <i>GetNextRequest-PDU</i> , <i>GetBulkRequest-PDU</i>
<b>Write</b>	Messages that change management information on a managed device to affect the device's operation.	<i>SetRequest-PDU</i>	<i>SetRequest-PDU</i>
<b>Response</b>	Messages sent in response to a previous request.	<i>GetResponse-PDU</i>	<i>Response-PDU</i>
<b>Notification</b>	Messages used by a device to send an interrupt-like notification to an SNMP manager.	<i>Trap-PDU</i>	<i>Trapv2-PDU</i> , <i>InformRequest-PDU</i>

The *GetBulkRequest-PDU* and *InformRequest-PDU* messages are new in SNMPv2/v3. The *GetResponse-PDU* message was renamed just *Response-PDU* (since it is in fact a response and not a message that “gets” anything), and the new *Trapv2-PDU* replaces *Trap-PDU*.

There are three other “special” classes defined by the current SNMP Framework that are of less interest to us because they don't define actively-used messages, but which I should mention for completeness. The *Internal* class contains a special message called *Report-PDU* defined for internal SNMP communication. The SNMP standards also provide two classes called *Confirmed* and *Unconfirmed*, used to categorize the messages in my table above based on whether or not they are acknowledged. The *Report-PDU*, *Trapv2-PDU*, and *Response-PDU* messages are considered *Unconfirmed* and the rest are *Confirmed*.

The next few topics will show how the major message types in the four main classes are used. Note that in general terms, all protocol exchanges in SNMP are described in terms of one [SNMP entity](#) sending messages to another. Most commonly, the entity sending requests is an SNMP manager and the one responding an SNMP agent, except for traps, which are sent by agents. For greater clarity, I try to use these more specific terms (manager or agent) when possible, rather than just “entity”.

**Key Concept:** SNMP messages consist of a set of fields wrapped around a data element called a *protocol data unit* or *PDU*. In some cases, the terms “message” and “PDU” are used interchangeably, though they are technically not the same. SNMP PDUs are arranged into *classes* based on their function.

---

---

## **SNMP Protocol Basic Request/Response Information Poll Using GetRequest and (Get)Response Messages**

The obvious place to begin our detailed look at SNMP protocol operations is with the simplest type of information exchange. This would be a simple *poll* operation to read one or more management information variables, used by one **SNMP entity** (typically an SNMP manager) to request or read information from another entity (normally an SNMP agent on a managed device). SNMP implements this as a simple two-message request/response protocol exchange, similar the request/reply processes found in so many TCP/IP protocols.

This information request process typically begins with the user of an application wanting to check the status of a device or look at information about it. As we've seen, all this information is stored on the device in the form of **MIB objects**. The communication, therefore, takes the form of a request for particular MIB objects and a reply from the device containing those objects' values. In simplified form, the steps in the process are as follows (and as shown in [Figure 274](#)):

1. **SNMP Manager Creates *GetRequest-PDU*:** Based on the information required by the application and user, the SNMP software on the network management station creates a *GetRequest-PDU* message. It contains the names of the MIB objects whose values the application wants to retrieve.
2. **SNMP Manager Sends *GetRequest-PDU*:** The SNMP manager sends the PDU to the device that is being polled.
3. **SNMP Agent Receives and Processes *GetRequest-PDU*:** The SNMP agent receives and processes the request. It looks at the list of MIB object names contained in the message and checks to see if they are valid (ones the agent actually implements). It looks up the value of each variable that was correctly specified.
4. **SNMP Agent Creates *Response-PDU*:** The agent creates a *Response-PDU* to send back to the SNMP Manager. This message contains the values of the MIB objects requested and/or error codes to indicate any problems with the request, such as an invalid object name.
5. **SNMP Agent Sends *Response-PDU*:** The agent sends the response back to the SNMP Manager.
6. **SNMP Manager Processes *Response-PDU*:** The manager processes the information in the *Response-PDU* received from the agent.

**Key Concept:** The most basic type of communication in SNMP is an *information poll*, which allows a network management station to read one or more MIB objects from a managed node using a simple request/reply message exchange.

---

The *Response-PDU* message is called *GetResponse-PDU* in SNMPv1. Presumably, this name was chosen from the fact that it was a response to a get operation, to make the names *GetRequest-PDU* and *GetResponse-PDU* somewhat symmetric. The problem is that this name is confusing, for two reasons. First, it sounds to some people like the purpose of the PDU is to “get a response”. Second, the *GetResponse-PDU* was also

**Figure 274: SNMP Information Poll Process**

The basic SNMP information polling process involves a simple exchange of a *GetRequest-PDU* sent by an SNMP manager and a *Response-PDU* returned by an SNMP agent.

defined as the response message for operations other than “gets”, including the reply message for *SetRequest-PDU*. Having a “GetResponse” message be sent in reply to a “SetRequest” is disconcerting; the new name is more generic and avoids these problems.

### **SNMP Protocol Table Traversal Using GetNextRequest and GetBulkRequest Messages**

The *GetRequest-PDU* message we examined [last topic](#) is the one used by applications to request values for regular, single variables in an SNMP managed object's management information base. As I mentioned in [the topic describing MIB objects](#), however, the Structure of Management Information (SMI) also allows a management information base to contain *tabular data*.

MIB tables are a useful way for a device to store and organize a set of related data items. It would be rather inefficient to try to structure these items just as collections of regular objects. For example, a device may have multiple IP addresses. It would be inefficient to define one MIB object called *ipAddr1*, and another called *ipAddr2*, and so on to store IP address information. Instead, an object called *ipAddrTable* is defined in the original SNMPv1 MIB, which specifies a table containing one or more entries called *ipAddrEntry*. Each entry contains the IP address and subnet mask for one of the interfaces of the device.

---

## SNMPv1 Table Traversal Using *GetNextRequest*

There needs to be a way to let an SNMP manager may wish to read the contents of these tables from a device. This can be done using the regular *GetRequest-PDU* message, by specifying each entry in the table one after the other. However, this is somewhat crude, and it leaves a problem: the SNMP manager may not know how many entries are in the table, and therefore, how many entries it should request.

The problem of *table traversal* was addressed in SNMPv1 through the creation of a new message type called *GetNextRequest-PDU*. You can think of this as a “relative” version of the regular *GetRequest-PDU*. The *GetNextRequest-PDU* contains the name of a tabular variable, as well as a particular entry in the table. The device receiving the *GetNextRequest-PDU* uses this to look up the next value in the table and return it in a *GetResponse-PDU* message.

The actual protocol exchange is about the same as [that described in the previous topic](#): a request is sent by the SNMP manager and a reply returned by the SNMP agent. The difference is that instead of the SNMP agent returning the value for the variable specified, it returns the value of the **next** variable in the table. This is then used as the value for the next request, and so on, until the last entry in the table is reached. Once this happens and a *GetNextRequest-PDU* is sent that contains this last entry, the responding device indicates this by returning the MIB object that conceptually follows the table in the implementation of the management information base. This signals to the SNMP manager that the table has been fully traversed.

**Key Concept:** The SNMP *GetNextRequest-PDU* message allows a network management station to request a series of consecutive variables in a management information base. This is most commonly used to allow tabular data to be more easily retrieved without requiring that each variable in the table be individually specified.

---

## SNMPv2/v3 Table Traversal Using *GetBulkRequest*

The *GetNextRequest-PDU* message is functional, but while it is more elegant than using regular *GetRequest-PDU* messages, it is not any more efficient—each entry in the table must still be requested one at a time. This means that retrieving the information in a table takes a long time, and also results in a great deal of traffic being generated due to the number of requests and replies that must be sent.

To make table traversal easier and more conservative of network resources, SNMPv2 introduced a new message type called *GetBulkRequest-PDU*. You can probably surmise the idea here from the name. Instead of specifying a particular MIB object to get or to “get next”, a *GetBulkRequest-PDU* allows an SNMP manager to send a single request that results in a number of entries in a table being returned in a *Response-PDU* message.

---

The *GetBulkRequest-PDU* is designed to allow both regular variable and tables to be retrieved in a single request. The PDU includes a list of objects, just as in a *GetRequest-PDU* or *GetNextRequest-PDU*. The list is organized so that regular objects appear first and table objects come afterwards. Two special parameters are included in the request, called *Non Repeaters* and *Max Repetitions*. The first of these specifies the number of non-repeating, regular objects to be retrieved; this is the number of regular objects at the start of the object list. The second specifies the number of iterations, or entries, to read for the remaining tabular objects.

For example, suppose an SNMP manager wanted to request 4 regular variables and 3 entries from a table. The *GetNextRequest-PDU* would contain five MIB object specifications, with the table last. The *Non Repeaters* field would be set to 4, and the *Max Repetitions* field set to 3.

The original method of traversing tables using *GetRequest-PDU* and *GetNextRequest-PDU* from SNMPv1 was retained in SNMPv2 and SNMPv3 when they were developed. However, the introduction of the more efficient *GetBulkRequest-PDU* means that *GetNextRequest-PDU* is not as important as it was in SNMPv1. Bear in mind, however, that using *GetBulkRequest-PDU* does require that the requesting entity know how many entries to ask for. So, some “trial and error” or multiple requests may be required to get a whole table if the number of entries is not known.

**Key Concept:** To improve the efficiency of table traversal, SNMPv2 introduced the *GetBulkRequest-PDU* message, which allows a network management station to request a sequence of MIB objects from a table using a single request to a managed node.

---

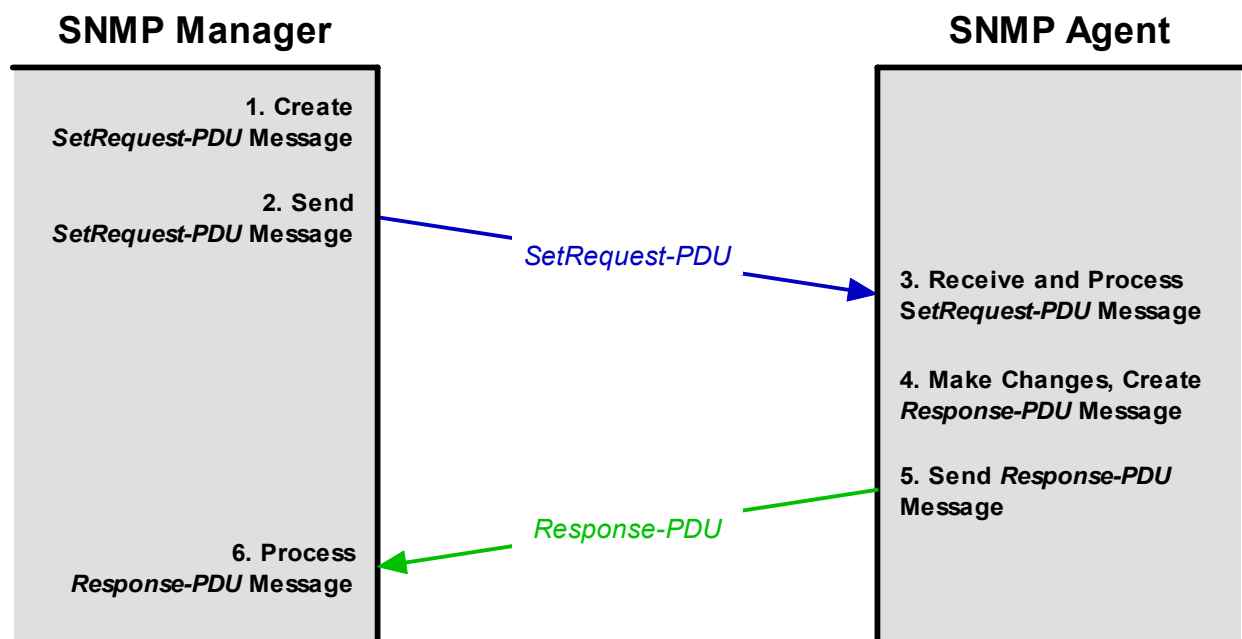

## **SNMP Protocol Object Modification Using SetRequest Messages**

The *GetRequest-PDU*, *GetNextRequest-PDU*, and *GetBulkRequest-PDU* messages are the three members of the SNMP “Read” [class of PDUs](#)—they are used to let an SNMP manager read MIB objects from an MIB agent. The opposite function is represented by the SNMP “Write” class, which contains a single member: the SNMP *SetRequest-PDU* message.

The use of this PDU is fairly obvious; where one of the three *Get* PDUs specifies a variable whose value is to be retrieved, the *SetRequest-PDU* message contains a specification for variables whose values are to be modified by the network administrator. Remember that [SNMP does not include specific commands](#) to let a network administrator control a managed device. This is in fact the “control method”, by setting variables that affect the operation of the managed device.

The set process is the complement of the get process; the same basic idea, pretty much, but a reversal in how the object values “travel” and what is done with them. The process follows these steps (see [Figure 275](#)):

1. **SNMP Manager Creates *SetRequest-PDU*:** Based on the information changes specified by the user through the SNMP application, the SNMP software on the network management station creates a *SetRequest-PDU* message. It contains a set of MIB object names and the values to which they are to be set.
2. **SNMP Manager Sends *SetRequest-PDU*:** The SNMP manager sends the PDU to the device being controlled.
3. **SNMP Agent Receives and Processes *SetRequest-PDU*:** The SNMP agent receives and processes the set request. It examines each object in the request along with the value to which the object is to be set, and determines if the request should or should not be honored.
4. **SNMP Agent Makes Changes and Creates *Response-PDU*:** Assuming that the information in the request was correct (and any security provisions have been satisfied), the SNMP agent makes changes to its internal variables. The agent creates a *Response-PDU* to send back to the SNMP Manager, which either indicates that the request succeeded, or contains error codes to indicate any problems with the request found during processing.
5. **SNMP Agent Sends *Response-PDU*:** The agent sends the response back to the SNMP Manager.
6. **SNMP Manager Processes *Response-PDU*:** The manager processes the information in the *Response-PDU* to see the results of the set.

**Figure 275: SNMP Object Modification Process**

The communication process for setting a MIB object value is very similar to that used for reading one. The main difference is that, of course, the object values are sent from the SNMP Manager to the SNMP Agent, carried in the *SetRequest-PDU* message.

---

## Verification of Object Modification Requests

Obviously, telling a device to change a variable's value is a more significant request than just asking the device to read the value. For this reason, the managed device must very carefully analyze and verify the information in the request to ensure that the request is valid. The checks performed include:

- ☉ Verifying the names of the objects to be changed.
- ☉ Verifying that the objects are allowed to be modified (based on their *Access* or *Max-Access* [object characteristic](#).)
- ☉ Checking the value included in the request to ensure that its type and size are valid for the object to be changed.

This is also a place where [general protocol security issues](#) become more important.

**Key Concept:** SNMP network management stations control the operation of managed devices by changing MIB objects on those devices. This is done using the *SetRequest-PDU* message, which specifies the objects to be modified and their values.

---

## SNMP Protocol Information Notification Using Trap(v2) and InformRequest Messages

The [first topic in this section](#) introduced the two basic methods of communicating information between SNMP devices: using polls or interrupts. All of the message types and exchanges we have examined thus far in this section have been poll-driven: they consist of an SNMP manager making a specific request that results in action being taken, and a response being generated by an SNMP agent.

### ***The Need for Traps in SNMP***

Polling is ideal for the exchange of routine information that needs to be gathered on a regular basis. For example, the regular *Get* requests could be used to verify the settings on a device, examine error counts over a period of time, or check its up-time or use statistics. And obviously, polling is the only real method for performing a *Set* operation, where data is changed.

But polling is not well-suited for important information that needs to be communicated quickly. The reason is that poll-driven communication is always initiated by the recipient of the information: the SNMP manager. If something significant occurs on a managed device that the manager wasn't expecting, the manager won't find out about it unless it specifically asks to see the variable that has changed. This means that important variables would need to be checked all the time by the SNMP manager, which is highly inefficient.

---

In the real world, using polling to implement situations where critical information needs to be sent would be like having the emergency response service in your town call everyone every hour to find out if they needed an ambulance or fire truck. Similarly, in SNMP, a mechanism was needed to let an SNMP agent initiate the communication of information. This capability was originally made part of the SNMPv1 protocol through the inclusion of the *Trap-PDU* message type.

In computer science, a *trap* is simply a set of conditions that a device monitors continuously. If the appropriate conditions occur, the trap is *triggered* and causes some sort of action to occur. In SNMP, traps are programmed into SNMP agents, and when they are triggered, an SNMP *Trap-PDU* message is sent to an SNMP Manager to inform it of the occurrence. Examples of traps in the SNMPv1 specification include ones that trigger in the event of a communication link failure, restart of the device, or an authentication problem.

### ***Use of SNMP Trap and Trapv2 Messages***

The communication in the case of a trap is trivial; the SNMP Agent sends the trap and the SNMP Manager is thereby considered “informed” of what happened. That's pretty much it. These are “Unconfirmed” messages and no reply is made back to the SNMP Agent. The triggering of the trap may lead the network administrator to take follow-up action at the device that sent the trap.

The designer of a particular management information base must determine what traps to create for a particular group of objects. The implementation must specify the conditions under which the traps will trigger, and also the destination to which the *Trap-PDU* message will be sent when this occurs. In SNMPv2, the original trap notification message was retained in the form of the *Trapv2-PDU* message.

### ***Use of the SNMPv2 InformRequest Message***

SNMPv2 also incorporates a second notification message type: *InformRequest-PDU*. This type of message is not the same as a trap, but it is related to traps for two reasons. First, both message types are used to communicate information without the recipient initiating the process, and second, the two messages are sometimes used in conjunction.

The purpose of the *InformRequest-PDU* is actually to facilitate the communication of information between network management stations. The SNMP Manager on one NMS can choose to “inform” another of some piece of information by sending an *InformRequest-PDU* to that other SNMP Manager. The receiving manager then replies back with a *Response-PDU* to the one that sent the *InformRequest-PDU*, confirming receipt of the inform message.

A common way that this message is used is to “spread the news” when a trap occurs. Suppose a device experiences a power failure, which results in a *Trapv2-PDU* being sent to NMS #1. The network administrator may want to set up NMS #1 so that receipt of particular traps causes the information in the trap to be “forwarded” to another. The *InformRequest-PDU* would be used to carry that information from NMS #1 to say, NMS #2.

**Key Concept:** SNMP managed devices can inform a network management station of an important occurrence by sending it a *Trap-PDU* or *Trapv2-PDU* message. Network administrators determine the circumstances under which one of these messages should be transmitted. SNMPv2 adds to this capability the *InformRequest-PDU* message, which can be used to propagate information about an event between management stations.

---

## **SNMP Protocol Security Issues and Methods**

In [my description of the various SNMP versions](#), it's possible that I may have been a bit harsh on those who worked on SNMP during the 1990s. The proliferation of many SNMP version 2 variants really was unfortunate, and not something we often see in the world of TCP/IP. However, now that we've seen the sort of work that SNMP does, the need for security in the protocol would seem to be clear. Given that, and given the very low level of security in the initial SNMPv1 protocol, it's understandable to some extent why a conflict over security issues arose.

### ***Why Security is Important in SNMP***

The need for security in SNMP is obvious because the MIB objects being communicated contain critical information about network devices. We don't want just anyone “snooping” into our network to find out our IP addresses, or how long our machines have been running, or whether our links are down, or pretty much anything else. When it comes to [object write operations](#) using *SetRequest-PDU*, the concerns are magnified even more: we **definitely** don't want strangers being able to control or interfere with our managed devices by issuing bogus commands to change MIB objects that control device operation!

### ***SNMPv1 Security***

Unfortunately, the security incorporated into SNMPv1 was extremely limited; it really took the form of only one policy and one simple technology:

- ☉ **“Weak Objects”:** SNMP was created with the mindset that the MIB objects used in the protocol would be relatively *weak*. This means that the objects are designed so that any problems in working with them result in minimal damage. The policy of the designers of SNMP was that MIB objects that are normally read should not contain critical information, and objects that are written should not control critical functions.

So, a read-only MIB object containing a description of a machine is fine, but one containing the administrative password is **not**. Similarly, a read-write MIB object that controls when the computer next reboots is acceptable, but one that tells the object to reformat its hard disk is (definitely) not!

- 
- 🕒 **Community Strings:** All the devices in an SNMP network managed by a particular set of network management stations are considered to be in a “community”. Each SNMPv1 message sent between members of the community is identified by a *community string* that appears in a field in the message header. This string is like a simple password; any messages received with the wrong string will be rejected by the recipient.

These security features are better than nothing, but not much. The use of weak objects is comparable to a policy that says not to leave your car in front of the convenience store with the doors unlocked and the key in the ignition—it is basically saying “don't ask for trouble”. This is wise, but it's not a complete security solution. The community strings protect against obvious tampering in the form of unauthorized messages. However, the strings are sent in plain open text and can easily be discovered and then used to compromise the “community”. So this is like locking your doors when parking your car—it protects against the casual thief but not a pro.

Of course, for some people, not leaving their car running and locking the doors when they park are enough security, and SNMPv1's security was also sufficient for some users of SNMP. But in newer, larger internetworks, especially ones spanning large distances or using public carriers, SNMPv1 wasn't up to the task. This is why all that fun stuff occurred with SNMP version 2.

### **SNMPv2/v3 Security Methods**

During the “evolution” of SNMPv2 variants, and eventually the creation of SNMPv3, several new security models were created to improve upon SNMPv1's security:

- 🕒 **Party-Based Security Model:** This was the security model for the original SNMPv2 standard, now called *SNMPv2p*. A logical entity called a *party* is defined for communication that specifies a particular authentication protocol and a privacy (encryption) protocol. The information is used to verify that a particular request is authentic, and to ensure that the sender and receiver agree on how to encrypt and decrypt data.
- 🕒 **User-Based Security Model (USM):** This was developed in the SNMPv2u variant and used in SNMPv2\* (SNMPv2 asterisk); it eventually was adopted in SNMPv3. The idea here is to move away from tying security to the machines and instead use more traditional security based on access rights of a user of a machine. A variety of authentication and encryption protocols can be used to ensure access rights are respected and to protect message privacy. The method relies on time stamps, clock synchronization and other techniques to protect against certain types of attacks.
- 🕒 **View-Based Access Control Model (VACM):** VACM is part of SNMPv3, and defines a method where more fine control can be placed on access to objects on a device. A *view* specifies a particular set of MIB objects that can be accessed by a particular group in a particular context. By controlling these views an administrator can manage what information is accessed by whom.

---

These descriptions are “grossly simplified”, to say the least. Security is probably the most complicated subtopic in networking, and describing these methods in detail would require dozens and dozens of topics. You can refer to the relevant standards if you want more information, though unless you are well-read on security topics, you will likely not be able to make heads or tails out of what is written in them.

### ***Use of SNMP Security Methods***

Party-based security pretty much died with SNMPv2p; USM and VACM are part of SNMPv3 and provide enhanced security for those who need it (though again, it's interesting to note how many networks continue to use SNMPv1, security warts and all.) SNMPv3 took another important security-related step in redefining the SNMP architecture to seamlessly support multiple security models. This enables different implementations to choose the security model that is best for them. USM is the default model in SNMPv3.

---

## **SNMP Protocol Messaging and Message Formats**

As we saw extensively in [the previous section](#), the communication of management information is accomplished through the exchange of SNMP messages that contain *protocol data units (PDUs)*. Like the messages of most TCP/IP protocols, these PDUs are designed to use a particular field format, and are created, addressed and transported according to specific protocol rules. SNMP messages include fields that control the operation of the protocol, and carry a “payload” of management information in the form of [Management Information Base \(MIB\) objects](#).

In this section I describe the details of how messaging is accomplished in the SNMP Protocol. I begin with a general discussion of issues related to message generation, addressing and transport, and a description of how retransmission of messages is handled when necessary. I discuss the way fields are defined in SNMP messages and describe their general format, explaining the difference between the overall message and the PDU it contains. I then examine the message format used in all of the important SNMP versions, showing the structure of each message type and the fields used.

### **SNMP Protocol Message Generation, Addressing, Transport and Retransmission**

The [section on SNMP protocol operations](#) described the way that SNMP messages are employed to communicate network management information. Those discussions focused primarily on the logical processes by which different tasks are accomplished using these messages. Let's now take a closer look at the lower-level details of exactly how these messages are created, addressed and sent by an SNMP device.

Message generation in SNMP is a bit different than the typical [TCP/IP client/server model](#) used for most other protocols. There aren't really any formal “clients” and “servers” in SNMP, since management information can be obtained from any device—it is distributed. Most of the message exchanges use a matched pair of request and reply messages. The [network management station \(NMS\)](#) usually *acts* as the client in these exchanges, sending a particular get or set request to an SNMP agent, which plays the role of server for the information it contains. However, SNMP agents aren't usually considered “servers” in the conventional sense of the term.

SNMP traps deviate from the normal request/reply model of message generation entirely. When a trap is triggered, an SNMP agent sends a trap message to a network management station on its own, not in reaction to receiving a request. Since trap messages are unconfirmed there is no reply. Note, however, that the SNMPv2/v3 *InformRequest-PDU* message *is* confirmed, and a response message is thus sent back to the NMS that generates it.

### ***SNMP Transport Mappings***

Once a message has been generated, it is sent using the protocols at the levels below the application layer where SNMP resides. As we saw in [the overview of the SNMP Protocol](#), the current SNMP standard set separates description of protocol operations and PDUs from

---

the methods used to actually send them. Starting with version 2, SNMP has defined several *transport mappings* that describe how SNMP PDUs can be sent over a variety of internet-working protocol suites, including TCP/IP, OSI, IPX/SPX (Novell) and Appletalk.

Many of the specific details of SNMP messaging depend on the transport mapping that is used in a particular implementation. SNMP is of course primarily used on TCP/IP internet-works, and TCP/IP is where our main interest lies in this part of the Guide. I will therefore continue this discussion by looking at transport issues when SNMP is used over IP.

### ***SNMP Message Transport Using UDP***

The standard IP transport mapping for SNMP calls for it to be carried using UDP. This decision goes back to the initial implementation of SNMPv1 (before there were distinct transport mappings.) UDP was likely chosen because it is more efficient for the simple request/reply messaging scheme SNMP uses; the many TCP features were not considered necessary and add overhead that SNMP's designers wanted to avoid. It is possible that TCP could be used to carry SNMP, defined as a different transport mapping, but I don't believe this is actually done.

Two [well-known UDP port numbers](#) are reserved for SNMP. The first is port 161, which is the “general-purpose” SNMP number. All devices that are set up to listen for SNMP requests—both agents and managers—listen on port 161. Each device receives any messages sent and replies back to the “client”, the SNMP entity that issued the request, which uses an [ephemeral port number](#) to identify the requesting process. The second UDP port number is 162, which is reserved for [SNMP traps](#). Having two numbers allows regular messages and traps to be kept separate. Normally only NMSes would listen on port 162, since agents are not recipients of traps.

The use of UDP allows SNMP information communication to be “streamlined”, since there is no need to establish a TCP connection, and since message headers are shorter and processing time slightly reduced. But the use of UDP introduces a couple of issues that SNMP implementations must be concerned with.

### **UDP Message Size Issues**

The first issue is that of message length. SNMP PDUs can carry many MIB objects, which means they could potentially be rather large. However, UDP is limited in the size of message it can carry (where [TCP is not](#)). The standards specify that SNMP entities must accept messages up to at least 484 bytes in size. They also recommend that SNMP implementations be able to accept even larger messages, up to 1472 bytes, which would correspond to the largest size message that can be encapsulated in an Ethernet frame (1,500 bytes, allowing 20 bytes for the IP header and 8 for the UDP header.)

The use of the *GetBulkRequest-PDU* message type in SNMPv2/v3 requires particular care, since it allows a single request to result in many MIB objects being sent back in a response. The *Max Repetitions* parameter must be chosen conservatively so the SNMP agent doesn't try to send an enormous message that won't fit.

---

## Dealing with Lost Transmissions

The second issue with UDP is the price we pay for its efficiency and simplicity: a lack of transport features. UDP doesn't guarantee data delivery or handle retransmissions, which means a request or reply could in theory be lost in transit. Only the device that initially sends a request can know if there was a problem with transport—it sends the request, and if it receives no reply knows either the request or response got lost. This puts the responsibility for retransmission on the part of the device that sends the request message.

NMSes sending requests to SNMP agents generally use a timer to keep track of how much time has elapsed since a request was sent. If the response doesn't arrive within a certain time interval, the request is sent again. Because of how SNMP works, having a request be received more than once accidentally will normally not cause any problems (a property known as *idempotence*). The NMS does need to employ an algorithm to ensure that it does not generate too many retransmissions and clog the network (especially since congestion might be causing the loss of its messages in the first place.)

## Handling Lost Trap Messages

Since traps are unconfirmed, there is no way for the intended recipient of a trap PDU to know if it did not arrive, nor is there any way for the sender of the trap PDU to know. This is just a weakness in the protocol; the overall reliability of TCP/IP (and the underlying networks) ensures that these messages are not lost very often.

**Key Concept:** SNMP is designed with a separately-defined set of *protocol operations* and *transport mappings*, so it can be carried over many different internetworking technologies. The most common of these is transport mechanisms is TCP/IP, where SNMP makes use of *UDP* running over IP, for its efficient and simple communication. The lack of reliability features in UDP means that requests must be tracked by the device sending them and retransmitted if no reply is received. The limited size of UDP messages restricts the amount of information that can be sent in any SNMP PDU.

---

## SNMP Message Field Definitions, General Message Format and Message Sections

To structure its messages for transport, SNMP uses a special field format, like most protocols. What's interesting about SNMP, however, is that its standards do not describe the SNMP message format using a simple list of fields the way most TCP/IP standards do. Instead, SNMP messages are defined using the same data description language (*Abstract Syntax Notation 1* or *ASN.1*) that is used to describe MIB objects.

The reason for this is that SNMP messages implement the various SNMP [protocol operations](#) with the ultimate goal of allowing MIB objects to be conveyed between SNMP entities. These MIB objects become fields within the messages to be sent. The MIB objects carried

---

in SNMP messages are defined using ASN.1 as described in the [Structure of Management Information \(SMI\)](#) standard. So it makes sense to define SNMP messages and all their fields using the same syntax.

Since all SNMP fields are defined like MIB objects, they are like objects in that they have certain characteristics. Specifically, each field has a name, and its contents are described using one of the standard [SMI data types](#). So, unlike normal message formats where each field has just a name and a length, an SNMP message format field has a name and a *syntax*, such as *Integer*, *Octet String* or *IpAddress*. The syntax of the field defines its length and how it is formatted and used.

Just as regular message formats use integers to represent specific values (for example, the numeric *Opcode* field in the [DNS message header](#), which indicates the DNS message type), this can be done in SNMP using an enumerated integer type. An example would be the *Error Status* field, where a range of integer values represents different error conditions.

The decision to define SNMP messages using ASN.1 allows the message format description to be consistent with how the objects in the format are described, which is nice. Unfortunately, it means that the field formats are very hard to determine from the standards, because they are not described in one place. Instead, the overall message format is defined as a set of components; those components contain subcomponents that may be defined elsewhere, and so on. In fact, the full message format isn't even defined in one standard; parts are spread across several standards. So you can't look in one place and see the whole message format.

Well, I should say that you can't if you use the standards, but you can if you look here. To make things easier for you, I have converted these “distributed” syntax descriptions into the same tabular field formats I use throughout the rest of this Guide. I will begin here by describing the general format used for SNMP messages, and in the next three topics explore the more specific formats used in each version of SNMP.

### **General Message Format**

To understand SNMP messages, it is important that we first grasp the difference between SNMP *messages* and SNMP *protocol data units (PDUs)*. We've seen in looking at SNMP protocol operations that the two terms are often used interchangeably. This is because each message carries one PDU, and the PDU is the most important part of the message.

However, strictly speaking, an SNMP PDU and an SNMP message are not exactly the same. The PDU is the actual piece of information that is being communicated between SNMP entities. It is carried *within* the SNMP message along with a number of header fields, which are used to carry identification and security information. Thus, conceptually, the SNMP message format can be considered to have two overall sections:

- ① **Message Header:** Contains fields used to control how the message is processed, including fields for implementing SNMP security.
- ② **Message Body (PDU):** Contains the main portion of the message. In this case, the message body is the protocol data unit (PDU) being transmitted.

---

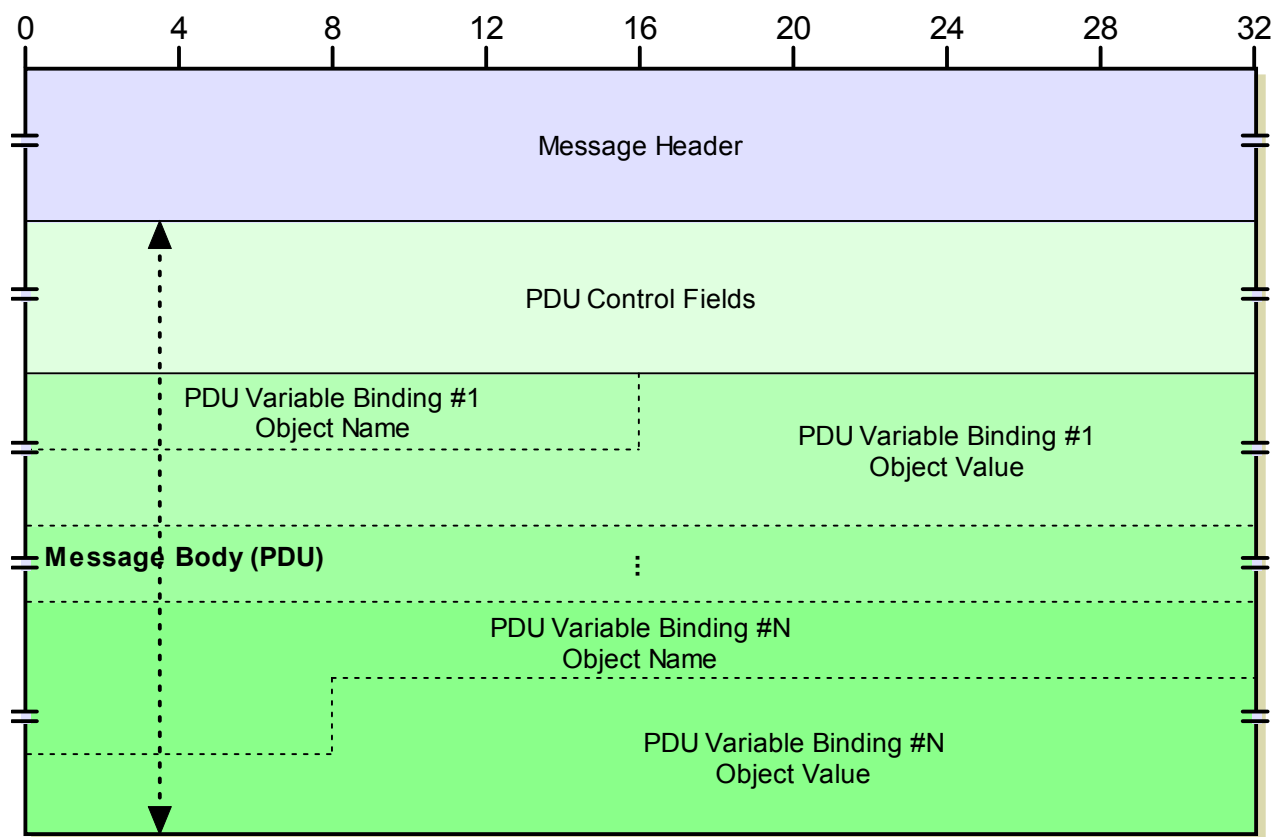

The overall SNMP message is sometimes called a *wrapper* for the PDU, since it encapsulates the PDU and precedes it with additional fields. The distinction between the PDU and the message format as a whole began as a formality in SNMP version 1, but became quite important in later versions. The reason is that it allows the fields used for basic protocol operations (which are in the PDU) to be kept separate from fields used to implement security features. In SNMPv2, the implementation of security became a very big deal indeed, as we will see, so this flexibility was quite important.

### **General PDU Format**

The fields in each PDU depend on the PDU type, but can again be divided into the following general substructure:

- ☉ **PDU Control Fields:** A set of fields that describe the PDU and communicate information from one SNMP entity to another.
- ☉ **PDU Variable Bindings:** A set of descriptions of the MIB objects in the PDU. Each object is described as a “binding” of a name to a value.

Each PDU will follow this general structure, which is shown in [Figure 276](#), differing only in the number of control fields, the number of variable bindings, and how they are used. In theory, each PDU could have a different message format using a distinct set of control fields, but in practice, most PDUs in a particular SNMP version use the same control fields (though there are exceptions.)

**Figure 276: SNMP General Message Format**

Each variable binding describes one MIB object. The binding consists of a pair of subfields, one specifying the name of the object in standard SNMP object identifier notation, and one its value, formatted to match the object's SMI syntax. For example, if the object is of type *Integer*, the value field would be 4 bytes wide and contain a numeric integer value. [Table 212](#) describes the subfield format for each PDU variable binding.

**Table 212: SNMP Variable Binding Format**

Subfield Name	Syntax	Size (bytes)	Description
<b>Object Name</b>	Sequence of <i>Integer</i>	Variable	<b>Object Name:</b> The numeric object identifier of the MIB object, specified as a sequence of integers. For example, the object <code>sysLocation</code> has the object identifier 1.3.6.1.2.1.1.6, so it would be specified as "1 3 6 1 2 1 1 6" using ASN.1
<b>Object Value</b>	Variable	Variable	<b>Object Value:</b> In any type of "get" request, this subfield is a "placeholder"; it is structured using the appropriate syntax for the object but has no value (since the "get" request is asking for that value!)  In a "set" request (SetRequest-PDU) or in a reply message carrying requested data (GetResponse-PDU or Response-PDU), the value of the object is placed here.

**Key Concept:** The general format of SNMP messages consists of a *message header* and a *message body*. The body of the message is also called the *protocol data unit* or *PDU*, and contains a set of *PDU control fields* and a number of *variable bindings*. Each variable binding describes one MIB object and consists of the object's name and value.

## SNMP Version 1 (SNMPv1) Message Format

The SNMP general message format was, of course, first used to define the format of messages in the original SNMP Protocol, SNMP version 1 (SNMPv1). This first version of SNMP is probably best known for its relative simplicity, compared to the versions that followed it. This is reflected in its message format, which is quite straight-forward.

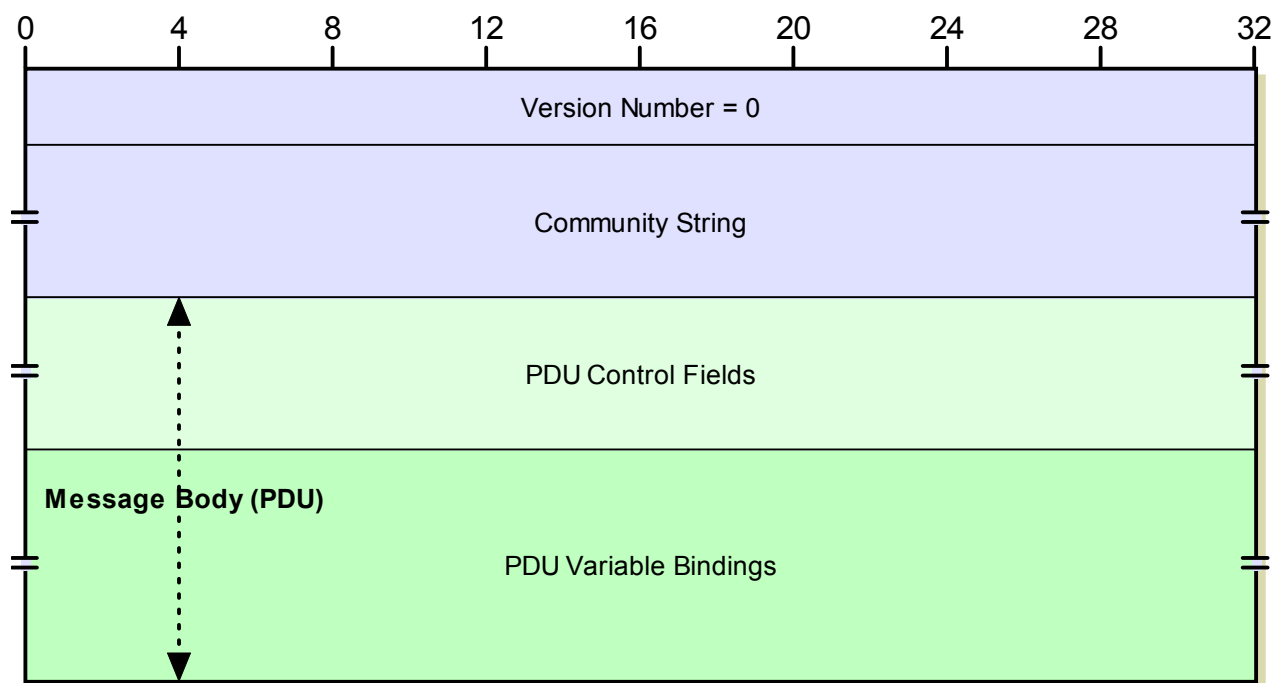

The general message format in SNMPv1 is a “wrapper” consisting of a small header and an encapsulated PDU. Not very many header fields were needed in SNMPv1 because the community-based security method in SNMPv1 is very rudimentary. Thus, the short overall format for SNMPv1 messages shown in [Table 213](#) and [Figure 277](#).

**Table 213: SNMP Version 1 (SNMPv1) General Message Format**

Field Name	Syntax	Size (bytes)	Description
<b>Version</b>	<i>Integer</i>	4	<b>Version Number:</b> Describes the SNMP version number of this message; used for ensuring compatibility between versions. For SNMPv1, this value is actually <b>0</b> , not 1.
<b>Community</b>	<i>Octet String</i>	Variable	<b>Community String:</b> Identifies the SNMP community in which the sender and recipient of this message are located. This is used to implement the simple SNMP <a href="#">community-based security mechanism</a>
<b>PDU</b>	—	Variable	<b>Protocol Data Unit:</b> The PDU being communicated as the body of the message.

## SNMPv1 PDU Formats

All of the PDUs in SNMPv1 have the same format, with one exception: *Trap-PDU*. The exact semantics of each field in the PDU depends on the particular message. For example, the *ErrorStatus* field only has meaning in a reply and not a request, and object values are used differently in requests and replies as well.

**Figure 277: SNMP Version 1 (SNMPv1) General Message Format**

#### SNMPv1 Common PDU Format

Table 214 and Figure 278 show the common format for most of the SNMPv1 PDUs: *GetRequest-PDU*, *GetNextRequest-PDU*, *SetRequest-PDU* and *GetResponse-PDU*:

**Table 214: SNMP Version 1 (SNMPv1) Common PDU Format (Page 1 of 2)**

Field Name	Syntax	Size (bytes)	Description										
<b>PDU Type</b>	<i>Integer (Enumerated)</i>	4	<b>PDU Type:</b> An integer value that indicates the PDU type: <table><tr><th>PDU Type Value</th><th>PDU Type</th></tr><tr><td>0</td><td><i>GetRequest-PDU</i></td></tr><tr><td>1</td><td><i>GetNextRequest-PDU</i></td></tr><tr><td>2</td><td><i>GetResponse-PDU</i></td></tr><tr><td>3</td><td><i>SetRequest-PDU</i></td></tr></table>	PDU Type Value	PDU Type	0	<i>GetRequest-PDU</i>	1	<i>GetNextRequest-PDU</i>	2	<i>GetResponse-PDU</i>	3	<i>SetRequest-PDU</i>
PDU Type Value	PDU Type												
0	<i>GetRequest-PDU</i>												
1	<i>GetNextRequest-PDU</i>												
2	<i>GetResponse-PDU</i>												
3	<i>SetRequest-PDU</i>												
<b>Request ID</b>	<i>Integer</i>	4	<b>Request Identifier:</b> A number used to match requests with replies. It is generated by the device that sends a request and copied into this field in a <i>GetResponse-PDU</i> by the responding SNMP entity.										

**Table 214: SNMP Version 1 (SNMPv1) Common PDU Format (Page 2 of 2)**

Field Name	Syntax	Size (bytes)	Description																					
Error Status	Integer (Enumerated)	4	<b>Error Status:</b> An integer value that is used in a <i>GetResponse-PDU</i> to tell the requesting SNMP entity the result of its request. A value of zero indicates that no error occurred; the other values indicate what sort of error happened:																					
			<table><tr><th>Error Status Value</th><th>Error Code</th><th>Description</th></tr><tr><td>0</td><td><i>noError</i></td><td>No error occurred. This code is also used in all request PDUs, since they have no error status to report.</td></tr><tr><td>1</td><td><i>tooBig</i></td><td>The size of the <i>GetResponse-PDU</i> would be too large to transport.</td></tr><tr><td>2</td><td><i>noSuchName</i></td><td>The name of a requested object was not found.</td></tr><tr><td>3</td><td><i>badValue</i></td><td>A value in the request didn't match the structure that the recipient of the request had for the object. For example, an object in the request was specified with an incorrect length or type.</td></tr><tr><td>4</td><td><i>readOnly</i></td><td>An attempt was made to set a variable that has an <i>Access</i> value indicating that it is read-only.</td></tr><tr><td>5</td><td><i>genErr</i></td><td>An error other than one of the preceding four specific types occurred.</td></tr></table>	Error Status Value	Error Code	Description	0	<i>noError</i>	No error occurred. This code is also used in all request PDUs, since they have no error status to report.	1	<i>tooBig</i>	The size of the <i>GetResponse-PDU</i> would be too large to transport.	2	<i>noSuchName</i>	The name of a requested object was not found.	3	<i>badValue</i>	A value in the request didn't match the structure that the recipient of the request had for the object. For example, an object in the request was specified with an incorrect length or type.	4	<i>readOnly</i>	An attempt was made to set a variable that has an <i>Access</i> value indicating that it is read-only.	5	<i>genErr</i>	An error other than one of the preceding four specific types occurred.
			Error Status Value	Error Code	Description																			
			0	<i>noError</i>	No error occurred. This code is also used in all request PDUs, since they have no error status to report.																			
			1	<i>tooBig</i>	The size of the <i>GetResponse-PDU</i> would be too large to transport.																			
			2	<i>noSuchName</i>	The name of a requested object was not found.																			
			3	<i>badValue</i>	A value in the request didn't match the structure that the recipient of the request had for the object. For example, an object in the request was specified with an incorrect length or type.																			
			4	<i>readOnly</i>	An attempt was made to set a variable that has an <i>Access</i> value indicating that it is read-only.																			
5	<i>genErr</i>	An error other than one of the preceding four specific types occurred.																						
Error Index	Integer	4	<b>Error Index:</b> When <i>Error Status</i> is non-zero, this field contains a pointer that specifies which object generated the error. Always zero in a request.																					
			<b>Variable Bindings:</b> A set of name-value pairs identifying the MIB objects in the PDU, and in the case of a <i>SetRequest-PDU</i> or <i>GetResponse-PDU</i> , containing their values. <a href="#">See the general message format topic for more on these bindings.</a>																					

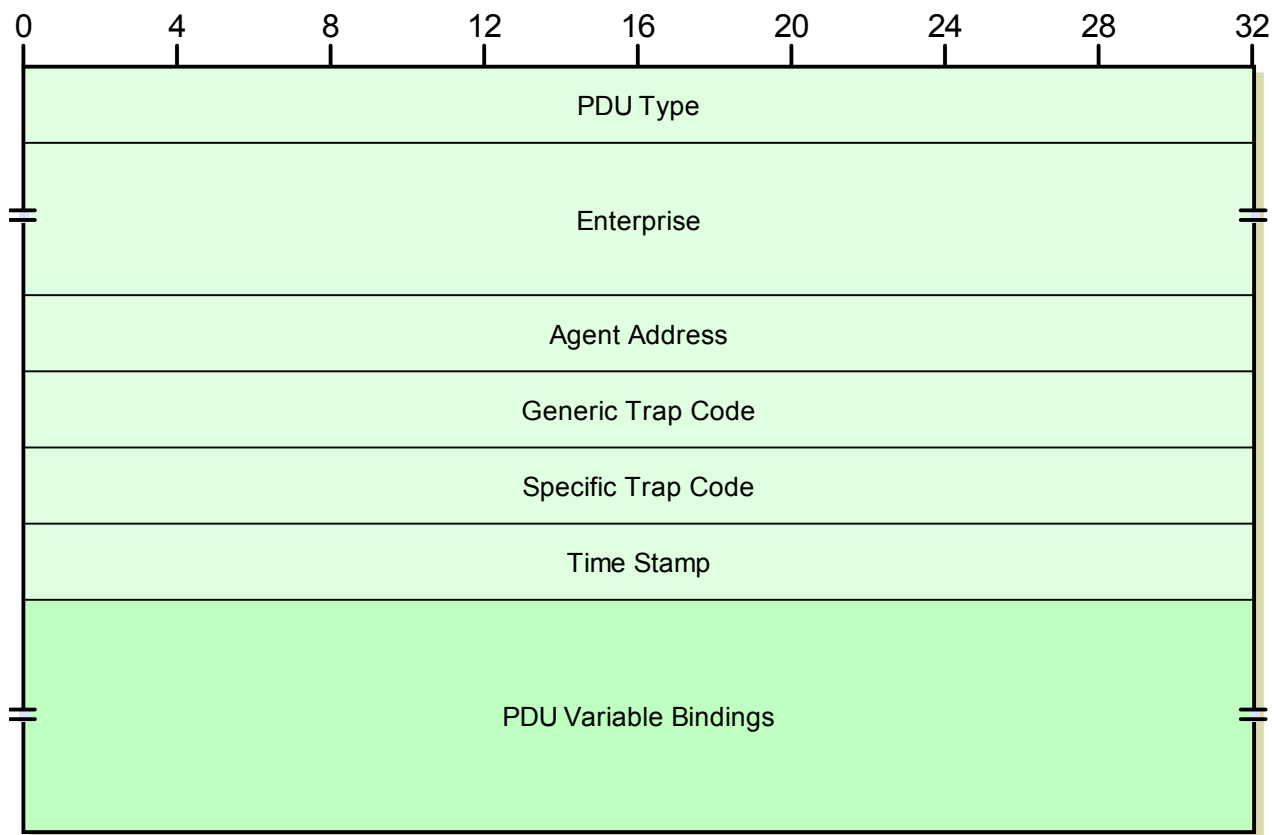

**Figure 278: SNMP Version 1 (SNMPv1) Common PDU Format**

#### SNMPv1 *Trap-PDU* Format

Table 215 and Figure 279 show the special format for the SNMPv1 *Trap-PDU*:

**Table 215: SNMP Version 1 (SNMPv1) *Trap-PDU* Format**

Field Name	Syntax	Size (bytes)	Description
<b><i>PDU Type</i></b>	<i>Integer (Enumerated)</i>	4	<b><i>PDU Type</i></b> : An integer value that indicates the PDU type, which is 4 for a <i>Trap-PDU</i> message.
<b><i>Enterprise</i></b>	Sequence of <i>Integer</i>	Variable	<b><i>Enterprise</i></b> : An object identifier for a group, which indicates the type of object that generated the trap.
<b><i>Agent Addr</i></b>	<i>NetworkAddress</i>	4	<b><i>Agent Address</i></b> : The IP address of the SNMP agent that generated the trap. This is of course also in the IP header at lower levels but inclusion in the SNMP message format allows for easier trap logging within SNMP. Also, in the case of a multihomed host, this specifies the preferred address.
<b><i>Generic Trap</i></b>	<i>Integer (Enumerated)</i>	4	<b><i>Generic Trap Code</i></b> : A code value specifying one of a number of predefined “generic” trap types.
<b><i>Specific Trap</i></b>	<i>Integer</i>	4	<b><i>Specific Trap Code</i></b> : A code value indicating an implementation-specific trap type.
<b><i>Time Stamp</i></b>	<i>TimeTicks</i>	4	<b><i>Time Stamp</i></b> : The amount of time since the SNMP entity sending this message last initialized or reinitialized. Used to time stamp traps for logging purposes.
<b><i>Variable Bindings</i></b>	Variable	Variable	<b><i>Variable Bindings</i></b> : A set of name-value pairs identifying the MIB objects in the PDU. <a href="#">See the general message format topic for more on these bindings.</a>

**Figure 279: SNMP Version 1 (SNMPv1) *Trap-PDU* Format**

## **SNMP Version 2 (SNMPv2) Message Formats**

After SNMP version 1 had been in use for several years, certain issues with it were noticed and areas for improvement identified. This led to the development of the original SNMP version 2, which was intended to enhance SNMPv1 in many areas, including MIB object definitions, protocol operations and security. This last area, security, led to the proliferation of SNMPv2 version “variants” that I described in [the topic on SNMP versions](#).

Since there are in fact several different “SNMPv2”s, there are also several message formats for SNMPv2, not just one. This is confusing enough, but would be even worse without the modular nature of SNMP messages “coming to the rescue”. The protocol operations in SNMPv2 were changed from SNMPv1, which necessitated some modifications to the format of SNMPv2 PDUs. However, the protocol operations are the same for all the SNMPv2 variations. The differences **between** SNMPv2 variants are in the areas of security implementation. Thus, the result of this is that the **PDU** format is the same for all the SNMPv2 types, while the overall **message** format differs for each variant. (This is why the distinction between a PDU and a message is not just an academic one!)

During the SNMPv2 “divergence”, four variations were defined: the original SNMPv2 (SNMPv2p); community-based SNMPv2 (SNMPv2c), user-based SNMPv2 (SNMPv2u) and “SNMPv2 star” (SNMPv2\*). Of these, the first three were [documented in sets of SNMP RFC](#)

---

[standards](#), the fourth was not. The structure of the overall message format for each variant is discussed in an administrative or security standard for the variation in question, which makes reference to the shared SNMPv2 standard for the PDU format (RFC 1905).

The overall message formats for SNMPv2p, SNMPv2c and SNMPv2u are as follows:

### ***SNMP Version 2 (SNMPv2p) Message Format***

The party-based security model is quite complex, but the basic messaging in this version is described through the definition of a *management communication*, which describes the source and destination party and makes reference to a *context* for the communication. The overall message format is described in detail in RFC 1445. This information is summarized in [Table 216](#) and shown graphically in [Figure 280](#).

**Table 216: SNMP Version 2 (SNMPv2p) General Message Format**

Field Name	Syntax	Size (bytes)	Description
<b>Version</b>	<i>Integer</i>	4	<b>Version Number:</b> Describes the SNMP version number of this message; used for ensuring compatibility between versions. For SNMPv2p, this value is 2.
<b>Dst Party</b>	Sequence of <i>Integer</i>	Variable	<b>Destination Party:</b> An object identifier that specifies the party that is the intended recipient of the message.
<b>Src Party</b>	Sequence of <i>Integer</i>	Variable	<b>Source Party:</b> An object identifier that specifies the party that is the sender of the message.
<b>Context</b>	Sequence of <i>Integer</i>	Variable	<b>Context:</b> Defines a set of MIB object resources that is accessible by a particular entity.
<b>PDU</b>	—	Variable	<b>PDU:</b> The protocol data unit of the message.

**Figure 280: SNMP Version 2 (SNMPv2p) General Message Format**

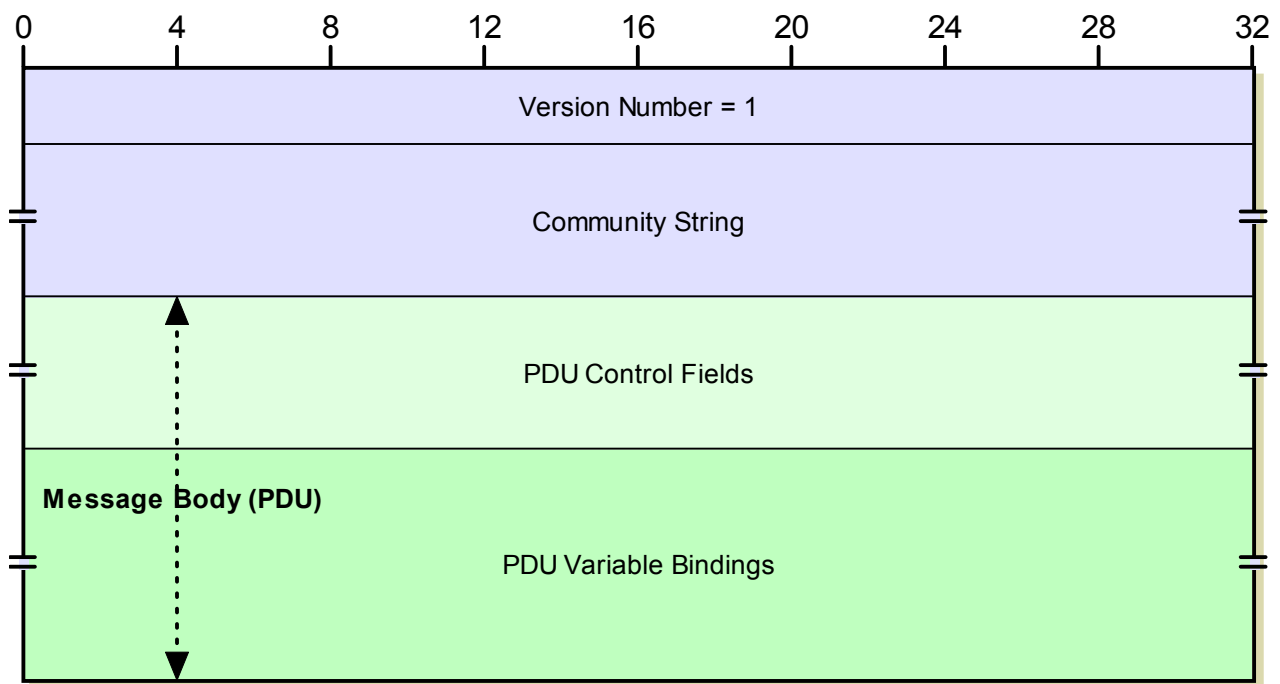

### ***Community-Based SNMP Version 2 (SNMPv2c) Message Format***

This version of SNMPv2 was intended to keep the new protocol enhancements introduced by SNMPv2p but go back to the simple SNMPv1 security model. As such, the defining document for SNMPv2c, RFC 1901, specifies that its overall message format is the same as that of SNMPv1, except that the version number is changed. This is shown in [Table 217](#) and [Figure 281](#).

**Table 217: Community-Based SNMP Version 2 (SNMPv2c) General Message Format**

Field Name	Syntax	Size (bytes)	Description
<b>Version</b>	<i>Integer</i>	4	<b>Version Number:</b> Describes the SNMP version number of this message; used for ensuring compatibility between versions. For SNMPv2c, this value is 1.
<b>Community</b>	<i>Octet String</i>	Variable	<b>Community String:</b> Identifies the SNMP community in which the sender and recipient of this message are located.
<b>PDU</b>	—	Variable	<b>Protocol Data Unit:</b> The PDU being communicated as the body of the message.

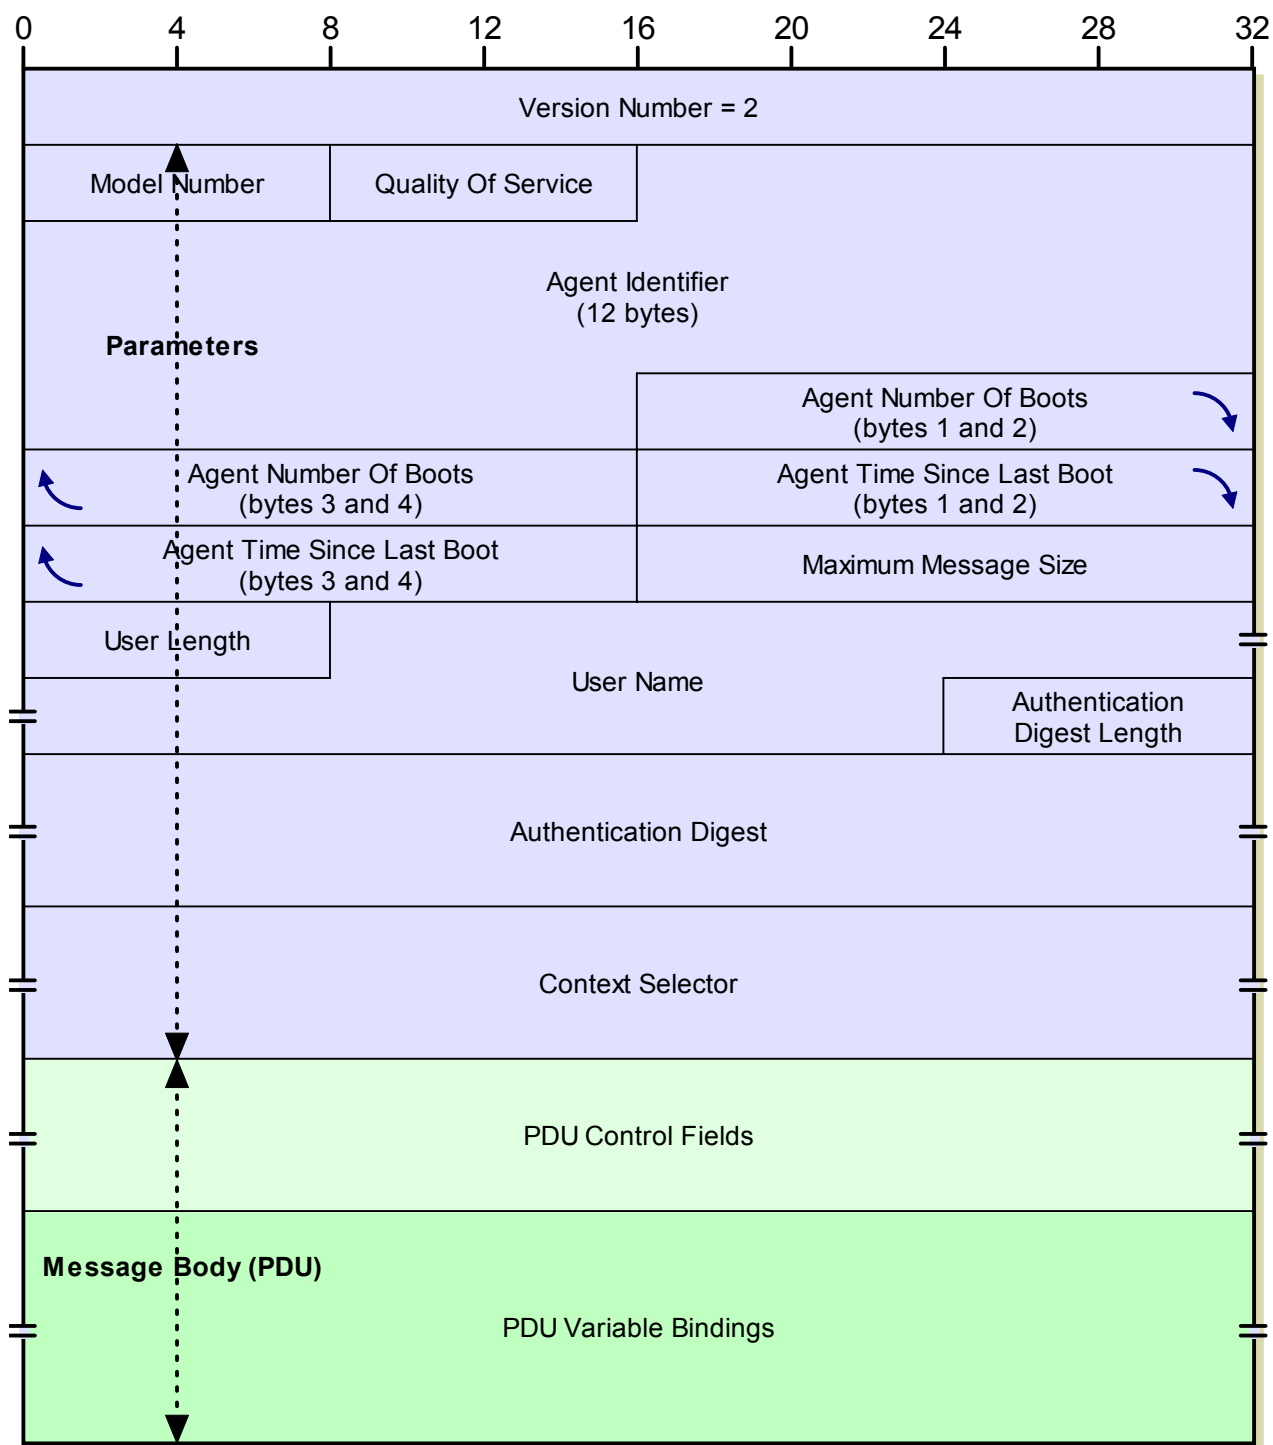

**Figure 281: Community-Based SNMP Version 2 (SNMPv2c) General Message Format**

## User-Based SNMP Version 2 (SNMPv2u) Message Format

SNMPv2u was defined as an optional security model at the time that SNMPv2c was standardized. RFC 1910 defines the user-based security model and the message format described in [Table 218](#) and [Figure 282](#).

**Table 218: User-Based SNMP Version 2 (SNMPv2u) General Message Format**

Field Name	Syntax	Size (bytes)	Description																																				
Version	Integer	4	<b>Version Number:</b> Describes the SNMP version number of this message; used for ensuring compatibility between versions. For SNMPv2u, this value is 2. Note that this is the same value as used for SNMPv2p.																																				
Parameters	Octet String	Variable	<b>Parameters:</b> A string of parameters used to implement the user-based security model, which is itself non-trivial to describe. Very briefly, these parameters are:																																				
			<table><tr><th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr><tr><td>Model</td><td>1</td><td><b>Model Number:</b> Set to 1 to identify the user-based model.</td></tr><tr><td>QoS</td><td>1</td><td><b>Quality of Service:</b> Indicates whether authentication and/or privacy (encryption) have been used, and whether generation of a <i>Report-PDU</i> is allowed.</td></tr><tr><td>Agent ID</td><td>12</td><td><b>Agent Identifier:</b> The identifier of the agent sending the message. Used to defeat replay attacks and certain other types of security attacks.</td></tr><tr><td>Agent Boots</td><td>4</td><td><b>Agent Number Of Boots:</b> The number of times the agent has been booted or rebooted since its Agent ID was set; used to defeat certain security attacks.</td></tr><tr><td>Agent Time</td><td>4</td><td><b>Agent Time Since Last Boot:</b> The number of seconds since the last boot of this agent. Again, used to defeat replay and other security attacks.</td></tr><tr><td>Max Size</td><td>2</td><td><b>Maximum Message Size:</b> The maximum size of message that the sender of this message can receive.</td></tr><tr><td>User Len</td><td>1</td><td><b>User Length:</b> The length of the <i>User Name</i> field below.</td></tr><tr><td>User Name</td><td>Variable (1 to 16)</td><td><b>User Name:</b> The name of the user on whose behalf the message is being sent.</td></tr><tr><td>Auth Len</td><td>1</td><td><b>Authentication Digest Length:</b> The length of the <i>Auth Digest</i> field below.</td></tr><tr><td>Auth Digest</td><td>Variable (0 to 255)</td><td><b>Authentication Digest:</b> An authentication value used to verify the identity and genuineness of this message, when authentication is used.</td></tr><tr><td>Context Selector</td><td>Variable (0 to 40)</td><td><b>Context Selector:</b> A string that is combined with the <i>Agent ID</i> to specify a particular context that contains the management information referenced by this message.</td></tr></table>	Subfield Name	Size (bytes)	Description	Model	1	<b>Model Number:</b> Set to 1 to identify the user-based model.	QoS	1	<b>Quality of Service:</b> Indicates whether authentication and/or privacy (encryption) have been used, and whether generation of a <i>Report-PDU</i> is allowed.	Agent ID	12	<b>Agent Identifier:</b> The identifier of the agent sending the message. Used to defeat replay attacks and certain other types of security attacks.	Agent Boots	4	<b>Agent Number Of Boots:</b> The number of times the agent has been booted or rebooted since its Agent ID was set; used to defeat certain security attacks.	Agent Time	4	<b>Agent Time Since Last Boot:</b> The number of seconds since the last boot of this agent. Again, used to defeat replay and other security attacks.	Max Size	2	<b>Maximum Message Size:</b> The maximum size of message that the sender of this message can receive.	User Len	1	<b>User Length:</b> The length of the <i>User Name</i> field below.	User Name	Variable (1 to 16)	<b>User Name:</b> The name of the user on whose behalf the message is being sent.	Auth Len	1	<b>Authentication Digest Length:</b> The length of the <i>Auth Digest</i> field below.	Auth Digest	Variable (0 to 255)	<b>Authentication Digest:</b> An authentication value used to verify the identity and genuineness of this message, when authentication is used.	Context Selector	Variable (0 to 40)	<b>Context Selector:</b> A string that is combined with the <i>Agent ID</i> to specify a particular context that contains the management information referenced by this message.
			Subfield Name	Size (bytes)	Description																																		
			Model	1	<b>Model Number:</b> Set to 1 to identify the user-based model.																																		
			QoS	1	<b>Quality of Service:</b> Indicates whether authentication and/or privacy (encryption) have been used, and whether generation of a <i>Report-PDU</i> is allowed.																																		
			Agent ID	12	<b>Agent Identifier:</b> The identifier of the agent sending the message. Used to defeat replay attacks and certain other types of security attacks.																																		
			Agent Boots	4	<b>Agent Number Of Boots:</b> The number of times the agent has been booted or rebooted since its Agent ID was set; used to defeat certain security attacks.																																		
			Agent Time	4	<b>Agent Time Since Last Boot:</b> The number of seconds since the last boot of this agent. Again, used to defeat replay and other security attacks.																																		
			Max Size	2	<b>Maximum Message Size:</b> The maximum size of message that the sender of this message can receive.																																		
			User Len	1	<b>User Length:</b> The length of the <i>User Name</i> field below.																																		
			User Name	Variable (1 to 16)	<b>User Name:</b> The name of the user on whose behalf the message is being sent.																																		
			Auth Len	1	<b>Authentication Digest Length:</b> The length of the <i>Auth Digest</i> field below.																																		
Auth Digest	Variable (0 to 255)	<b>Authentication Digest:</b> An authentication value used to verify the identity and genuineness of this message, when authentication is used.																																					
Context Selector	Variable (0 to 40)	<b>Context Selector:</b> A string that is combined with the <i>Agent ID</i> to specify a particular context that contains the management information referenced by this message.																																					
PDU	—	Variable	<b>Protocol Data Unit:</b> The PDU being communicated as the body of the message. This may be in either encrypted or unencrypted form.																																				

**Figure 282: User-Based SNMP Version 2 (SNMPv2u) General Message Format**

## SNMPv2 PDU Formats

The format of protocol data units in SNMPv2 is described in RFC 1905, and is similar to that of SNMPv1. The format for all PDUs in SNMPv2 is the same, except for the *GetBulkRequest-PDU* message. (Oddly, this includes the *Trapv2-PDU* message, even though the *Trap-PDU* message in SNMPv1 used a distinct format).

### SNMPv2 Common PDU Format

Table 219 and Figure 283 show this common PDU format. Table 220 contains a listing of the different values for the *Error Status* field and how they are interpreted.

**Table 219: SNMP Version 2 (SNMPv2) Common PDU Format (Page 1 of 2)**

Field Name	Syntax	Size (bytes)	Description																				
PDU Type	Integer (Enumerated)	4	<b>PDU Type:</b> An integer value that indicates the PDU type:																				
			<table><tr><th>PDU Type Value</th><th>PDU Type</th></tr><tr><td>0</td><td>GetRequest-PDU</td></tr><tr><td>1</td><td>GetNextRequest-PDU</td></tr><tr><td>2</td><td>Response-PDU</td></tr><tr><td>3</td><td>SetRequest-PDU</td></tr><tr><td>4</td><td>Obsolete, not used (this was the old <i>Trap-PDU</i> in SNMPv1)</td></tr><tr><td>5</td><td>GetBulkRequest-PDU (has its own format, see below)</td></tr><tr><td>6</td><td>InformRequest-PDU</td></tr><tr><td>7</td><td>Trapv2-PDU</td></tr><tr><td>8</td><td>Report-PDU</td></tr></table>	PDU Type Value	PDU Type	0	GetRequest-PDU	1	GetNextRequest-PDU	2	Response-PDU	3	SetRequest-PDU	4	Obsolete, not used (this was the old <i>Trap-PDU</i> in SNMPv1)	5	GetBulkRequest-PDU (has its own format, see below)	6	InformRequest-PDU	7	Trapv2-PDU	8	Report-PDU
			PDU Type Value	PDU Type																			
			0	GetRequest-PDU																			
			1	GetNextRequest-PDU																			
			2	Response-PDU																			
			3	SetRequest-PDU																			
			4	Obsolete, not used (this was the old <i>Trap-PDU</i> in SNMPv1)																			
			5	GetBulkRequest-PDU (has its own format, see below)																			
			6	InformRequest-PDU																			
7	Trapv2-PDU																						
8	Report-PDU																						
Request ID	Integer	4	<b>Request Identifier:</b> A number used to match requests with replies. It is generated by the device that sends a request and copied into this field in a <i>Response-PDU</i> by the responding SNMP entity.																				
Error Status	Integer (Enumerated)	4	<b>Error Status:</b> An integer value that is used in a <i>Response-PDU</i> to tell the requesting SNMP entity the result of its request. A value of zero indicates that no error occurred; the other values indicate what sort of error happened.  Note that the first six values (0 to 5) are maintained as used in SNMPv1 for compatibility, but SNMPv2 adds many new error codes that provide more specific indication of the exact nature of an error in a request. The <i>genErr</i> code is still used only when none of specific error types (either the old codes or the new ones) apply.  Since there are so many different <i>Error Status</i> codes, I have listed them separately in <a href="#">Table 220</a> .																				

**Table 219: SNMP Version 2 (SNMPv2) Common PDU Format (Page 2 of 2)**

Field Name	Syntax	Size (bytes)	Description
<b>Error Index</b>	<i>Integer</i>	4	<b>Error Index:</b> When <i>Error Status</i> is non-zero, this field contains a pointer that specifies which object generated the error. Always zero in a request.
<b>Variable Bindings</b>	Variable	Variable	<b>Variable Bindings:</b> A set of name-value pairs identifying the MIB objects in the PDU, and in the case of messages other than requests, containing their values. <a href="#">See the general message format topic for more on these bindings.</a>

**Table 220: SNMP Version 2 (SNMPv2) PDU Error Status Field Values (Page 1 of 2)**

Error Status Value	Error Code	Description
0	noError	No error occurred. This code is also used in all request PDUs, since they have no error status to report.
1	tooBig	The size of the <i>Response-PDU</i> would be too large to transport.
2	noSuchName	The name of a requested object was not found.
3	badValue	A value in the request didn't match the structure that the recipient of the request had for the object. For example, an object in the request was specified with an incorrect length or type.
4	readOnly	An attempt was made to set a variable that has an <i>Access</i> value indicating that it is read-only.
5	genErr	An error occurred other than one indicated by a more specific error code in this table.
6	noAccess	Access was denied to the object for security reasons.
7	wrongType	The object type in a variable binding is incorrect for the object.
8	wrongLength	A variable binding specifies a length incorrect for the object.
9	wrongEncoding	A variable binding specifies an encoding incorrect for the object.
10	wrongValue	The value given in a variable binding is not possible for the object.
11	noCreation	A specified variable does not exist and cannot be created.
12	inconsistentValue	A variable binding specifies a value that could be held by the variable but cannot be assigned to it at this time.
13	resource-Unavailable	An attempt to set a variable required a resource that is not available.
14	commitFailed	An attempt to set a particular variable failed.
15	undoFailed	An attempt to set a particular variable as part of a group of variables failed, and the attempt to then undo the setting of other variables was not successful.
16	authorization-Error	A problem occurred in authorization.

**Table 220: SNMP Version 2 (SNMPv2) PDU Error Status Field Values (Page 2 of 2)**

Error Status Value	Error Code	Description
17	notWritable	The variable cannot be written or created.
18	inconsistentName	The name in a variable binding specifies a variable that does not exist.

**Figure 283: SNMP Version 2 (SNMPv2) Common PDU Format**

#### SNMPv2 *GetBulkRequest-PDU* Format

The special format of the SNMPv2 *GetBulkRequest-PDU* message is shown in [Table 221](#) and [Figure 284](#).

**Table 221: SNMP Version 2 (SNMPv2) *GetBulkRequest-PDU* Format (Page 1 of 2)**

Field Name	Syntax	Size (bytes)	Description
<b><i>PDU Type</i></b>	<i>Integer (Enumerated)</i>	4	<b><i>PDU Type:</i></b> An integer value that indicates the PDU type, which is 5 for a <i>GetBulkRequest-PDU</i> message.
<b><i>Request ID</i></b>	<i>Integer</i>	4	<b><i>Request Identifier:</i></b> A number used to match requests with replies. It is generated by the device that sends a request and copied into this field in a <i>Response-PDU</i> by the responding SNMP entity.
<b><i>Non Repeaters</i></b>	<i>Integer</i>	4	<b><i>Non Repeaters:</i></b> Specifies the number of non-repeating, regular objects at the start of the variable list in the request.

**Table 221: SNMP Version 2 (SNMPv2) *GetBulkRequest-PDU* Format (Page 2 of 2)**

Field Name	Syntax	Size (bytes)	Description
<b>Max Repetitions</b>	<i>Integer</i>	4	<b>Max Repetitions:</b> The number of iterations in the table to be read for the repeating objects that follow the non-repeating objects.
<b>Variable Bindings</b>	Variable	Variable	<b>Variable Bindings:</b> A set of name-value pairs identifying the MIB objects in the PDU. <a href="#">See the general message format topic for more on these bindings.</a>

**Figure 284: SNMP Version 2 (SNMPv2) *GetBulkRequest-PDU* Format**

**Note:** [The topic on SNMP table traversal](#) contains full details on how *Non Repeaters* and *Max Repetitions* are used.

## **SNMP Version 3 (SNMPv3) Message Format**

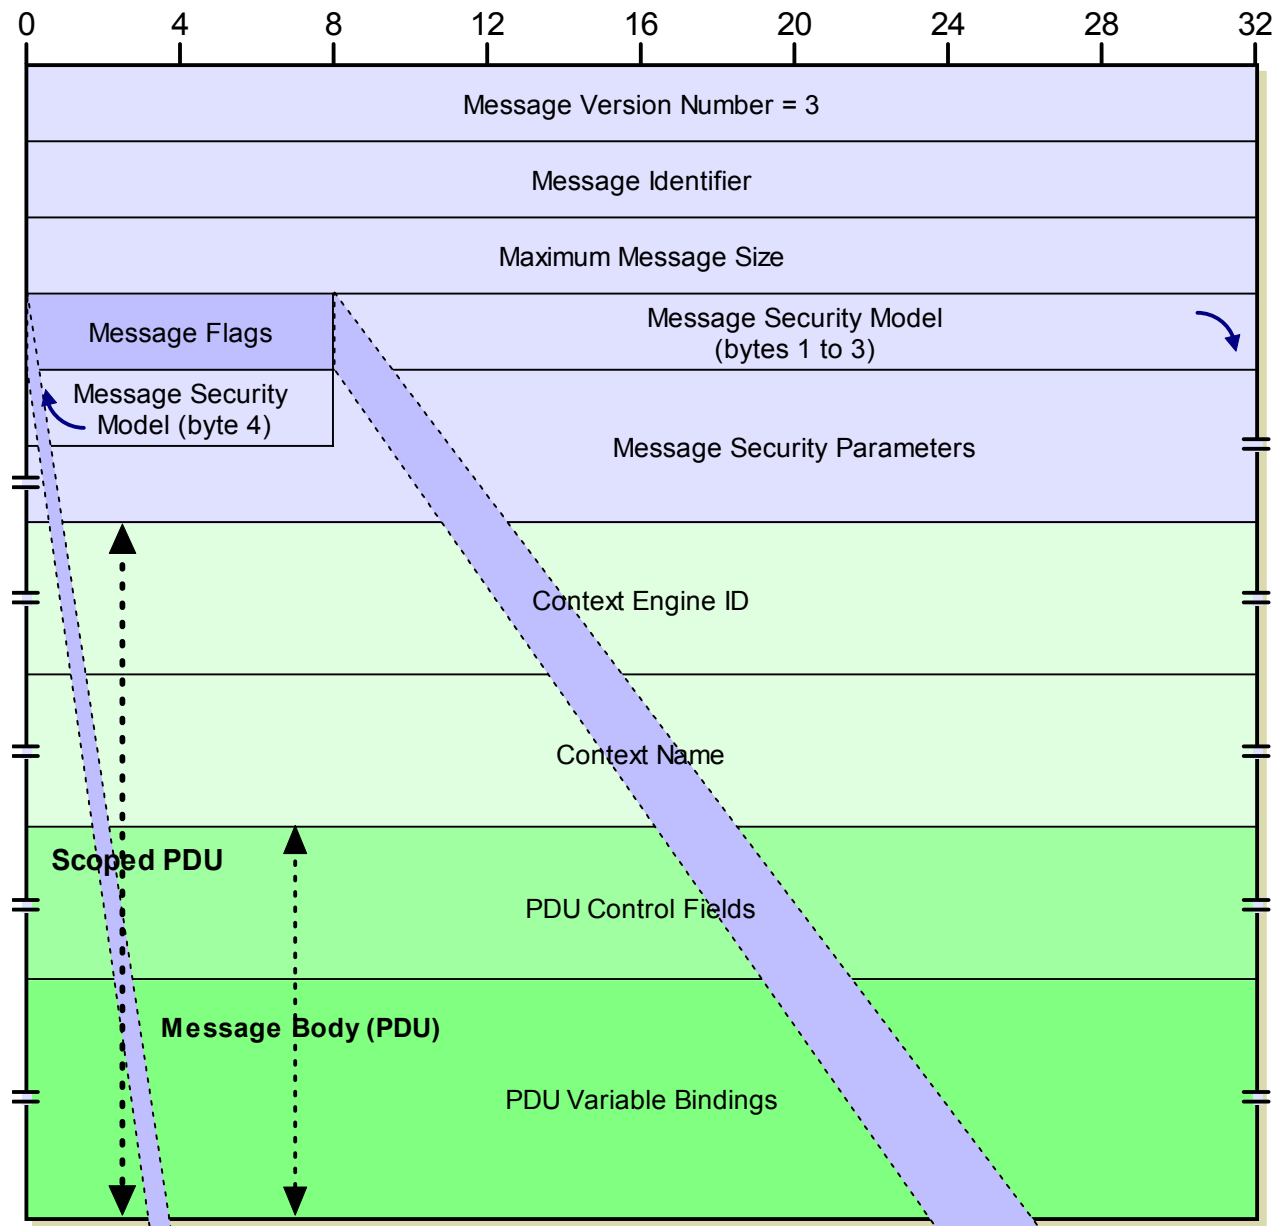

In the late 1990s, SNMP version 3 was created to resolve the problems that occurred with the [many different variations of SNMPv2](#). The SNMPv3 Framework adopts many components that were created in SNMPv2, including the SNMPv2 protocol operations, PDU types and PDU format. Amongst the significant changes made in SNMPv3 include a more flexible way of defining security methods and parameters, to allow the coexistence of multiple security techniques.

---

The general message format for SNMPv3 still follows the same idea of an overall message “wrapper” that contains a header and an encapsulated PDU. However, in version 3 this concept is further refined. The fields in the header have themselves been divided into those dealing with security and those that do not deal with security matters. The “non-security” fields are common to all SNMPv3 implementations, while the use of the security fields can be tailored by each SNMPv3 security model, and processed by the module in an SNMP entity that deals with security. This solution provides considerable flexibility while avoiding the problems that plagued SNMPv2.

---

### Figure 285: SNMP Version 3 (SNMPv3) General Message Format

**Table 222: SNMP Version 3 (SNMPv3) General Message Format (Page 1 of 2)**

Field Name	Syntax	Size (bytes)	Description															
<b>Msg Version</b>	<i>Integer</i>	4	<b>Message Version Number:</b> Describes the SNMP version number of this message; used for ensuring compatibility between versions. For SNMPv3, this value is 3.															
<b>Msg ID</b>	<i>Integer</i>	4	<b>Message Identifier:</b> A number used to identify an SNMPv3 message and to match response messages to request messages. The use of this field is similar to that of the <i>Request ID</i> field in the PDU format (see <a href="#">Table 219</a> ), but they are not identical. This field was created to allow matching at the message processing level regardless of the contents of the PDU, to protect against certain security attacks. Thus, <i>Msg ID</i> and <i>Request ID</i> are used independently.															
<b>Msg Max Size</b>	<i>Integer</i>	4	<b>Maximum Message Size:</b> The maximum size of message that the sender of this message can receive. Minimum value of this field is 484.															
<b>Msg Flags</b>	<i>Octet String</i>	1	<b>Message Flags:</b> A set of flags that controls processing of the message. The current substructure of this field is:															
			<table><tr><th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr><tr><td><b>Reserved</b></td><td>5/8 (5 bits)</td><td><b>Reserved:</b> Reserved for future use.</td></tr><tr><td><b>Reportable Flag</b></td><td>1/8 (1 bit)</td><td><b>Reportable Flag:</b> When set to 1, a device receiving this message must send back a <i>Report-PDU</i> whenever conditions arise where such a PDU should be generated.</td></tr><tr><td><b>Priv Flag</b></td><td>1/8 (1 bit)</td><td><b>Privacy Flag:</b> When set to 1, indicates that encryption was used to protect the privacy of the message. May not be set to 1 unless <i>Auth Flag</i> is also set to 1.</td></tr><tr><td><b>Auth Flag</b></td><td>1/8 (1 bit)</td><td><b>Authentication Flag:</b> When set to 1, indicates that authentication was used to protect the authenticity of this message.</td></tr></table>	Subfield Name	Size (bytes)	Description	<b>Reserved</b>	5/8 (5 bits)	<b>Reserved:</b> Reserved for future use.	<b>Reportable Flag</b>	1/8 (1 bit)	<b>Reportable Flag:</b> When set to 1, a device receiving this message must send back a <i>Report-PDU</i> whenever conditions arise where such a PDU should be generated.	<b>Priv Flag</b>	1/8 (1 bit)	<b>Privacy Flag:</b> When set to 1, indicates that encryption was used to protect the privacy of the message. May not be set to 1 unless <i>Auth Flag</i> is also set to 1.	<b>Auth Flag</b>	1/8 (1 bit)	<b>Authentication Flag:</b> When set to 1, indicates that authentication was used to protect the authenticity of this message.
			Subfield Name	Size (bytes)	Description													
			<b>Reserved</b>	5/8 (5 bits)	<b>Reserved:</b> Reserved for future use.													
			<b>Reportable Flag</b>	1/8 (1 bit)	<b>Reportable Flag:</b> When set to 1, a device receiving this message must send back a <i>Report-PDU</i> whenever conditions arise where such a PDU should be generated.													
			<b>Priv Flag</b>	1/8 (1 bit)	<b>Privacy Flag:</b> When set to 1, indicates that encryption was used to protect the privacy of the message. May not be set to 1 unless <i>Auth Flag</i> is also set to 1.													
<b>Auth Flag</b>	1/8 (1 bit)	<b>Authentication Flag:</b> When set to 1, indicates that authentication was used to protect the authenticity of this message.																
<b>Msg Security Model</b>	<i>Integer</i>	4	<b>Message Security Model:</b> An integer value indicating which security model was used for this message. For the user-based security model (the default in SNMPv3) this value is 3.															

**Table 222: SNMP Version 3 (SNMPv3) General Message Format (Page 2 of 2)**

Field Name	Syntax	Size (bytes)	Description																
<b>Msg Security Parameters</b>	—	Variable	<b>Message Security Parameters:</b> A set of fields that contain parameters required to implement the particular security model used for this message. The contents of this field are specified in each document describing an SNMPv3 security model. For example, the parameters for the user-based model are in RFC 3414.																
<b>Scoped PDU</b>	—	Variable	<p><b>Scoped PDU:</b> Contains the PDU to be transmitted, along with parameters that identify an SNMP context, which describes a set of management information accessible by a particular entity. The PDU is said to be “scoped” because it is applied within the scope of this context. (Yeah, security stuff is confusing, sorry; it would take pages and pages to properly explain contexts; see RFC 3411.) The field may be encrypted or unencrypted depending on the value of <i>Priv Flag</i> and its structure is:</p> <table> <tr> <th>Subfield Name</th><th>Syntax</th><th>Size (bytes)</th><th>Description</th></tr> <tr> <td><b>Context Engine ID</b></td><td><i>Octet String</i></td><td>Variable</td><td><b>Context Engine ID:</b> Used to identify to which application the PDU will be sent for processing.</td></tr> <tr> <td><b>Context Name</b></td><td><i>Octet String</i></td><td>Variable</td><td><b>Context Name:</b> An object identifier specifying the particular context associated with this PDU.</td></tr> <tr> <td><b>PDU</b></td><td>—</td><td>Variable</td><td><b>PDU:</b> The protocol data unit being transmitted.</td></tr> </table>	Subfield Name	Syntax	Size (bytes)	Description	<b>Context Engine ID</b>	<i>Octet String</i>	Variable	<b>Context Engine ID:</b> Used to identify to which application the PDU will be sent for processing.	<b>Context Name</b>	<i>Octet String</i>	Variable	<b>Context Name:</b> An object identifier specifying the particular context associated with this PDU.	<b>PDU</b>	—	Variable	<b>PDU:</b> The protocol data unit being transmitted.
Subfield Name	Syntax	Size (bytes)	Description																
<b>Context Engine ID</b>	<i>Octet String</i>	Variable	<b>Context Engine ID:</b> Used to identify to which application the PDU will be sent for processing.																
<b>Context Name</b>	<i>Octet String</i>	Variable	<b>Context Name:</b> An object identifier specifying the particular context associated with this PDU.																
<b>PDU</b>	—	Variable	<b>PDU:</b> The protocol data unit being transmitted.																

And now, let's look at the PDU format for SNMPv3. Ah ha! We are spared this, because SNMPv3 uses the protocol operations from SNMPv2; this is described in RFC 3416, which is just an update of RFC 1904. Thus, the PDU formats are the same as in [the previous topic](#). Phew!

---

## **TCP/IP Remote Network Monitoring (RMON)**

The Simple Network Management Protocol (SNMP) defines both a [framework](#) and a [specific protocol](#) for exchanging network information on a TCP/IP internetwork. The [general model used by SNMP](#) is that of a network management station (NMS) that sends requests to SNMP agents running on managed devices. The SNMP agents may also initiate certain types of communication by sending *trap* messages to tell the NMS when particular events occur.

This model works well, which is why SNMP has become so popular. However, one fundamental limitation of the protocol and the model it uses is that it is oriented around the communication of network information from SNMP agents that are normally part of regular TCP/IP devices, such as hosts and routers. The amount of information gathered by these devices is usually somewhat limited, because obviously hosts and routers have “real work to do”—that is, doing the jobs of being hosts and routers. They can't devote themselves to network management tasks.

Thus, in situations where more information is needed about a network than is gathered by traditional devices, administrators often use special hardware units called *network analyzers*, *monitors* or *probes*. These are dedicated pieces of equipment that are connected to a network and used strictly for the purpose of gathering statistics and watching for events of interest or concern to the administrator. It would obviously be very useful if these devices could use SNMP to allow the information they gather to be retrieved, and to let them generate traps when they notice something important.

To enable this, the *Remote Network Monitoring (RMON)* specification was created. RMON is often called a protocol, and you will sometimes see SNMP and RMON referred to as “the TCP/IP network management protocols”. However, RMON really isn't a separate protocol at all—it defines no protocol operations. RMON is in fact part of SNMP, and the RMON specification is simply a [management information base \(MIB\) module](#) that defines a particular set of MIB objects for use by network monitoring probes. Architecturally, it is just one of the many MIB modules that comprise the SNMP Framework.

**Key Concept:** SNMP *Remote Network Monitoring (RMON)* was created to enable the efficient management of networks using dedicated management devices such as network analyzers, monitors or probes. RMON is often called a “protocol”, but does not in fact define any new protocol operations; it is a MIB module for SNMP that describes objects that permit advanced network management capabilities.

---

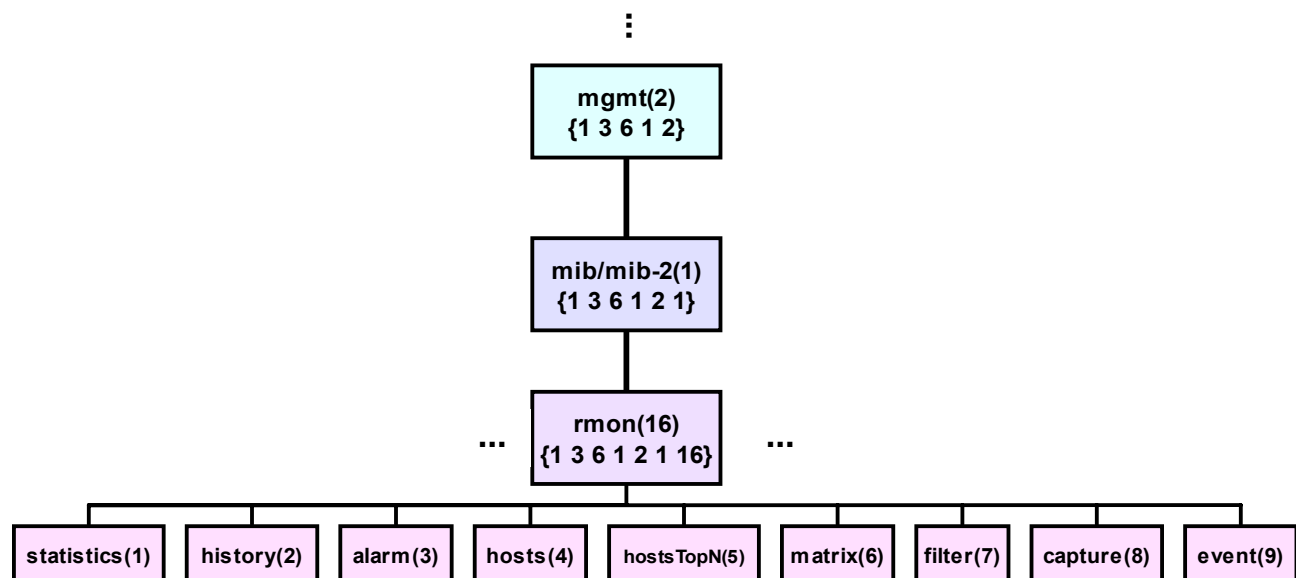

---

## RMON Standards

The first standard documenting RMON was RFC 1271, *Remote Network Monitoring Management Information Base*, published in 1991. RFC 1271 was replaced by RFC 1757 in 1995, which made a couple of changes to the specification. RFC 2819, May 2000, updates RMON to use the new [Structure of Management Information version 2 \(SMIv2\)](#) specification that is part of SNMPv2 but is functionally the same as RFC 1757.

## RMON MIB Hierarchy and Object Groups

Since RMON is a MIB module, it consists almost entirely of descriptions for MIB objects, with each having the standard characteristics belonging to all such objects. All the objects within RMON are arranged into the SNMP object name hierarchy within the *rmon* group, which is group number 16 within the SNMP *mib* (*mib-2*) object tree, 1.3.6.1.2.1. So, all RMON objects have identifiers starting with 1.3.6.1.2.1.16. This single RMON group is broken down into several lower-level groups that provide more structure for the RMON objects defined by the specification. [Figure 286](#) shows this structure.

**Figure 286: SNMP Remote Network Monitoring (RMON) MIB Hierarchy**

RMON uses a special MIB module, *rmon(16)*, which fits into the overall SNMP object hierarchy tree under *mib/mib-2(1)* within *mgmt(2)*—just like other MIB object groups such as *sys(1)* and *if(2)*; see [Figure 273](#).

Within this group, which has the group identifier 1.3.6.1.2.1.16, are 9 subgroups of RMON objects.

Table 223 describes each of the RMON groups, showing for each its name, its group code (which is used as the prefix for [object descriptors](#) in the group), and its RMON group number and SNMP object hierarchy identifier:

**Table 223: SNMP RMON MIB Object Groups (Page 1 of 2)**

RMON Group Name	RMON Group Code	RMON Group Number	Full Group Identifier	Description
<b>statistics</b>	<b>etherStats</b>	1	1.3.6.1.2.1.16.1	Objects that keep track of network statistics measured by the device. Example statistics include network traffic load, average packet size, number of broadcasts observed, counts of errors that have occurred, the number of packets in various size ranges and so forth.
<b>history</b>	<b>history, ether-History</b>	2	1.3.6.1.2.1.16.2	The history group contains a single table object that controls how often statistical data is sampled by the probe. The additional <i>ether-History</i> group is optional and contains extra Ethernet-specific information; it is contained logically within the <i>history</i> group.
<b>alarm</b>	<b>alarm</b>	3	1.3.6.1.2.1.16.3	This group defines the parameters under which an alarm may be generated to inform an administrator of an occurrence of import. The <i>alarm</i> group contains a table that describes the thresholds that will cause an event to be triggered (see the <i>event</i> group below).
<b>hosts</b>	<b>host</b>	4	1.3.6.1.2.1.16.4	Contains objects that keep track of information for each host on a network.
<b>hostsTopN</b>	<b>hostTopN</b>	5	1.3.6.1.2.1.16.5	This group contains objects that facilitate reporting of hosts sorted in a particular way. The administrator determines how these ordered statistics are tracked. For example, an administrator could generate a report listing hosts sorted by the number of packets transmitted, showing the most active devices.
<b>matrix</b>	<b>matrix</b>	6	1.3.6.1.2.1.16.6	This group keeps track of statistics for data exchanges between particular pairs of hosts. So, the amount of data sent between any two devices on the network could be tracked here. Since a large network could have thousands of such device pairs, to conserve resources on the probe, often only the most recent “conversations” between device pairs are kept in the management information base.
<b>filter</b>	<b>filter</b>	7	1.3.6.1.2.1.16.7	This RMON group allows an administrator to set up filters that control what sorts of network packets the probe will capture.

**Table 223: SNMP RMON MIB Object Groups (Page 2 of 2)**

RMON Group Name	RMON Group Code	RMON Group Number	Full Group Identifier	Description
<i>capture</i>	<i>buffer, capture</i>	8	1.3.6.1.2.1.16.8	This group is used to allow a probe to capture packets based on particular parameters set up in the filter group.
<i>event</i>	<i>event</i>	9	1.3.6.1.2.1.16.9	When a particular alarm is triggered based on the parameters in the objects in the <i>alarm</i> group, an event is generated. This group controls how these events are processed, including creating and sending an SNMP trap message to a network monitoring station.

The original RMON standard was heavily oriented around Ethernet LANs, and you can see some of that in the table above. Probes can also gather and report information related to other networking technologies, by using other RMON groups created for that purpose. The best example of this was the definition of a set of groups specifically for Token Ring, which was defined in RFC 1513 in 1993.

### ***RMON Alarms, Events and Statistics***

Alarms and events are particularly useful constructs in RMON, as they allow the immediate communication of important information to a network management station. The administrator has full control over what conditions will cause an alarm to be “sounded” and how an event is generated. This includes specifying what variables or statistics to monitor, how often to check them, and what values will trigger an alarm. A log entry may also be recorded when an event occurs. If an event results in transmission of a trap message, the administrator will thus be notified and can decide how to respond, depending on the severity of the event.

Like all MIB modules and groups, a particular manufacturer may decide which RMON groups to implement. However, certain groups are related, such as *alarm* and *event*, and some groups such as *statistics* are pretty much always implemented in all RMON probes. Obviously, when RMON is used, the network management station must be aware of RMON groups and must allow a network management application to be run that will exploit the capabilities of the RMON MIB objects.

---

# TCP/IP Key Applications and Application Protocols

For centuries, philosophers have struggled with this question: “what's it all about?” Needless to say, the meaning of life is a bit beyond the scope of this Guide. ☺ However, we **can** examine this quandary within the scope of networking itself. What is networking for? Why do we bother creating networks anyway? What's it all about?

The simplified answer is that all of the hardware devices, software modules and layered protocols examined in this Guide are means to one real end: enabling people to use networking *applications*. The true **power of layering** is that it allows applications to be created that automatically make use of lower-level technologies to communicate without having to worry about the details of how the communication is accomplished. This frees application programmers to create a wide variety of applications that find many different ways to facilitate the exchange information.

The **TCP/IP protocol suite** is the foundation of modern internetworking, and for this reason, has been used as the primary platform for the development and implementation of networking applications. Over the last few decade, as the global TCP/IP Internet has grown, hundreds of new applications have been created. These programs enable a myriad of different tasks and functions to be accomplished, ranging from implementing essential business tasks to pure entertainment, by users who may be in the same room or on different continents.

It would be impossible to try to describe every possible TCP/IP application, and pointless to even try. However, of all the TCP/IP applications, there are a small number that are widely considered to be “key applications” of TCP/IP. Most have been around for a very long time—in some cases, longer than even the modern Internet Protocol itself. They are generally implemented as TCP/IP *application protocols* and are defined using the same **RFC process and standards** as other TCP/IP protocol suite components.

This section describes some of these definitive TCP/IP applications and application layer protocols. Before getting into the applications themselves, I explain the universal system set up for TCP/IP applications to use for addressing Internet resources: uniform resource identifiers (URIs), which can be either uniform resource locators (URLs) or uniform resource names (URNs). These are best known for their use on the World Wide Web, but can in fact be used by a variety of applications.

I then provide several subsections that discuss the application groups themselves. The first describes file and message transfer applications; this group is the largest, as it contains many of the applications we consider central to TCP/IP networking, such as electronic mail, file transfer and the World Wide Web. The second describes interactive and remote application protocols, which are used traditionally to allow a user of one computer to access another, or to permit the real-time exchange of information. The third discusses TCP/IP administration and troubleshooting utilities, which can be employed by both administrators and end users alike.

---

## **TCP/IP Application Layer Addressing: Uniform Resource Identifiers, Locators and Names (URIs, URLs and URNs)**

The Internet consists of millions of interconnected servers, each of which is capable of providing useful information to Internet users who request it. The more information a network has, the richer it is, but the more difficult it becomes to locate. In order to use information, we need to be able to find it, and that requires at a minimum that we employ some means for labeling each file or object.

For this purpose, TCP/IP has defined a system of *Uniform Resource Identifiers (URIs)* that can be used both on the Internet and on private TCP/IP networks. Each URI uniquely specifies how a client can locate a particular resource and access it so it can be used. URIs are subdivided into *Uniform Resource Locators (URLs)* and *Uniform Resource Names (URNs)*, which serve a similar purpose but work in different ways.

In this section I describe the system of addressing used on the Internet to identify files, objects and resources. I begin with an overview, which introduces the concept of Uniform Resource Identifiers (URIs), and explains the differences between URIs, URLs and URNs. At the present time, URLs are used much more often than URNs. Therefore, I have included a full subsection with several topics that cover in detail the syntax of URLs, as well as important issues related to how they are used. I also have a summary topic that gives a summary overview of URNs and their role in Internet addressing.

---

## **Uniform Resource Identifiers, Locators and Names (URIs, URLs and URNs): Overview, History, Significance and Standards**

If you've been “working your way up” the [OSI Reference Model layers](#) in reading this Guide, you might well have expected that you'd be done with addressing by this point. After all, we have already discussed [MAC addresses at layer two](#) and [IP addresses at layer three](#), and [mechanisms for converting between them](#). We even have [ports and sockets that provide transport layer addressing capabilities](#) to let each device run multiple software applications. Given all this, the idea of “application layer addressing” may seem a bit strange, and I am aware that using the term to refer to the subject of this section may be a bit unorthodox.

### ***The Rationale for Application Layer Addressing***

The concept of addressing for applications isn't really as odd as it might seem at first, however. It's true that with an IP address and a port number we can theoretically access any resource on a TCP/IP internet—the problem is *finding it*. Application layer addressing is not something that is required by the computer software; it is something that makes it easier for humans to identify and locate resources.

This is in fact very much the same rationale that is used to justify the creation of [name systems](#), such as the [Domain Name System \(DNS\)](#). DNS is a form of high-level addressing that allows names to be used instead of IP addresses. It too is important not so much for computers but rather for people, who understand what “www.intel.com” means much more than “198.175.96.33”.

The idea behind a comprehensive application layer addressing scheme is to extend to the next level what DNS has already accomplished. DNS names provide essential high-level abstract addressing, but only of whole devices (whether real or virtual). These names can be used as the basis for a more complete labeling scheme that points not just to a site or device, but to a specific file, object or other resource. In TCP/IP, these labels are called *Uniform Resource Identifiers (URIs)*.

URIs were one of the key technologies developed as part of the [World Wide Web \(WWW\)](#), and are still most often associated with WWW and the protocol that implements it, [HTTP](#). You have likely used URIs thousands of times in the past; whenever you have entered something like “http://www.myfavoritewebsite.com” into a Web browser, you were using a URI. (URI? Isn't that a URL? I'm getting there, I promise.)

The reason why URIs are so important to the Web is that they combine into one string all of the information necessary to refer to a resource. This *compactness of expression* is essential to the entire concept of hypertext resource linking. If we want to be able to have an object in one document point to another, we need to have a simple way of describing that object without requiring a whole set of instructions. URIs allow us to do exactly that.

In fact, URIs are so associated with the Web that they are usually described as being part of Web technology specifically. They are not, however, unique to the Web, which is why this section is separate from that discussing WWW/HTTP.

---

## URI Categories

URIs are in fact a general purpose method for referring to many kinds of TCP/IP resources. They are currently divided into two primary categories based on how they describe a resource:

- ☉ **Uniform Resource Locators (URLs):** A [URL](#) is a uniform resource identifier that refers to a resource through the combination of a protocol or access mechanism and a specific resource location. A URL begins with the name of the protocol to be used for accessing the resource and then contains sufficient information to point to how it can be obtained.
- ☉ **Uniform Resource Names (URNs):** A [URN](#) is a uniform resource identifier that provides a way of uniquely naming a resource without specifying an access protocol or mechanism, and without specifying a particular location.

The difference between a URL and a URN is that the former is much more specific and oriented around **how** to access a resource, while the latter is more abstract and designed more to identify **what** the resource is than describe how to get it. Giving someone a URL is like giving them directions to find a book, as follows: “Take the train to Albuquerque, then Bus #11 to 41 Albert Street, a red brick house owned by Joanne Johnson. The book you want is the third from the right on the bottom of the bookshelf on the second floor”. A URN is more like referring to a book using its International Standard Book Number (ISBN); it uniquely identifies the book regardless of where the book may be located, and doesn't tell you how to access it. (In fact, ISBNs are one of the identification systems used with URNs.)

While URLs and URNs are theoretical peers, in practice, URLs are used far more than URNs. In fact, URLs are so dominant that most people have never even **heard of** URIs or URNs. The reason is that even though the example above suggests that URNs are more “natural” than URLs, URLs are easier to use in practice—they provide the information needed to access a resource, and without being able to access a resource, simply knowing how to identify it is of limited value. URNs are an attractive concept because they identify a resource without tying it to a specific access mechanism or location. However, the implementation of URNs requires some means of tying the permanent identifier of a resource to where it is at any given moment, which is not a simple task. For this reason, URNs and the methods for using them have been in development for a number of years, while URLs have been in active use all that time.

While URLs began with the Web and most URLs are still used with HTTP, they can and do refer to resources that are accessed using many other protocols, such as [FTP](#) and [Telnet](#). Again here, the compactness of URIs makes them very powerful; with a URL, we can use one string to tell a program to retrieve a file using FTP. This replaces the [complete FTP process](#) of starting an FTP client, establishing a session, logging in and issuing commands.

**Key Concept:** Some sort of mechanism is needed on any internetwork to allow resources such as files, directories and programs to be identified and accessed. In TCP/IP, *Uniform Resource Identifiers (URIs)* are used for this sort of “application layer addressing”. The two types of URIs are *Uniform Resource Locators (URLs)*, which specify how to access an object using a combination of an access method and location, and *Uniform Resource Names (URNs)*, which identify an object by name but do not indicate how to access it.

---

## **URI Standards**

A number of Internet standards published in the 1990s describe the syntax and basic use of URIs, URLs and URNs. The first was RFC 1630, *Universal Resource Identifiers in WWW*, which was published in 1994 and is still a good overview of the topic. In December 1994 a pair of documents, RFCs 1737 and 1738, provided more specific information about URNs and URLs respectively. RFC 1808 describes how to define and use [relative URLs](#), while RFC 2141 provides more information on URN syntax.

RFC 2396, *Uniform Resource Identifiers (URI): Generic Syntax*, was published in August 1998 to revise and replace some of the information in many of the previous RFCs just mentioned. It is probably the definitive standard on URIs at the present time, though RFCs continue to be published discussing issues related to URIs. This is especially true of URNs, which as I said before, are still in active development.

The base documents such as RFC 2396 describe how URLs can be specified for a number of common protocols (called *schemes* in URL-speak, as we will see when we look at URLs more closely). To provide flexibility, a mechanism was also defined to allow new URL schemes to be registered. This is described in RFC 2717, *Registration Procedures for URL Scheme Names*, and RFC 2718, *Guidelines for new URL Schemes*. There are also a few RFCs that describe specific URL schemes for different protocols, including RFCs 2192 ([IMAP](#)), 2224 ([NFS](#)), 2368 ([e-mail](#)) and 2384 ([POP](#)).

---

## Uniform Resource Locators (URLs)

Uniform Resource Locators (URLs) are text strings that allow a resource such as a file or other object to be labelled based on its location on an internetwork and the primary method or protocol by which it may be accessed. URLs have become the most common type of [Uniform Resource Identifier \(URI\)](#) used for application layer addressing in TCP/IP because of their simplicity.

In this section I provide a detailed explanation of Uniform Resource Locators and how they are used. I begin with an overview of the general syntax used for standard URLs, sometimes called “absolute” URLs to distinguish them from relative URLs. I then provide a description of the URL schemes used for the most common applications and access methods, and the specific syntax used by each. I then discuss how relative URLs work and why they are important. Finally, I discuss some of the real world issues associated with using URLs; this includes problems related to long and complex URLs, as well as the intentional obfuscation “games” being played by some unscrupulous people.

**Background Information:** Please be sure you have read [the overview topic on URIs, URLs and URNs](#) before reading this section, as that topic contains an essential overall introduction to what URLs are.

---

### URL General Syntax

Uniform Resource Locators (URLs) are a subset of [Uniform Resource Identifiers \(URIs\)](#) that consist of two components that identify how to access a resource on a TCP/IP internetwork. These two components are the *location* of the resource, and the *method* to be used to access it. These two pieces of information, taken together, allow a user with the appropriate software to obtain, read or otherwise work with many different kinds of resources such as files, objects, programs and much more.

The most general form of syntax for a URL contains only two elements, which correspond to the two pieces of information just described:

`<scheme>:<scheme-specific-part>`

The term *scheme* refers to a type of access method, which describes the way that the resource is to be used; it usually refers to either an application protocol, such as “http” or “ftp”, or a resource type such as “file”. A scheme name must contain only letters, plus signs (“+”), periods (“.”) and hyphens (“-”). In practice, they usually contain only letters. Schemes are case-insensitive but usually expressed in lower case.

The rest of the URL after the scheme (and the required colon separator) is scheme-specific. This is necessary because various protocols and access methods require different types and quantities of information to identify a particular resource. When a URL is read, the scheme name tells the program parsing it how to interpret the syntax of the rest of the URL.

**Key Concept:** *Uniform Resource Locators (URLs)* are the most widely-used type of URI. In its most basic form, a URL consists of two elements: a *scheme* that defines the protocol or other mechanism for accessing the resource, and a *scheme-specific part* that contains information that identifies the specific resource and indicates how it should be used. Some schemes use a common syntax for their scheme-specific parts, while others use a syntax unique to the scheme.

---

### **Common Internet Scheme Syntax**

In theory, each scheme may use a completely different syntax entirely for the “<scheme-specific-part>”. However, many of these schemes share a common syntax for this part, by virtue of the similarities in how they refer to internetwork devices and resources on those devices. For example, both HTTP and FTP are used to point to specific TCP/IP devices using a DNS name or IP address, and then access resources stored in a hierarchical directory structure. It makes sense that their URLs would be at least somewhat similar.

The most general form of this common Internet scheme syntax is as follows:

`<scheme>://<user>:<password>@<host>:<port>/<url-path>;<params>?<query>#<fragment>`

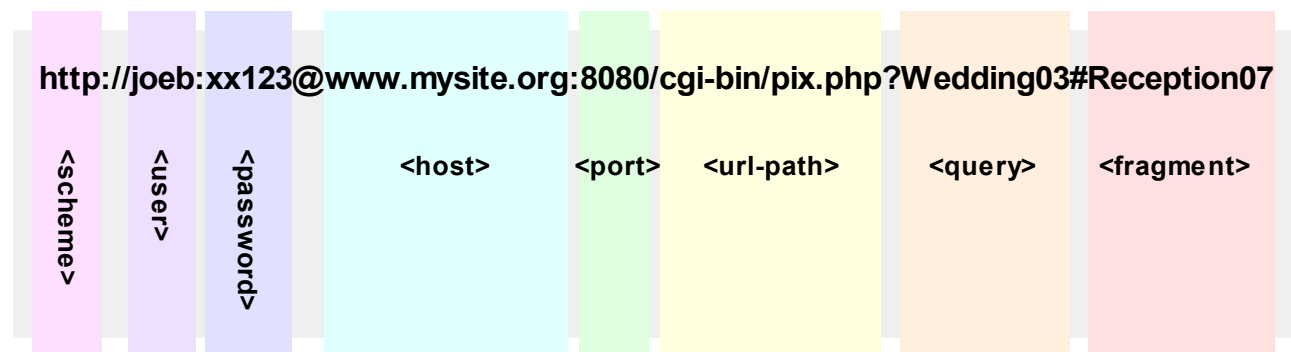

The elements of this syntax are as follows:

- ① **<scheme>**: The URL scheme, as described above.
- ② **<user> and <password>**: Authentication information for schemes requiring a login, in the form of a user name and password.
- ③ **<host>**: An Internet host, usually specified either as a [fully qualified DNS domain name](#), or an IP address in dotted-decimal notation.
- ④ **<port>**: A [TCP or UDP port number](#) to use when invoking the protocol appropriate to the scheme.
- ⑤ **<url-path>**: A resource location path. This is usually a full directory path expressing the sequence of directories to be traversed from the root directory to the place where the resource is located, and then the resource's name. For example, if on a device there is a directory called “project1” and within it a subdirectory called “memos” containing a text file called “June11th-minutes.txt”, the URL path “project1/memos/June11th-minutes.txt” would refer to that resource.

Note that the slash before the <url-path> is required, and while it is technically not considered part of the path, it serves the purpose of “acting” like the slash denoting the root directory in many file systems. Also, the <url-path> may end in a slash, which means that the path refers specifically to a directory. However, this is often not required, as the server will treat the URL as a directory reference by context when needed. A path may also refer to a virtual file, program or resource other than a “normal” file.

- ☉ **<params>**: Scheme-specific parameters included to control how the scheme is used to access the resource. Each parameter is generally of the form “<parameter>=<value>”, with each parameter specification separated from the next using a semi-colon.
- ☉ **<query>**: An optional query or other information to be passed to the server when the resource is accessed.
- ☉ **<fragment>**: Identifies a particular place within a resource that the user of the URL is interested in.

Figure 287 illustrates this common syntax and its elements using an example HTTP URL.

**Figure 287: Example Uniform Resource Locator (URL)**

This diagram shows a sample URL that includes almost all of the possible elements in the general scheme syntax, each of them highlighted using snazzy rainbow-colored boxes. ☉ This URL identifies a Web (HTTP) resource that must be accessed using a particular password at the site “www.mysite.org” using port 8080. The resource in this case is a PHP program in the site’s “cgi-bin” directory that causes a particular page of photographs to be displayed. The “<fragment>” specifier will cause the picture “Reception07” on the retrieved page of wedding photos to be displayed to the user.

### ***Omission of URL Syntax Elements***

The full URL syntax may seem very complicated, but bear in mind that this is a formal definition and shows all of the possible elements in a URL at once. Most schemes do not use every one of these elements, and furthermore, many of them are optional even when they are valid in a particular scheme. For example, the <login> and <password> are officially supported for HTTP URLs, but are very rarely used. Similarly, port numbers are most often omitted, telling the client software to just use the default port number for the scheme. [The next topic](#) describes some of the most common URL schemes and the specific syntaxes used for them, including discussing how and when these elements are employed.

Even though the richness of the URL syntax isn't often needed, it can be useful for supplying a wide variety of information in special cases. URLs are also very flexible in terms of how they may be expressed. For example, while a “<host>” is usually a DNS name, it can also be an IP address expressed in many forms including dotted-decimal, regular decimal, hexadecimal, octal and even a combination of these. Unfortunately, the lack of familiarity

---

that most people have with some of these “esoterics” has led to [URLs being abused through deliberate obscurity](#), to get people to visit “resources” they would normally want to avoid.

## **URL Fragments**

Technically, a “<fragment>” is not considered a formal part of the URL by the standards that describe resource naming. The reason is that it only identifies a portion of a resource, and is not part of the information required to identify the resource itself. It is not sent to the server but retained by the client software, to guide it in how to display or use the resource. Some would make a valid argument, however, that this distinction is somewhat arbitrary; consider, for example, that the scheme itself is also used only by the client, as is the host itself.

The most common example of a URL fragment is specifying a particular bookmark to “scroll” to in displaying a Web page. In practice, a fragment identifier is often treated **as if** it were part of a URL since it is part of the string that specifies a URL.

## ***“Unsafe” Characters and Special Encodings***

URLs are normally expressed in the standard US ASCII character set, which is the default used by most TCP/IP application protocols. Certain characters in the set are called *unsafe*, because they have special meaning in different contexts, and including them in a URL would lead to ambiguity or problems in of how they should be interpreted. The “space” character is the classical “unsafe” character because spaces are normally used to separate URLs, so including one in a URL would break the URL into “pieces”. Other characters are “unsafe” because they have special significance in a URL, such as the colon (“:”).

The “safe” characters in a URL are alphanumerics (A to Z, a to z and 0 to 9) and the following special characters: the dollar sign (“\$”), hyphen (“-”), underscore (“\_”), period (“.”), plus sign (“+”), exclamation point (“!”), asterisk (“\*”), apostrophe (“’”), left parenthesis (“(”), and right parenthesis (“)” ). All other “unsafe” characters can be represented in a URL using an encoding scheme consisting of a percent sign (“%”) followed by the hexadecimal ASCII value of the character. The most common examples are given in [Table 224](#).

**Table 224: URL Special Character Encodings**

Character	Encoding	Character	Encoding	Character	Encoding
<space>	%20	<	%3C	>	%3E
#	%23	%	%25	{	%7B
}	%7D		%7C	\	%5C
^	%5E	~	%7E	[	%5B
]	%5D		`%60	;	%3B
/	%2F	?	%3F	:	%3A
@	%40	=	%3D	%	%26

---

When these sequences are encountered, they are interpreted as the literal character they represent, without any “significance”. So, the URL “http://www.myfavesite.com/are%20you%20there%3F” points to a file called “are you there?” on “www.myfavesite.com”. The “%20” codes prevent the spaces from breaking up the URL, and the “3F” prevents the question mark in the file name from being interpreted as a special URL character.

**Note:** Since the percent sign is used for this encoding mechanism, it itself is “special”; any time it is seen the next values are interpreted as character encodings, so to embed a literal percent sign, it must be encoded as “%25”.

Again, these encodings are sometimes abused for nefarious purposes, unfortunately, such as using them for regular ASCII characters to [obscure URLs](#).

## **URL Schemes (Applications / Access Methods) and Scheme-Specific Syntaxes**

Uniform Resource Locators (URLs) use a general syntax that describes the location and method for accessing a TCP/IP resource. Each access method, called a *scheme*, has its own specific URL syntax, including the various pieces of information required by the method to identify a resource. RFC 1738 includes a description of the specific syntaxes used by several popular URL schemes. Others have been defined in subsequent RFCs using the procedure established for URL scheme registration.

Several of the URL schemes use the common Internet pattern given in my [overview of URL syntax](#). Other schemes use entirely different (usually simpler) structures based on their needs. For reference, I will repeat the general syntax again here, as it will help you understand the rest of the topic:

`<scheme>://<user>:<password>@<host>:<port>/<url-path>;<params>?<query>#<fragment>`

The following are the most common URL schemes and the scheme-specific syntaxes they use.

### ***World Wide Web / Hypertext Transfer Protocol URL Syntax (http)***

[The Web](#) potentially uses most of the elements of the common Internet scheme syntax, as follows:

`http://<user>:<password>@<host>:<port>/<url-path>?<query>#<bookmark>`

As discussed in the overview, the Web is the primary application using URLs today. A URL can theoretically contain most of the common URL syntax elements, but in practice most are omitted. Most URLs contain only a host and a path to a resource. The port number is usually omitted, implying that the default value of 80 should be used. The “<query>” construct is often used to pass arguments or information from the client to the Web server.

---

I have provided full details on how Web URLs are used in [a separate topic in the section on HTTP](#).

### ***File Transfer Protocol URL Syntax (ftp)***

The syntax for FTP URLs is:

*ftp://<user>:<password>@<host>:<port>/<url-path>;type=<typecode>*

**FTP** is an interactive command-based protocol, so it may seem odd to use a URL for FTP. However, one of the most common uses of FTP is to access and read a single, particular file, and this is what an FTP URL allows a client to do. The <user> and <password> are used for login and may be omitted for [anonymous FTP access](#). The port number is usually omitted and defaults to the standard FTP control channel port, 21.

The “<url-path>” is interpreted as a directory structure and file name. The appropriate “CWD” (“change working directory”) [commands](#) are issued to go to the specified directory, and then a “RETR” (“retrieve”) command is issued for the named file. The optional “type” parameter can be used to indicate the [file type](#): “a” to specify an ASCII file retrieval or “i” for an image (binary) file. The “type” parameter is often omitted from the URL, with the correct mode being set automatically by the client based on the name of the file.

For example, consider this URL:

*ftp://ftp.hardwarecompanyx.com/drivers/widgetdriver.zip*

This is equivalent to starting an FTP client, making an anonymous FTP connection to “ftp.hardwarecompanyx.com”, then changing to the “drivers” directory and retrieving the file “widgetdriver.zip”. The client will retrieve the file in binary mode because it is a compressed “zip” file.

It is also possible to use an FTP URL to get a listing of the files within a particular directory. This allows a user to navigate an FTP server's directory structure using URL links to find the file he or she wants, and then retrieve it. This is done by specifying a directory name for the <url-path> and using the “type” parameter with a “<typecode>” of “d” to request a directory listing. Again, the “type” parameter is usually omitted and the software figures out to send a “LIST” command to the server when a directory name is given in a URL.

### ***URL Syntax for Sending Electronic Mail (mailto)***

A special syntax is defined to allow a URL to represent the command to send mail to a user:

*mailto:<e-mail-address>*

The [e-mail address](#) is in standard Internet form: “<username>@<domainname>”. This is really an unusual type of URL because it does not really represent an object at all, though a person can be considered a type of “resource”.

**Note:** Note that optional parameters, such as the subject of the e-mail, can also be included in a *mailto* URL. This facility is not often used, however.

---

### **Gopher Protocol URL Syntax (*gopher*)**

The syntax for the Gopher Protocol is similar to that of HTTP and FTP:

*gopher://<host>:<port>/<gopher-path>*

See the [topic on the Gopher protocol](#) for more information on Gopher paths and how the protocol operates.

### **Network News / Usenet URL Syntaxes (*news*)**

Two syntaxes are defined for URL specification of Usenet (NetNews):

*news://<newsgroup-name>*  
*news://<message-id>*

Both of these URLs are used to access a [Usenet newsgroup](#) or a specific message, referenced by message ID. Like the “mailto” scheme, this is a special type of URL because it defines an access method but does not provide the detailed information to describe how to locate a newsgroup or message.

By definition, the first form of this URL is interpreted as being “local”. So for example, “news://alt.food.sushi” means “access the newsgroup *alt.food.sushi* on the local news server, using the default news protocol”. The default news protocol is normally NNTP (see below). The second URL form is global, because message IDs are unique on Usenet (or at least, are supposed to be!)

### **Network News Transfer Protocol URL Syntax (*nttp*)**

This is a different URL type for news access:

*nttp://<host>:<port>/<newsgroup-name>/<article-number>*

Unlike “news”, this URL form specifically requests the use of [NNTP](#) and identifies a particular NNTP server. Then it tells the server which newsgroup to access and which article number within that newsgroup. Note that articles are numbered using a different sequence by each server, so this is still a “local” form of news addressing. The port number defaults to 119.

---

Even though the “nntp” form seems to provide a more complete resource specification, the “news” URL is more often used, because it is simpler. It's easier just to set up the appropriate NNTP server in the client software once than to specify it each time, since clients usually only use one NNTP server.

### ***Telnet URL Syntax (telnet)***

This scheme is used to open a [Telnet](#) connection to a server. This is the syntax:

*telnet://<user>:<password>@<host>:<port>*

In practice, the user name and password are often omitted, which causes the Telnet server to prompt for this information. Alternately, the “<user>” can be supplied and the password left out (to prevent it being seen) and the server will prompt for just the password. The port number defaults to the standard port for Telnet, 23, and is also often omitted.

This type of URL is interesting in that it identifies a resource that is not an object but rather a *service*.

### ***Local File URL Syntax (file)***

This is a special URL type used for referring to files on a particular host computer. The standard syntax is:

*file://<host>:<url-path>*

This type of URL is also somewhat interesting, in that it describes the location of an object but not an access method. It is not sufficiently general to allow access to a file anywhere on an internetwork, but is often used for referencing files on computers on a local area network where names have been assigned to different devices.

A special syntax is also defined to refer specifically to files on the local computer:

*file:///<url-path>*

Here, the entire “//<host>:” element has been replaced by a set of three slashes, meaning specifically, “look on the local host”.

### ***Additional URL Syntax Rules***

Additional syntax rules are often used by browsers to support the quirks of Microsoft operating systems, especially for the “file” scheme. First, the backslashes used by Microsoft Windows are expressed as forward slashes as required by TCP/IP. Second, since colons are used in drive letters specifications in Microsoft operating systems, these are replaced by the “vertical pipe” character, “[|]”, which “sorta looks like a colon” (play along, please. ☺)

---

So, to refer to the file “C:\WINDOWS\SYSTEM32\DRIVERS\ETC\HOSTS”, the following URL could be used:

`file:///C:/WINDOWS/SYSTEM32/DRIVERS/ETC/HOSTS`

Note however that some browsers actually **do** allow the colon in the drive specification.

## **URL Relative Syntax and Base URLs**

The Uniform Resource Locator syntax described in [the first topic of this section](#) is sometimes said to specify an *absolute* URL. This is because the information in the URL is sufficient to completely identify the resource. Absolute URLs thus have the property of being *context-independent*, meaning that one can access and retrieve the resource using the URL without any additional information required.

Since the entire point of a URL is to provide the information needed to locate and access a resource, it makes sense that we would want them to be absolute in definition most of the time. The problem with absolute URLs is that they can be long and cumbersome. There are cases where many different resources need to be identified that have a relationship to each other; the URLs for these resources often have many common elements. Using absolute URLs in such situations leads to a lot of excess and redundant “verbiage”.

### ***The Motivation for Relative URLs***

In my [overview of URIs](#) I gave a “real world” analogy to a URL in the form of a description of an “access method” and location for a person retrieving a book: “Take the train to Albuquerque, then Bus #11 to 41 Albert Street, a red brick house owned by Joanne Johnson. The book you want is the third from the right on the bottom of the bookshelf on the second floor”.

What if I also wanted the same person to get a second book located in the same house on the ground floor after getting the first one? Should I start by saying again “take the train to Albuquerque, then Bus #11 to 41 Albert Street, a red brick house owned by Joanne Johnson”? Why bother, when they are already there at that house? No, I would give a second instruction in **relative** terms: “go back downstairs, and also get the blue book on the wood table”. This instruction only makes sense in the context of the original one.

The same need arises in URLs. Consider a Web page located at “http://www.longdomain-namesareirritating.com/index.htm” that has 37 embedded graphic images in it. The poor guy stuck with maintaining this site doesn’t want to have to put “http://www.longdomain-namesareirritating.com/” in front of the URL of every image.

Similarly, if we have just taken a directory listing at “ftp://ftp.somesitesomewhere.org/very/deep/directory/structures/also/stink/” and we want to explore the parent directory, we would like to just say “go up one level” without having to say “ftp://ftp.somesitesomewhere.org/very/deep/directory/structures/also/”.

---

## Creating and Interpreting Relative URLs

It is for these reasons that URL syntax was extended to include a *relative* form. In simplest terms, a relative URL is the same as an absolute URL but with pieces of information omitted that are implied by context. Like our “go downstairs” instruction, a relative URL does not by itself contain enough information to specify a resource. A relative URL **must** be interpreted within a context that provides the missing information.

The context needed to find a resource from a relative URL is provided in the form of a *base URL* that provides the missing information. A base URL must be either a specific absolute URL, or itself a relative URL that refers to some other absolute base. The base URL may be either explicitly stated or may be inferred from use. The RFCs dealing with URLs define three methods for determining the base URL, which are arranged into the following precedence:

1. **Base URL Within Document:** Some documents allow the base URL to be explicitly stated. If present, this specification is used for any relative URLs in the document.
2. **Base URL From Encapsulating Entity:** In cases where no explicit base URL is specified in a document, but the document is part of a higher-level entity enclosing it, the base URL is the URL of the “parent” document. For example, a document within a body part of a [MIME multipart message](#) can use the URL of the message as a whole as the base URL for relative references.
3. **Base URL From Retrieval URL:** If neither of those two methods are feasible, the base URL is inferred from the URL used to retrieve the document containing the relative URL.

Of these three methods, #1 and #3 are the most common. [HTML](#), the language used for the Web, allows a base URL to be explicitly stated which removes any doubt about how relative URLs are to be interpreted. Failing this, method #3 is commonly used for images and other links in HTML documents that are specified in relative terms.

For example, let's go back to the poor slob maintaining “<http://www.longdomainnamesareirritating.com/index.htm>”. By default, any images referenced from that “index.htm” HTML document can use relative URLs—the base URL will be assumed from the name of the document itself. So he can just say “companylogo.gif” instead of “<http://www.longdomainnamesareirritating.com/companylogo.gif>”, as long as that file is in the same directory on the same server as “index.htm”.

If all three of these methods fail for whatever reason, then no base URL can be determined. Relative URLs in such a document will be interpreted as absolute URLs, and since they do not contain complete information, they will not work properly.

Also, relative URLs only have meaning for certain URL schemes. For others, they make no sense and cannot be used. In particular, relative URLs are never used for the “telnet”, “mailto” and “news” schemes. They are very commonly used for HTTP documents, and may also be used for FTP and file URLs.

**Key Concept:** Regular URLs are *absolute*, meaning that they include all of the information needed to fully specify how to access a resource. In situations where many resources need to be accessed that are approximately in the same place or are related in some way, completely specifying a URL can be inefficient. Instead, *relative* URLs can be used, which specify how to access a resource relative to the location of another one. A relative URL can only be interpreted within the context of a base URL that provides any information missing from the relative reference.

---

### ***Practical Interpretation of Relative URLs***

The description above probably seems confusing, but relative URLs are actually fairly easy to understand, because they are interpreted in a rather “common sense” way. You simply take the base URL and the relative URL, and you substitute whatever information is in the relative URL for the appropriate information in the base URL to get the resulting equivalent absolute reference. In so doing, you must “drop” any elements that are more specific than the ones being replaced.

What do I mean by “more specific”? Well, most URLs can be considered to move from “most general” to “most specific” in terms of the location they specify. As you go from left to right, you go through the host name, then high-level directories, subdirectories, the file name, and optionally, parameters/query/fragment applied to the file name. If a relative URL specifies a new file name, it replaces the file name in the base URL, and any parameters/query/fragment are dropped as they no longer have meaning given that the file name has changed. If the relative URL changes the host name, the entire directory structure, file name and everything else “to the right” of the host name “goes away”, replaced with any that might have been included in the new host name specification.

This is hard to explain in words but easy to understand with a few examples. Let's assume we start with the following explicit base URL:

`http://site.net/dir1/subdir1/file1?query1#bookmark1`

Table 225 shows some example of relative URLs and how they would be interpreted.

**Table 225: Relative URL Specifications and Absolute Equivalents**

Relative URL	Equivalent Absolute URL	Explanation
<b>#bookmark2</b>	http://site.net/dir1/subdir1/file1?query1#bookmark2	The URL is the same except that the bookmark is different. This can be used to reference different places in the same document in HTML.  (Technically, the URL has not changed here, since the “fragment” (bookmark) is not part of the actual URL. A Web browser given a new bookmark name will usually not try to re-access the resource.)
<b>?query2</b>	http://site.net/dir1/subdir1/file1?query2	The same file but with a different query string. Note that the bookmark reference from the base URL is “stripped off”.
<b>file2</b>	http://site.net/dir1/subdir1/file2	Here we have referred to a file using the name “file2”, which replaces “file1” in the base URL. Here both the query and bookmark are removed.
<b>/file2</b>	http://site.net/file2	Since a single slash was included, this means “file2” is in the root directory; this relative URL replaces the entire <url-path> of the base URL.
<b>..</b>	http://site.net/dir1/	The pair of dots refers to the parent directory of the one in the base URL. Since the directory in the base URL is “dir1/subdir1”, this refers to “dir1”.
<b>../file2</b>	http://site.net/dir1/file2	Specifies that we should go up to the parent directory to find the file “file2” in “dir1”.
<b>../subdir2/file2</b>	http://site.net/dir1/subdir2/file2	Go up one directory with “..”, then enter the subdirectory “subdir2” to find “file2”.
<b>../../dir2/subdir2/file2</b>	http://site.net/dir2/subdir2/file2	Same thing as above but going up two directory levels, then down through “dir2” and “subdir2” to find “file2”.
<b>//file2</b>	http://file2	Two slashes means that “file2” replaces the host name, causing everything to the right of the host name to be stripped. This is probably not what was intended, and shows how important it is to watch those slashes. ☺
<b>//www.newsite.net/otherfile.htm</b>	http://www.newsite.net/otherfile.htm	Here everything but the scheme has been replaced. (In practice this form of relative URL is not that common—the scheme is usually included if the site name is specified, for completeness.)
<b>file2?query2#bookmark2</b>	http://site.net/dir1/subdir1/file2?query2#bookmark2	Here we replace the file name, query name and bookmark name.
<b>ftp://differentsite.net/whatever</b>	ftp://differentsite.net/whatever	Using a new scheme forces the URL to be interpreted as absolute.

---

## Improving Document Portability Using Relative URLs

There is one other very important benefit of using relative URLs: avoiding absolute URLs in a document allows it to be more portable by eliminating “hard-coded” references to names that might change. Going back to our previous example, if the guy maintaining the site “<http://www.longdomainnamesareirritating.com/>” uses only relative links to refer to graphics and other embedded objects, then if the site is migrated to “[www.muchshortername.com](http://www.muchshortername.com/)”, he will not have to edit all of his links to the new name. The significance of this in Web URLs is explored further in [the detailed topic on HTTP URLs](#).

**Key Concept:** In addition to being more efficient than absolute URLs, relative URLs have the advantage that they allow a resource designer to avoid the specific mention of names. This increases the portability of documents between locations within a site, or between sites.

---

## URL Length and Complexity Issues

Uniform Resource Locators (URLs) are the most ubiquitous form of resource addressing for some very good reasons: they represent a simple, convenient and easy-to-understand way of finding documents. Popularized by their use on the World Wide Web, URLs can now be seen in everything from electronic document lists to television commercials, a testament to their universality and ease of use.

At least, this is true *most* of the time!

When URLs work, they work very well. Unfortunately, there are also some concerns that arise with respect to how URLs are used. Both accidental and intentional misuse of URLs occurs on a regular basis. Part of why I have devoted so much effort to describing URLs is that most people don't really understand how they work, and this is part of why problems occur.

Many of the issues with URLs are directly due to the related matters of *length* and *complexity*. URLs work best when they are short and simple, so it is clear what they are about and so they are easy to manipulate. For example, “<http://www.ibm.com/>” is recognizable to almost everyone as the [World Wide Web \(WWW\)](#) site of the International Business Machines Corporation (IBM). Similarly, you can probably figure out what this URL does without any explanation: “<ftp://www.somecomputercompany.com/drivers/videodrivers.zip>”.

However, as we have seen earlier in this section, URLs can be much more complex. In particular, the [common Internet syntax](#) used by protocols such as HTTP and FTP is extremely flexible, containing a large number of optional elements that can be used when required to provide the information necessary for a particular resource access.

---

## ***Reasons Why Long URLs are Common***

The point that many elements in URL syntax are **optional** is important. The majority of the time, most of these optional parts are omitted, which makes URLs much simpler in practical use than they are “on paper”. For example, even though an HTTP URL theoretically contains a user name, password, host, port, path, query and bookmark, most URLs use only a host name and a path. This is what helps keep URLs short and easy to use.

Despite this, you will still find some rather long URLs used on the Internet. Here are some of the most common reasons why.

### **Long DNS Domain and Host Names**

Some people don't realize that long host names are hard to remember. If you run the “Super Auto Body Shop & Pizza Parlor”, having a Web site called “www.superauto.com” will make it easier for your customers to find you than trying to register “www.superautobodyshopand-pizza.com”. Yet DNS names of 15, 20 or even more characters are surprisingly common.

### **Long Document or Directory Names**

Similarly, short file names are better than long ones, and again, many people don't think about this before putting files on the Internet, which makes things more difficult for those who must access them.

### **Use of “Unsafe” Characters**

URLs have [a mechanism for dealing with “unsafe” characters](#), but it makes them longer and harder to decipher. Suppose you have a file named:

“{ABC Corp} budget; draft #3; third quarter 2004.htm”

The URL for this will have to be:

“%7BABC%20Corp%7D%20budget%3B%20draft%20%233%3B%20third%20quarter%202004.htm”

The original long file name was readable, but the URL is a mess because of the special character encodings.

Naming the file “ABC budget draft 3, 3Q2004.htm” would be a better choice, and still includes enough information to be understandable. Even better, you could replace the spaces with underscores, to avoid the need for “%20”s entirely: “ABC\_budget\_draft 3,\_3Q2004.htm”.

---

## Parameter Strings

In HTTP URLs, the syntax for specifying a query (following a question mark character) is often used to allow a Web browser to send various types of information to a Web server, especially parameters for interactive queries. These parameter strings can get quite lengthy. For example, I typed in a query to the great Web search engine Google to find recipes for potato salad. This is what the URL for one of the recipe files looks like:

```
"http://groups.google.com/groups?q=%22potato+salad%22&hl=en&lr=&ie=UTF-8&safe=off&selm=B826FB57.89C0%25sbrooks%40ev1.net&rnum=2".
```

Almost all of that consists of parameters that tell the Google server exactly what document I want based on my query. It is necessary, but still cumbersome.

### ***URL Wrapping and Delimiting Issues***

For humans, long and complex URLs are hard to remember and use. In addition to the sheer difficulty of remembering all those characters, there is the issue of URL *wrapping*, which occurs when they are presented in certain forms. Most programs can only display 78 or 80 characters in a single line. If a URL is longer than this, the characters of the URL will “wrap” onto multiple lines; when you read that Google example just above, you probably noticed that.

URL wrapping can lead to mistakes when copying a URL from one form to another, such as if you copied it from this document into your Web browser. If a URL is 81 characters long and 80 are on the first line and the last character on the second line, many users may not realize that the URL has “wrapped” at all. I have seen URLs that are hundreds of characters long, requiring several manual “copy and paste” operations to get the URL to work.

Perhaps surprisingly, some software may not handle this “wrapping” properly either. While this is not a problem when a hyperlink is used in something like an HTML document, it can be troublesome when links are included in an e-mail message or Usenet article.

Another issue is delimiting where a URL starts and ends when it appears. A URL begins with a scheme name that could in theory be used in other contexts that are not URLs. Without a clear way of labeling a URL as being a URL, a software program might not recognize it. Consider discussion of a URL in a document like this one; if I say “Please visit <http://www.thissite.com>; you will see the information you need there”, then we all know the semicolon is part of the sentence and not part of the URL, but a computer program might not be so sure. And again, this problem is worse when a URL is long and complex and wraps on to multiple lines of text?—how does the program recognize the end of the URL?

---

## ***Explicit URL Delimiting and URL Redirectors***

To resolve both the wrapping and delimiting problems, a special URL “super-syntax” is sometimes employed, especially when URLs are used in other text. This is done by surrounding the URL in angle brackets, possibly including the label “URL:” before the scheme name. For example, all of the following are equivalent:

`http://www.networkingistoodarnedcomplicated.com`

`<http://www.networkingistoodarnedcomplicated.com>`

`<URL:http://www.networkingistoodarnedcomplicated.com>`

The angle brackets indicate clearly where the URL begins and ends, making it easier for both programs and humans to deal with long URLs.

Another solution sometimes used for long URLs are *redirection services*, provided by many Web sites. For example, <http://www.tinyurl.com> is a free service that allows someone to create a short URL that automatically loads a resource at a much longer URL.

## ***URL Abbreviation***

One final issue I want to discuss isn't related directly to long or complex URLs, but is related indirectly to the matter of length: URL abbreviation. Many people use URLs so often that they become, well, lazy when it comes to specifying URLs. They tend to leave off portions of the full URL syntax to save time and energy. I don't mean by this that they specify relative URLs, but rather, they specify absolute URLs with “missing pieces”.

For example, rather than type “`http://www.sitename.com`”, they might type “`http:www.sitename.com`”, leaving off the two slashes. More commonly, people omit the scheme name entirely, just entering “`www.sitename.com`”. Technically, this is not a URL, it is just a domain name. However, most Web browsers can handle this, assuming by default that the scheme is “`http://`” if none is provided. (Don't feel bad, I do it too! ☺)

## **URL Obscuration, Obfuscation and General Trickery**

Most of the time, the owner of a resource wants the URL that refers to the resource to be short, simple and easily-understood. Thus, [long and complex URLs](#) are usually the result of necessity, accident or ignorance. Some resources need to have long names for whatever reason, such as the use of the long query string in the Google example; other times, URLs are made long because the owner of the resource doesn't realize that using a long DNS host name or file name will make for a long and unwieldy URL.

Whatever the reasons for these situations, they are not deliberate. Recent years, however, have seen a dramatic rise in the use of *intentionally* long, complex, confusing and deliberately deceptive URLs. These URLs are either structured so that it is impossible to tell what they are, or worse, they are made to appear as if they point to one resource when they really go to another.

---

Why would people do this? Simple: because they fear being open and honest about their “resources”. And who would these people be? Why, they would be the spammers and con artists who overload our Internet e-mail boxes with offers of every sort imaginable, from making you rich beyond your wildest dreams, to inflating the dimensions of certain body parts to unnatural sizes...

They are afraid that if the URL indicated clearly what the “resource” was, you might not click on the link; or that if you identify them as a spammer you might filter out their e-mail. They also figure that if they can make the URL appear to be something interesting, you'll load it. Even if it turns out to be something you didn't expect, maybe you'll pay attention anyway.

(You mean you are too smart to be tricked into buying a product through a deceptive URL? And you would never support a spammer anyway? What a coincidence, same with me! Yet the spam keeps coming; it must work or they wouldn't keep doing it... would they? ☺)

### ***Common Obscuration and Obfuscation Techniques***

It is a cruel irony that [the complex syntax that was built into URLs](#) to allow them to be so flexible, has been exploited by the obnoxious into tricking people. They know that most people are used to seeing simple URLs like “http://www.myfavoritesite.com” and do not realize that the full URL syntax allows the same resource to be specified in literally millions of different ways.

So these people, desperate for hits to their Web sites at any cost, keep coming up with new tricks for manipulating URLs. These are focused on HTTP scheme URLs, though in theory the tricks can be applied to several other types as well (though obviously they won't work with some schemes). Here are some of the more common gimmicks that have been used, past and present (note that if you are trying these out as you read, some examples may not work on certain browsers):

#### **Excessive Length**

In some cases, a URL is just made really long by the addition of lots of gibberish as a “query string”, so that the user's eyes glaze over just looking at it. This is a relatively “unsophisticated” technique, however, since one can easily tell what the real host name is by looking at the start of the URL. Most of the better scammers have moved beyond such simple tricks today.

#### **Regular IP Address Hosts**

Internet users are so accustomed to using [DNS names](#) that they don't realize that one can access a URL using an IP address at all. So most people don't realize that The PC Guide can be accessed as easily using <http://209.68.14.80> as <http://www.PCGuide.com>. (Note that this is not true of all Internet hosts; those that use virtual names cannot be accessed using just an IP address.)

---

This is not really trickery per se. It is quite legitimate, and in some ways even necessary—for example, for accessing a site that is having DNS problems. The problem here is that usually one cannot tell what a site is from the IP address alone, and many people will just click on an IP address link without bothering to find out what it is.

### Numeric Domain Names

It is possible to register a DNS domain name consisting of just a single number. For example, one could register “114.com”. And then one could create subdomains within it such as “42.12.205.114.com”. At first glance this appears to be an IP address specification, so someone might think it would resolve to the address 42.12.205.114—when in reality, it is some other address.

I believe that DNS name registrars have been cracking down on this sort of trickery, so it may not be as prevalent now as it once was.

### Bogus Authentication Information

HTTP URLs theoretically support the inclusion of authentication information, by including “<user>:<password>@” before the host in the URL. Yet the vast majority of Web sites are “open” and neither require nor use it. If you specify an authentication string and it is not needed, it is ignored.

This is one of the most popular techniques at present. One way it is used is by including “authentication information” that looks like a “benign” host, to make the user think the URL is for that host. For example, if I wanted to trick you into visiting The PC Guide, I might use this URL to make it look like clicking it would go to CNN:

<http://www.cnn.com@www.PCGuide.com>

This is still too obvious, however, so this “method” is often combined with some of the techniques below.

### Deceptive Character Encoding

The use of the percent sign to [encode special characters](#) such as spaces and punctuation can also be **abused** to obscure the name of a domain. For example, the following is another way of expressing the DNS name for The PC Guide:

<http://%57%57%57.%50%43%47%55%49%44%45.%43%4F%4D>

Try it. ☺

### IP Address Math Trickery

Okay, this is where things get **really** bizarre. Most of the time, we express an IP address as a [dotted decimal number](#). Remember, however, that to computers, the IP address is just a 32-bit binary number. Most browsers support a rather shocking number of methods for

---

expressing these numbers. This is unfortunate, because this flexibility is really not needed and almost never used for legitimate purposes. It can lead to some really bizarre URLs that are unrecognizable, or that look like regular IP addresses but are not.

Here are some examples, all of which are the same as the IP address form of The PC Guide (<http://209.68.14.80>):

- ☛ **IP Address in Dotted Octal:** A leading zero signifies an IP address where each byte is in octal:

<http://0321.0104.016.0120>

- ☛ **IP Address in Dotted Hexadecimal:** A leading zero followed by an “x” signifies an IP address where each byte is in hexadecimal:

<http://0xD1.0x44.0x0E.0x50>.

- ☛ **IP Address As Single Number:** We can even take the entire 32-bit number and express it as a single number and that will work too. In decimal:

<http://3510898256/>

In octal:

<http://032121007120/>

And, in hexadecimal:

<http://0xd1440e50/>.

### ***Making Matters Worse: Combining Deceptive Tricks***

As if these tricks weren't bad enough taken individually, we can have some real fun by **combining** them! For example, start with the regular PC Guide URL:

<http://www.PCGuide.com>

And convert it to IP:

<http://209.68.14.80>

Then add some bogus authentication gibberish:

<http://www.cnn.com@209.68.14.80>

And convert the real URL into a single number so it looks like a document on the CNN web site:

<http://www.cnn.com@3510898256>

---

Alternately, we can use the octal form, and even include lots of extra leading zeroes just for fun:

```
<http://www.cnn.com@0000000000000321.00000000104.00000000000016.00000120>
```

Believe it or not, this is just the tip of the iceberg. In some browsers, even the IP address numbers can be expressed using “percent sign” ASCII encoding!

While quite irritating, I must give these people points for creativity at least—some of the tricks are quite ingenious. At the same time, their inventiveness is potentially hazardous. While these false URLs are usually more a waste of time than anything harmful, there are sometimes good reasons a person would go to great lengths to hide the identity of a resource. Deceptive URLs are just one more danger that network administrators must deal with today.

**Key Concept:** The syntax of Internet URLs includes many elements that provide great flexibility in how URLs can be constructed. Unfortunately, these capabilities of expression are now often abused by people who create intentionally obfuscated URLs to trick users into accessing their Web sites and other resources. Some of these can be potentially hazardous, which means that care is required before clicking unknown links or accessing strange URLs.

---

---

## **Uniform Resource Names (URNs)**

“HTTP 404 - NOT FOUND”

Have you ever tried to access a Web site or other Internet resource, only to see those dreaded words appear? You probably have, and in seeing them, you have experienced first-hand one of the most common problems with [Uniform Resource Locators \(URLs\)](#).

URLs specify a resource using two key pieces of information: the resource's location, and a method by which the resource may be accessed or retrieved. This focus on the means of access for the resource makes URLs very practical, in that the URL usually contains all the data we need to use the resource. This is why URLs are so widely used today. However, this “access orientation” also means that URLs have a number of serious limitations.

### ***The Problem With URLs***

The main difficulty with URLs is that since they describe a resource based on its location, they tie the resource and its location together inextricably. While this may not seem to be a big deal, it is actually a fairly serious matter in a number of ways, because a resource and its location are not the same thing. It is only because most Internet resources rarely change location that we don't notice this issue more often with URLs.

Suppose that your name is Joe Xavier Zachariah and you live at 44 Glendale Crescent in Sydney, Australia. If someone asked you who you were, would you say “Joe Xavier Zachariah”, or “the man living at 44 Glendale Crescent in Sydney, Australia”? Almost certainly, the former; but a URL would be like describing yourself as a “resource” using the latter description.

Since we realize that Mr. Zachariah is obviously not always going to be at 44 Glendale Crescent, we know that describing him using just a location is not sufficient. The same thing occurs with Internet resources when they are identified using only location.

However, the problem with Internet resources and URLs goes beyond just the matter of movement. Consider a situation where a particular resource is very popular; we might want to duplicate the same resource in multiple locations. Using URLs, we would need a different identifier for each copy of the resource, even though each copy is the same. Again, the problem is that we are not identifying the resource itself but rather the place where it can be found.

### ***Overview of URNs***

In recognition of this issue, an alternative identification mechanism for Internet resources was developed, called *Uniform Resource Names (URNs)*. The basic standard describing URNs is RFC 1737, *Functional Requirements for Uniform Resource Names*, which was published in 1994. In 1997, RFC 2141 was published, which specifies the syntax of URNs.

---

As you can probably tell from that term, a URN is intended to label a resource based on its actual identity, rather than where it can be found. So, where a URL is like Joe Zachariah's address, a URN would be his name. Or, as I gave as an example in [the overview of URIs](#), a URN would be identifying a book based on its ISBN number rather than specifying what bookshelf it is on in a building.

To be useful in identifying a particular resource, it is necessary that a URN be globally unique, and that's not always as simple as it may at first appear. Consider human names, for example. Even though there is probably only one Charles Marlin Kozierok in the entire world, if your name is John Paul Smith or José Garcia, you likely share that name with thousands of others. This means using common names may not be sufficient for identifying human “resources” and some other method might need to be devised.

### ***URN Namespaces and Syntax***

There are many types of resources that URNs are intended to identify on the Internet, each of which may require a different form of naming. To allow URNs to represent many kinds of resources, numerous URN *namespaces* are defined. A namespace is referenced using a unique string that tells the person or computer interpreting the URN what type of resource the URN identifies. The namespace also ensures the uniqueness of URNs, when a particular identifier might exist in more than one context. For example, both North American telephone numbers and ISBN numbers consist of ten digits, so a particular number such as “4167819249” could represent both a telephone number and a book number; the namespace identifier tells us what the number means when it is encountered in a URN.

The general syntax of a URN is:

URN:<namespace-ID>:<resource-identifier>

For example, a book with the ISBN number 0-679-73669-7 could be represented as:

URN:isbn:0-679-73669-7

This string identifies that particular book uniquely, wherever it might happen to be in the world. Many other namespaces have also been defined to specify the URNs for other types of resources, such as documents on the Internet.

**Key Concept:** Where Uniform Resource Locators (URLs) specify a resource based on an access method and location, *Uniform Resource Names (URNs)* identify a resource by name. A URN consists of a *namespace identifier*, which indicates what type of name it contains, and a *resource identifier* that specifies the individual resource within the context of that namespace.

---

---

## ***URN Resolution and Implementation Difficulties***

URNs are a more “natural” way of identifying resources, which gives them intuitive appeal. Despite this, URNs are still not widely used, even though they have been in development for over a decade. The main reason for this is somewhat ironic: it is in fact because of the fact that URNs are independent of location. The very characteristic that provides URNs with identification advantages over URLs also makes URNs much harder to use practically, which has led to long delays in workable URN systems.

To understand the problem, consider the example string “URN:isbn:0-679-73669-7”. This uniquely identifies a particular book, and will always refer to it no matter where the book may be, unlike a URL. The problem is that while the URL-equivalent tells us how to actually find this book, the URN does not. The same thing goes for our human example before: identifying Joe Xavier Zachariah by his name is more “sensible” than identifying him as “the man living at 44 Glendale Crescent in Sydney, Australia”, but at least with the latter, we know where Joe is!

In order for URNs to be useful on an internetwork, they require an additional mechanism for translating a simple URN identification string into a particular location and/or access method. In other words, we need to be able to change a URN into the equivalent of a URL, so that the resource can be found. This requirement is analogous to the problem of [resolving Internet DNS domain names into IP addresses](#), and the same term is used to describe it: *URN resolution*.

Ideally, we want to be able to use some sort of technique where we specify the name “Joe Xavier Zachariah” and we are told where Joe is so we can find him. Or, we provide the string “URN:isbn:0-679-73669-7” and are provided with a list of libraries or other places where the book can be found. The power of URNs can also be exploited in such a system, by having the resolution system specify the location of a copy of the resource that is closest (in terms of network distance, cost or other measurements) to the entity making the request.

However, setting up URN resolution mechanisms is a non-trivial task. The matter of URN resolution has been the subject of much of the work on URNs over the last decade. RFC 2483, *URI Resolution Services Necessary for URN Resolution*, was published in 1999 and discusses some of the important issues in URN resolution. In October 2002, a series of RFCs, 3401 to 3405, defined a new system called the *Dynamic Delegation Discovery System (DDDS)* that was designed not just to resolve URNs, but to handle the entire class of resolution problems where an identifier is given and the output is information about where to get more information about that identifier. RFC 3406 was published at the same time, providing more information about URN namespaces.

**Key Concept:** Since URNs identify resources by name rather than location, they are a more *natural* way of identifying resources than using URLs. Unfortunately, this advantage is also a disadvantage, since URNs don't, by themselves, provide a user with the necessary information to find the resource so it can be used. A process of *URN resolution* must be performed to transform the URN into a set of information that allows the resource to be accessed.

---

Although progress on URNs has been slow, it has been steady. While it may yet be a few years before URNs are widely used, I believe it is likely that they will play an increasingly prominent role in identifying resources on the Internet in the future.

---

## **TCP/IP File and Message Transfer Applications and Protocols** **(FTP, TFTP, Electronic Mail, USENET, HTTP/WWW, Gopher)**

The purpose of networking applications is to allow different types of information to be sent between networked devices. In the world of computers, information is most often arranged into discrete units called *files*. When those files are created specifically for the purpose of communication, they are often called *messages*. One of the most important groups of TCP/IP applications is the one that describes the basic mechanisms for moving these files between internetworked devices: *file and message transfer applications*.

In this section I describe in detail the most important applications used in TCP/IP for file and message transfer, and the protocols that implement them. I begin with an overview of these applications, and a description of the differences between them. I then include four subsections that describe the four most important file/message transfer application families: explicit file transfer, electronic mail, network news (Usenet) and hypertext (the World Wide Web). I also provide a brief look at the Gopher protocol, which has fallen out of favor but is worth a quick mention, especially due to its role as an historical precursor of the Web.

**Related Information:** I have made the decision to draw a distinction between application protocols that are normally used **explicitly** by a user to move messages and files, and those that are used **implicitly** to share files. The former usually use specific commands to transfer data and are described in this section. The latter work by creating the appearance to the user that a file on a remote device is actually local, by transmitting commands and data over the network automatically, and are described in a separate section on [network file and resource sharing protocols](#). In TCP/IP, this sharing function is most often performed by the [Network File System \(NFS\)](#).

---

---

## **File and Message Transfer Overview and Application Categories**

I said in [the introduction to this section](#) that file and message transfer applications are one of the most important types used in TCP/IP. Transferring files between networked computers is the most basic type of network communication. In fact, it wouldn't even be an exaggeration to say that this may be *the* most important class of internetworking applications. Some of the members of this group are so common that many people use them every day without even thinking about it.

To understand these applications, let's first take a quick step back to look at the fundamental concept of a "file". Simply put, a file is just a collection of information that is treated as a single unit by a computer system. Files are stored in directories or folders in a *file system*. In modern computers, files are normally expressed as a sequence of bytes or characters, and each file is read, written, copied or otherwise manipulated as an independent object. In addition to the data it contains, each file has associated with it file *attributes* that describe it.

For our purposes, the critical characteristic of a file is that it is a self-contained object carrying arbitrary information. Since files are the building blocks of information in computer systems, it's no surprise that the transfer of information in networking was originally defined in terms of the movement of these files. Some of the protocols describing how to transfer files predate all of the modern protocols in the lower levels of TCP/IP, including [IP version 4](#), [TCP](#) and [UDP](#). It's not the case that file transfer was an early application of internetworking, but that internetworking was invented in large part to permit file transfer!

Files in modern computing systems are inherently designed to be generic; they can contain any type of information. The significance of the contents of a file depends entirely on the user or software program that examines it. The TCP/IP file and message transfer protocols have in common the notion of moving files from one computer to another. Where they differ is in how the files are handled and processed. There are two basic approaches: general file transfer, and message transfer.

### ***General File Transfer***

General transfer applications normally treat the file as a "black box", moving them from place to place and paying little or no attention to what the files contain. The TCP/IP [File Transfer Protocol \(FTP\)](#) and [Trivial File Transfer Protocol \(TFTP\)](#) fall into this category. FTP has been around in one form or another for over 30 years now and is still widely used.

### ***Message Transfer***

Other TCP/IP applications work with particular types of files, processing and interpreting them in various ways. These files are usually designed for the specific purpose of communication, and are thus called *messages*; these applications allow users to construct, send and receive messages that fit a particular message format. There are several prominent TCP/IP messaging applications we'll examine in this Guide:

- 
- ☉ **Electronic Mail (E-Mail):** A system that allows users to exchange “letters” (in fact any type of document) in a manner equivalent to the conventional postal system, but with the advantages of great speed and simplicity. Electronic mail has not replaced regular mail entirely, but many people now use it for the vast majority of their correspondence.
  - ☉ **Network News (Usenet):** An application that is like electronic mail in that it allows users to send messages. However, while e-mail is normally used to allow a message to be sent to one user or a small number of recipients, [network news is a way for thousands of users to share messages](#) on various topics. Any user can contribute a message that can be seen by others, any of whom can respond. Unlike the case with e-mail, recipients do not need to be explicitly identified, which makes network news far more suitable to communication amongst large groups of people who may not even know each other. This was one of the first TCP/IP applications to create something like an “electronic bulletin board”: an online community.
  - ☉ **Hypertext (World Wide Web):** You probably don't even need me to explain what the [World Wide Web](#) is, such is its great significance in modern internetworking. Hypertext moves the idea of messaging beyond the simple exchange of text messages or plain files, to the notion of *rich* messages that can contain a variety of types of information. This includes text, graphics, multimedia and embedded files. Most importantly, hypertext allows one document to be linked to another, forming the “web” of related documents that led to the name “World Wide Web”. The Web is almost certainly the single most important TCP/IP application, used daily by millions of people.

Each of these applications was at one point somewhat distinct, but in recent years a number of developments have caused the lines between them to become greatly blurred. Electronic mail is no longer limited to simple text messages; it can now be used to carry general files by encoding them into text form using special methods, and even to carry hypertext documents. World Wide Web clients (browsers) continue to be enhanced to let them access other types of servers and files, and can also be used for general file transfer. These developments all mean even more functionality and flexibility for the TCP/IP user—and a bit more care required on the part of the TCP/IP learner.

**Key Concept:** One of the most important groups of TCP/IP applications is the one that enables files to be moved between devices on an internetwork: *file and message transfer* applications. This group contains many of the common applications that TCP/IP users employ every day to communicate. It can be broken into two main categories: *general file transfer* applications that are used to move any type of file between devices, and *message transfer* applications, which allow different types of communication using special file types, such as electronic-mail messages or hypertext files.

---

---

## **TCP/IP General File Transfer Protocols (FTP and TFTP)**

As I mentioned in [the preceding overview of file and message transfer protocols](#), they represent the most basic type of network communication: the simple movement of blocks of data. Of the many file and message transfer methods, the most fundamental application is what I call *general file transfer*. General file transfer protocols perform one main function: allowing files to be copied from one computer to another.

Since file transfer protocols move files from place to place without considering their contents much, they are relatively “unsophisticated” compared to certain message-processing applications. However, the idea of being able to move files around is so important that general file transfer protocols were one of the very first applications in inter-networking. While many people now use electronic mail or Web browsers to perform the functions formerly performed exclusively using general file transfer, these older protocols are still very important and widely used, and important to understand.

In this section I take a look at the two TCP/IP general file transfer protocols. The first is called simply the File Transfer Protocol (FTP). The second is called the Trivial File Transfer Protocol (TFTP). Each is described in its own subsection.

The relationship between FTP and TFTP is similar to that of the [Transmission Control Protocol \(TCP\)](#) and [User Datagram Protocol \(UDP\)](#) at layer four. FTP is full-featured, session-oriented and somewhat complex. It is the more often-used of the two protocols, providing a full command interface and taking advantage of the reliability and stream transfer functions of [TCP](#), over which it runs. TFTP, like the [UDP](#) it uses at the transport layer, is a “stripped down” version of FTP. It has far fewer commands and capabilities than FTP, but is ideal for cases where simplicity and small software program size is important, such as embedded software in devices.

---

## **File Transfer Protocol (FTP)**

The primary general file transfer protocol in the TCP/IP suite shows its “generality” directly through its unqualified name: the *File Transfer Protocol (FTP)*. FTP is one of the most widely used application protocols in the world. It was designed to allow the efficient transfer of files between any two devices on a TCP/IP internetwork. It automatically takes care of the details of how files are moved, provides a rich command syntax to allow various supporting file operations to be performed (such as navigating the directory structure and deleting files) and operates using the TCP transport service for reliability.

In this section I describe the operation of the File Transfer Protocol. I begin with an overview of FTP, a discussion of its long history and the standards that define it. I then describe how FTP works in two subsections. The first discusses the key concepts behind how FTP functions and discusses its operation in general terms. The second provides specific details of FTP commands and reply codes. Finally, I provide a sample illustration of a user FTP session showing the internal commands used for each action.

---

## **FTP Overview, History and Standards**

The [TCP/IP protocol suite](#) as we know it today was developed in the late 1970s and early 1980s, with the watershed event probably the publishing of the version 4 standards of the Internet Protocol and Transmission Control Protocol in 1980. Modern TCP/IP was the result of [experimentation and development work](#) that had been underway since the 1960s. This work included both the design and implementation of the protocols that would implement internetworks, and also the creation of the first networking applications to allow users to perform different tasks.

### ***FTP Development and Standardization***

The developers of early applications conceptually divided methods of network use into two categories: *direct* and *indirect*. Direct network applications let a user access a remote host and use it as if it were local, creating the illusion that the network doesn't even exist (or at least, minimizing the importance of distance). Indirect network use meant getting resources from a remote host and using them on the local system, then transferring them back. These two methods of use became the models for the first two formalized TCP/IP networking applications: [Telnet](#) for direct access and the *File Transfer Protocol (FTP)* for indirect network use.

The first FTP standard was RFC 114, published in April 1971, before TCP and IP even existed. This standard defined the basic commands of the protocol and the formal means by which devices communicate using it. At this time the predecessor of TCP (called simply the *Network Control Protocol* or *NCP*) was used for conveying network traffic. There was no Internet back then. Its precursor, the ARPAnet, was tiny, consisting of only a small group of development computers.

A number of subsequent RFCs refined the operation of this early version of FTP, with revisions published as RFC 172 in June 1971 and RFC 265 in November 1971. The first major revision was RFC 354, July 1972, which for the first time contained a description of the overall communication model used by modern TCP, and details on many of the current features of the protocol. In subsequent months many additional RFCs were published, defining features for FTP or raising issues with it. RFC 542, August 1973, the FTP specification looks remarkably similar to the one we use today, over three decades later, except that it was still defined to run over NCP.

After a number of subsequent RFCs to define and discuss changes, the formal standard for modern FTP was published in RFC 765, *File Transfer Protocol Specification*, June 1980. This was the first standard to define FTP operation over modern TCP/IP, and was created at around the same time as the other primary defining standards for TCP/IP.

RFC 959, *File Transfer Protocol (FTP)*, was published in October 1985 and made some revisions to RFC 765, including the addition of several new commands, and is now the base specification for FTP. Since that time a number of other standards have been published that define extensions to FTP, better security measures and other features. (Some of these are discussed in the [general operation section](#) in the appropriate places.)

---

## Overview of FTP Operation

FTP was created with the overall goal of allowing indirect use of computers on a network, by making it easy for users to move files from one place to another. Like most TCP/IP protocols, it is based on a [client/server model](#), with an FTP client on a user machine creating a connection to an FTP server to send and retrieve files to and from the server. The main objectives of FTP were to make file transfer simple, and to shield the user from implementation details of how the files are actually moved from one place to another. To this end, FTP is designed to automatically deal with many of the issues that can potentially arise due to format differences in files stored on differing systems.

To ensure that files are sent and received without loss of data that could corrupt them, FTP uses the reliable [Transmission Control Protocol \(TCP\)](#) at the transport layer. An authentication system is used to ensure that only authorized clients are allowed to access a server. At the same time, a feature sometimes called *anonymous FTP* allows an organization that wishes it to set up a general information server to provide files to anyone who might want to retrieve them.

After a TCP connection is established, an [FTP control connection is created](#). Internal FTP commands are passed over this logical connection based on formatting rules established by the Telnet protocol. Each command sent by the client receives a reply from the server to indicate whether it succeeded or failed. A [data connection](#) is established for each individual data transfer to be performed. FTP supports either normal or passive data connections, allowing either the server or client to initiate the data connection. [Multiple data types](#) and file types are supported to allow flexibility for various types of transfers.

The interface between an FTP user and the protocol is provided in the form of a set of [interactive user commands](#). After establishing a connection and completing authentication, two basic commands can be used to send or receive files. Additional support commands are provided to manage the FTP connection, as well as to perform support functions such as listing the contents of a directory or deleting or renaming files. In recent years, graphical implementations of FTP have been created to allow users to transfer files using mouse clicks instead of memorizing commands. FTP can also be used directly by other applications to move files from one place to another.

**Key Concept:** The most important general file transfer protocol in TCP/IP is the simply-named *File Transfer Protocol (FTP)*. The need to be able to move files of any type between machines is so fundamental that FTP's history goes back more than 30 years. FTP runs over TCP, to ensure that files are transferred reliably with no data loss. The protocol uses a set of *FTP commands* sent from an FTP client to an FTP server to perform file transfer operations; the FTP server sends to the client *FTP replies* that indicate the success or failure of commands.

---

---

## **FTP Concepts and General Operation**

The developers of the File Transfer Protocol (FTP) had to balance the need for a rich set of functionality with the desire for a protocol that was as simple and easy to implement as possible. FTP is therefore not nearly as simple as its “little brother”, the [Trivial File Transfer Protocol \(TFTP\)](#), but given what the protocol can do, it's much less complicated than one might expect. The operation of the protocol can in fact be broken down into a number of rather straight-forward elements that work together to establish connections and pass commands and data.

In this section I describe the most important concepts behind the File Transfer Protocol and explain its operation in general terms. I begin with a discussion of the FTP communication and operational model, which shows the internal components of the protocol and how they communicate over the internetwork. I describe the process by which FTP control connections are established, and how user authentication is performed. I explain the two main methods of creating data connections (normal and passive) and discuss the issues that pertain to when each is used. I then describe how FTP communication works in general and the various transmission modes. I conclude with a discussion of the different options for data representation used for files sent with FTP.

**Related Information:** In this section I will make limited mention of commands used to communicate between an FTP client and server. The details of FTP commands can be found in [a separate section](#).

---

### **FTP Operational Model, Protocol Components and Key Terminology**

The standards that define the File Transfer Protocol (FTP) describe its overall operation using a simple conceptual tool called the *FTP model*. This model defines the roles of the devices that participate in a file transfer, and the two communication channels that are established between them. It also describes the components of FTP that manage these channels, and defines the terminology used for the components. This makes it an ideal place for us to see how FTP works in broad terms.

#### ***The Server-FTP Process and User-FTP Process***

FTP is a classical client/server protocol, as I mentioned in the [overview](#). However, the client is not called by that name but rather is called the *user*. The name comes from the fact that the human user that issues FTP commands works on the client machine. The full set of FTP software operating on a device is called a *process*. The FTP software on the server is called the *Server-FTP Process*, while the software on the client is the *User-FTP Process*.

**Key Concept:** The FTP client is sometimes called the *user device*, since the human user interacts with the client directly. The FTP client software is called the *User-FTP Process*; the FTP server software, the *Server-FTP Process*.

---

### ***FTP Control Connection and Data Connection***

A critical concept in understanding FTP is that while it uses TCP like many other applications, it does **not** use just one TCP connection for all communication the way most protocols do. The FTP model is designed around **two** logical channels of communication between the server and user FTP processes:

- ☛ **Control Connection:** This is the main logical TCP connection that is created when an FTP session is established. It is maintained throughout the FTP session and is used only for passing control information, such as FTP commands and replies. It is not used to send files.
- ☛ **Data Connection:** Each time that data is sent from the server to the client or vice-versa, a distinct TCP data connection is established between them. Data is transferred over this connection. When the file transfer is complete, the connection is terminated.

The reason for having these separate channels is that it provides flexibility in how the protocol is used, as we will see later in this section. It does, however, add complexity to FTP.

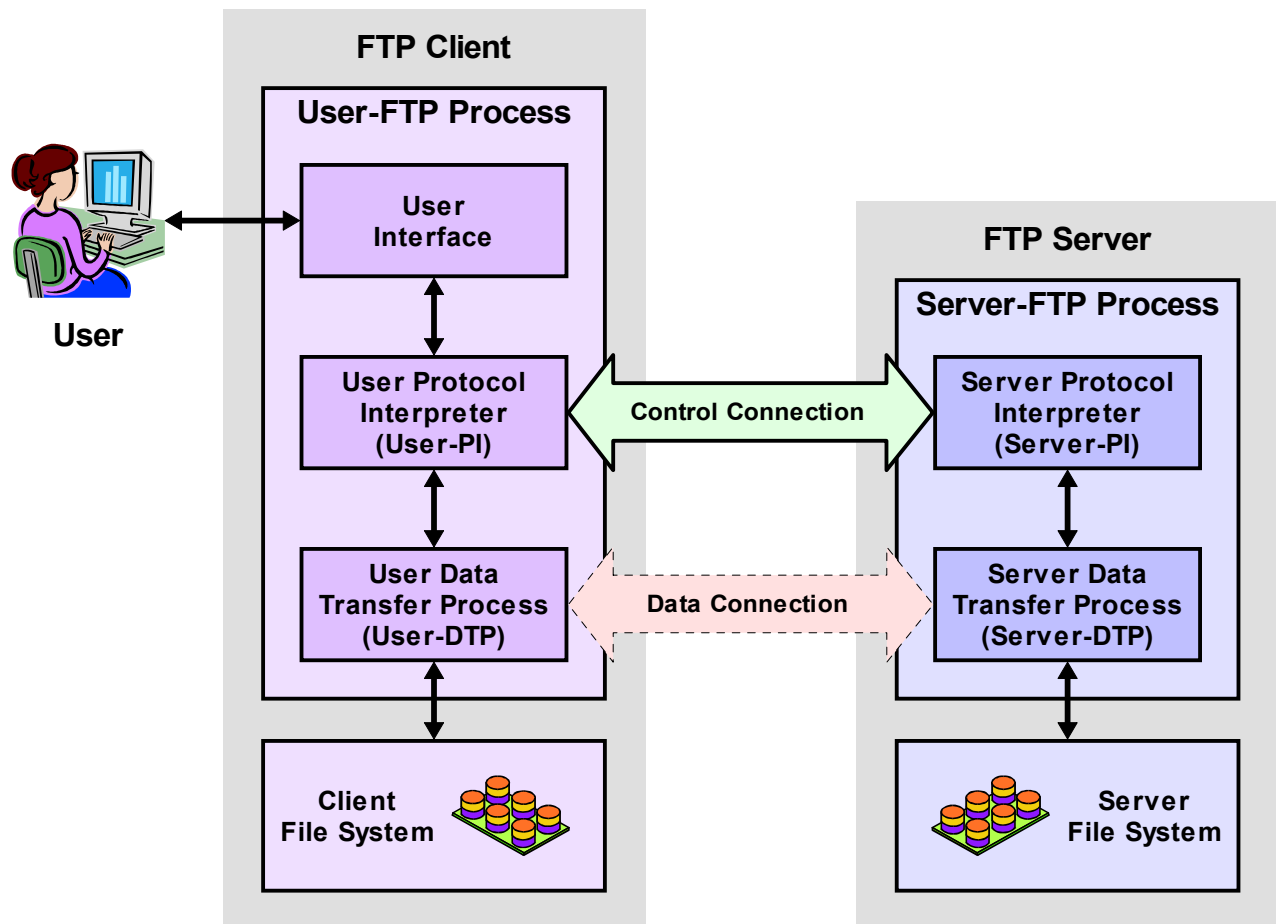

**Key Concept:** Unlike most protocols, FTP does not use a single TCP connection. When a session is set up, a permanent *control connection* is established using TCP, for passing commands and replies. When files or other data are to be sent, they are passed over separate TCP *data connections* that are created and then dismantled as needed.

---

### ***FTP Process Components and Terminology***

Since the control and data functions are communicated using distinct channels, the FTP model divides the software on each device into two logical protocol components that are responsible for each channel. The *protocol interpreter (PI)* is a piece of software that is charged with managing the control connection, issuing and receiving commands and replies. The *data transfer process (DTP)* is responsible for actually sending and receiving data between the client and server. In addition to these two elements, the user FTP process includes a third component, a *user interface*, that interacts with the human FTP user; it is not present on the server side.

Thus, there are two server process components and three client (user) process components in FTP. These components are referred to in the FTP model by specific names, which are used in the standard to describe the detailed operation of the protocol. I plan to do the same in this section, so I will now describe more fully the components in each device of this model, which are illustrated in [Figure 288](#).

**Figure 288: File Transfer Protocol (FTP) Operational Model**

FTP is a client/server protocol, with communication taking place between the *User-FTP Process* on the client and the *Server-FTP Process* on the server. Commands, replies and status information are passed between the *User-PI* and *Server-PI* over the *control connection*, which is established once and maintained for the session. Data is moved between devices over *data connections* that are set up for each transfer.

### **Server-FTP Process Components**

The Server-FTP Process contains these two protocol elements:

- ☉ **Server Protocol Interpreter (Server-PI):** The protocol interpreter responsible for managing the control connection on the server. It listens on the main reserved FTP port for incoming connection requests from users (clients). Once a connection is established, it receives commands from the User-PI, sends back replies, and manages the server data transfer process.

- 
- ☛ **Server Data Transfer Process (Server-DTP):** The DTP on the server side, used to send or receive data to or from the User-DTP. The Server-DTP may either establish a data connection or listen for a data connection coming from the user. It interacts with the server's local file system to read and write files.

### ***User-FTP Process Components***

The User-FTP Process contains these three protocol elements:

- ☛ **User Protocol Interpreter (User-PI):** The protocol interpreter responsible for managing the control connection on the client. It initiates the FTP session by issuing a request to the Server-PI. Once a connection is established, it processes commands received from the user interface, sends them to the Server-PI, and receives back replies. It also manages the user data transfer process.
- ☛ **User Data Transfer Process (User-DTP):** The DTP on the user side, which sends or receives data to or from the Server-DTP. The User-DTP may either establish a data connection or listen for a data connection coming from the server. It interacts with the client device's local file system.
- ☛ **User Interface:** The user interface provides a more “friendly” FTP interface to a human user. It allows simpler user-oriented commands to be used for FTP functions rather than the somewhat cryptic internal FTP commands, and also allows results and information to be conveyed back to the person operating the FTP session.

**Key Concept:** The Server-FTP Process and User-FTP Process both contain a *Protocol Interpreter (PI)* element and a *Data Transfer Process (DTP)* element. The *Server-PI* and *User-PI* are logically linked by the FTP control connection; the *Server-DTP* and *User-DTP* by data connections. The User-FTP Process includes a third component, the *User Interface*, which provides the means for the human user to issue commands and see responses from the FTP software.

---

### ***Third-Party File Transfer (Proxy FTP)***

The FTP standard actually defines a separate model for an alternative way of using the protocol. In this technique, a user on one host performs a file transfer from one server to another. This is done by opening two control connections: one each from the User-PI on the user's machine to the two Server-PI's on the two servers. Then, a Server-DTP is invoked on each server to send data; the User-DTP is not used.

This method, sometimes called *third-party file transfer* or *proxy FTP*, is not widely used today. A major reason for this is that it raises security concerns, and has been exploited in the past. Thus, while I felt it was worth mentioning, I will not be discussing it further in my coverage of FTP.

---

## **FTP Control Connection Establishment, User Authentication and Anonymous FTP Access**

The [FTP operational model](#) describes the distinct logical data and control channels that are established between an FTP client (user) and an FTP server. Before the data connection can be used to send actual files, the control connection must be established. A specific process is followed to set up this connection and thereby create the permanent FTP session between devices that can be used for transferring files.

As with other client/server protocols, the FTP server assumes a passive role in the control connection process. The server protocol interpreter (Server-PI) “listens” on the special [well-known TCP port](#) reserved for FTP control connections: port 21. The User-PI initiates the connection by opening a TCP connection from the user device to the server on this port. It uses an [ephemeral port number](#) as its source port in the TCP connection.

Once TCP has been set up, the control connection between the devices is established, allowing commands to be sent from the User-PI to the Server-PI, and reply codes to be sent back in response. The first order of business after the channel is operating is *user authentication*, which the FTP standard calls the *login sequence*. There are two purposes for this process:

- ① **Access Control:** The authentication process allows access to the server to be restricted to only authorized users. It also lets the server control what types of access each user has.
- ② **Resource Selection:** By identifying the user making the connection, the FTP server can make decisions about what resources to make available to the user.

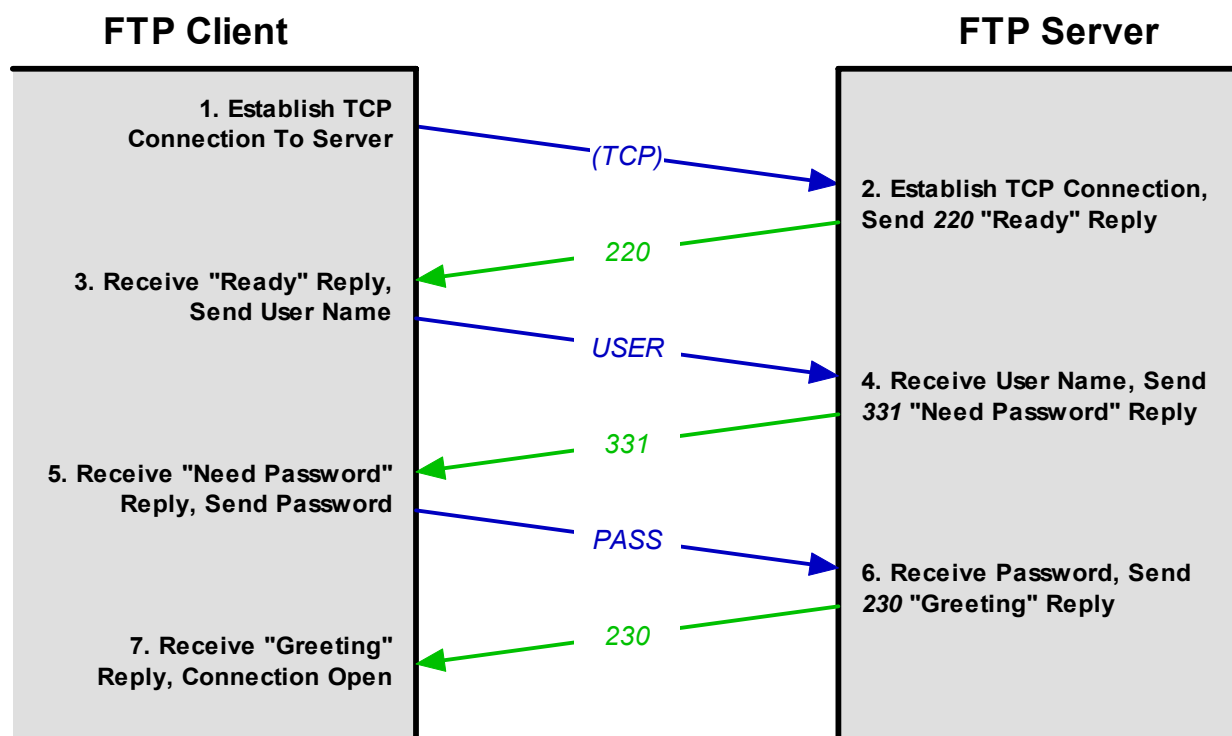

### ***FTP Login Sequence and Authentication***

FTP’s regular authentication scheme is quite rudimentary: it is a simple “username / password” login scheme, shown in [Figure 289](#). Most of us are familiar with this type of authentication for various types of access, on the Internet and elsewhere. First, the user is identified by sending a user name from the User-PI to the Server-PI using the *USER* command. Then, the user’s password is sent using the *PASS* command.

The server checks the user name and password against its user database, to verify that the connecting user has valid authority to access the server. If the information is valid, the server sends back a greeting to the client to indicate that the session is opened. If the user improperly authenticates (by specifying an incorrect user name or password), the server will request that the user attempt authorization again. After a number of invalid authorization tries, the server may time out and terminate the connection.

Assuming that the authentication succeeds, the server then sets up the connection to allow the type of access to which the user is authorized. Some users may have access to only certain files or certain types of files. Some servers may allow particular users to read and write files on the server, while other users may only retrieve files. The administrator can thus tailor FTP access as needed.

**Figure 289: FTP Connection Establishment and User Authentication**

An FTP session begins with the establishment of a TCP connection between the client and server. The client then sends the user name and password to authenticate with the server. Assuming that the information is accepted by the server, it sends a greeting reply to the client and the session is open.

Once the connection is established, the server can also make resource selection decisions based on the user's identity. For example, on a system with multiple users, the administrator can set up FTP so that when any user connects, he or she automatically is taken to his or her own "home directory". The optional *ACCT* (account) command also allows a user to select a particular account if he or she has more than one.

### ***FTP Security Extensions***

Like most older protocols, the simple login scheme used by FTP is a legacy of the relatively "closed" nature of the early Internet. It is not considered secure by today's global Internet standards, because the user name and password are sent across the control connection in clear text. This makes it relatively easy for login information to be intercepted by intermediate systems and accounts to be compromised. RFC 2228, *FTP Security Extensions*, defines more sophisticated authentication and encryption options for those who need added security in their FTP software.

**Key Concept:** An FTP session begins with the establishment of a control connection between an FTP client and server. After the TCP connection is made, the user must *authenticate* with the server, using a simple user/password exchange between client and server. This provides only rudimentary security, so if more is required, it must be implemented using FTP security extensions or through other means.

---

### ***Anonymous FTP***

Perhaps surprisingly, however, many organizations did not see the need for this enhanced level of security. They in fact went in the opposite direction: using FTP without any authentication at all. This may seem surprising; why would anyone want to allow just anybody to access their FTP server? The answer is pretty simple, however: anyone who wants to use the server to provide information to the general public.

Today, most organizations use the [World Wide Web](#) to distribute documents, software and other files to customers and others who want to obtain them. But in the 1980s, before the Web became popular, FTP was the way that this was often done. For example, today, if you have a 3Com network interface card and want a driver for it, you would go to the Web server [www.3com.com](http://www.3com.com), but several years ago, you might have accessed the 3Com FTP server (<ftp.3com.com>) to download a driver for it.

Clearly, requiring every customer to have a user name and password on such a server would be ridiculous. For this reason, RFC 1635 in 1994 defined a use for the protocol called *anonymous FTP*. In this technique, a client connects to a server and provides a default user name to log in as a *guest*. Usually the names “anonymous” or “ftp” are supported. Seeing this name, the server responds back with a special message, saying something like “Guest login ok, send your complete e-mail address as password.”. The password in this case isn't really a password, of course, it is just used to allow the server to log who is accessing it.

The guest is then able to access the site, though the server will usually severely restrict the access rights of guests on the system. Many FTP servers support both identified and anonymous access, with authorized users having more permissions (such as being able to traverse the full directory path, and having the right to delete or rename files) while anonymous ones may only be able to read files from a particular directory set up for public access.

**Key Concept:** Many FTP servers support *anonymous FTP*, which allows a guest who has no account on the server to have limited access to server resources. This is often used by organizations that wish to make files available to the public for purposes such as technical support, customer support, or distribution.

---

---

## **FTP Data Connection Management, Normal (Active) and Passive Data Connections and Port Usage**

The control channel created between the Server-PI and the User-PI using the [FTP connection establishment and authentication process](#) is maintained throughout the FTP session. Commands and replies are exchanged between the protocol interpreters over this channel, but not data.

Each time files or other data need to be sent between the server and user FTP processes, a [data connection](#) must be created. The data connection links the User-DTP with the Server-DTP. This connection is required both for explicit file transfer actions (getting or receiving a file) and also for implicit data transfers, such as requesting a list of files from a directory on the server.

The FTP standard specifies two different ways of creating a data connection, though it doesn't really explain them in a way that is very easy to understand. That's my job. The two methods differ primarily in which device, the client or the server, initiates the connection. This may at first seem like a trivial matter, but as we'll see shortly, it is actually quite important.

### ***Normal (Active) Data Connections***

The first method is sometimes called creating a *normal* data connection (because it is the default method) and sometimes an *active* data connection (to contrast it to the passive method we will see in a moment). In this type of connection, the Server-DTP initiates the data channel by opening a TCP connection to the User-DTP. The server uses the special reserved port number 20 (one less than the well-known control FTP port number, 21) for the data connection. On the client machine, the default port number used is the same as the ephemeral port number used for the control connection, but as we'll see shortly, the client will often choose a different port for each transfer.

Let's take an example to see how this works. Suppose the User-PI established a control connection from its ephemeral port number 1678 to the server's FTP control port of 21. Then, to create a data connection for data transfer, the Server-PI would instruct the Server-DTP to initiate a TCP connection from the server's port 20 to the client's port 1678. The client would acknowledge this and then data could be transferred (in either direction — remember that TCP is bidirectional).

In practice, having the client's control and data connection on the same port is not a good idea; it complicates the operation of FTP and can lead to some tricky problems. For this reason, it is strongly recommended that the client specify a different port number using the *PORT* command prior to the data transfer. For example, suppose the client specifies port 1742 using *PORT*. The Server-DTP would then create a connection from its port 20 to the client's port 1742 instead of 1678. This process is shown in [Figure 290](#).

**Figure 290: FTP Active Data Connection**

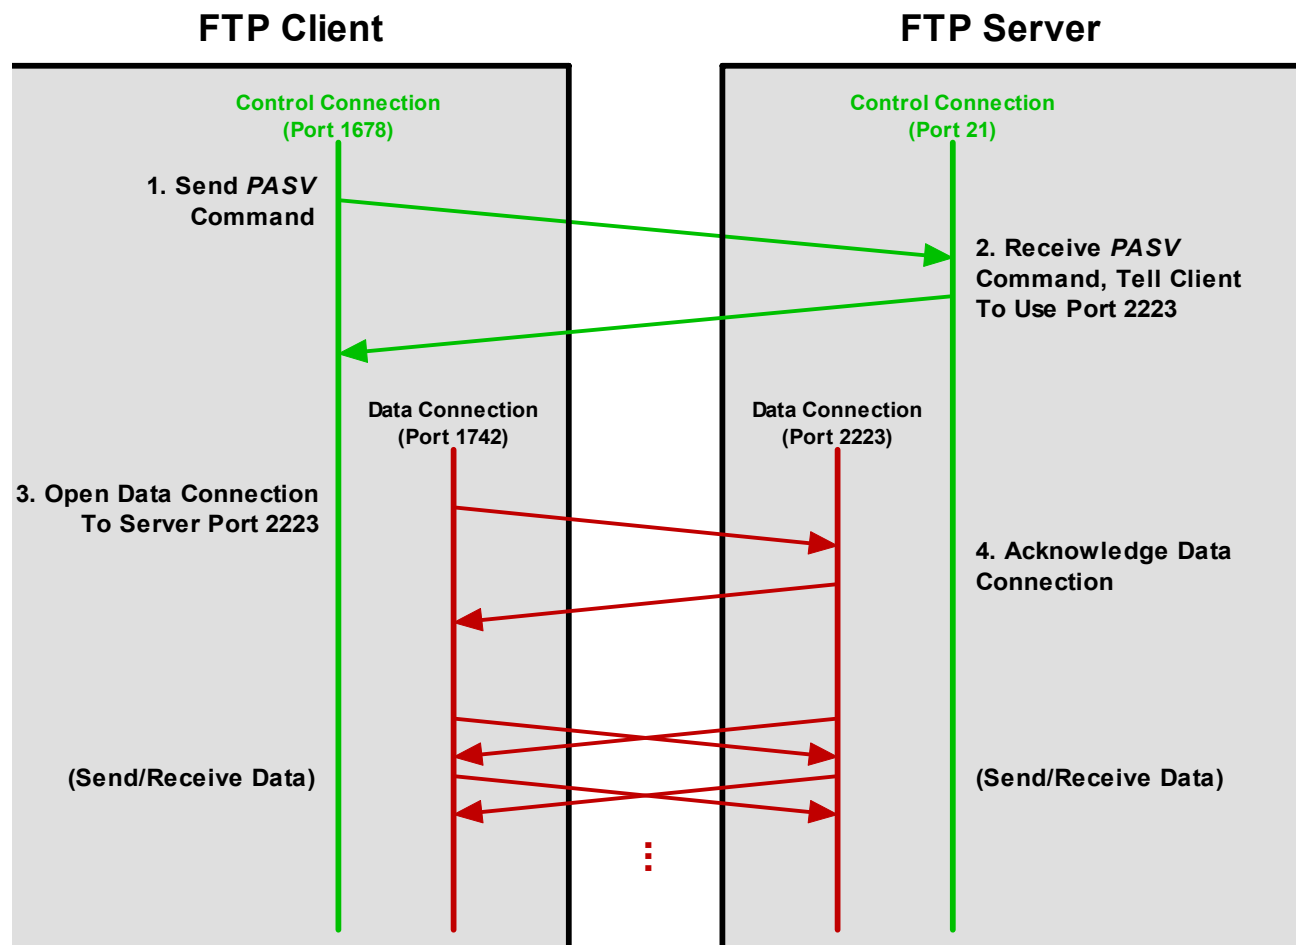

In a conventional, or active, FTP data connection, the server initiates the transfer of data by opening the data connection to the client. In this case, the client first sends a *PORT* command to tell the server to use port 1742. The server then opens the data connection from its default port number of 20 to client port 1742. Data is then exchanged between the devices using these ports. Contrast to [Figure 291](#).

### ***Passive Data Connections***

The second method is called a *passive* data connection. The client tells the server to be “passive”, that is, to accept an incoming data connection initiated by the client. The server replies back giving the client the server IP address and port number that it should use. The Server-DTP then listens on this port for an incoming TCP connection from the User-DTP. By default, the user machine uses the same port number it used for the control connection, as in the active case. However, here again, the client can choose to use a different port number for the data connection if necessary (typically an ephemeral port number.)

Let's consider our example again, with the control connection from port 1678 on the client to port 21 on the server, but this time consider data transfer using a passive connection, as illustrated in [Figure 291](#). The client would issue the *PASV* command to tell the server it wanted to use passive data control. The Server-PI would reply back with a port number for

the client to use, say port 2223. The Server-PI would then instruct the Server-DTP to listen on this port 2223. The User-PI would instruct the User-DTP to create a connection from client port 1742 to server port 2223. The server would acknowledge this and then data could be sent and received, again in either direction.

**Figure 291: FTP Passive Data Connection**

In a passive FTP data connection, the client uses the *PASV* command to tell the server to wait for the client to establish the data connection. The server responds, telling the client what port it should use on the server for the data transmission, in this case port 2223. The client then opens the data connection using that port number on the server and a client port number of its own choosing, in this case 1742. Contrast to [Figure 291](#).

### ***Efficiency and Security Issues In Choosing a Connection Method***

This leaves one nagging question, of course: who cares? ☺ I already said that in either case, the data transfer can go in both directions. So what does it matter who initiates the data connection? Isn't this like arguing over who makes a local telephone call?

The answer is related to the dreaded “S word”: *security*. The fact that FTP uses more than one TCP connection can cause problems for the hardware and software that people use to ensure the security of their systems.

---

Consider what is happening in the case of an active data connection as described in the example above. From the perspective of the client, there's an established control connection from the client's port 1678 to the server's port 21. But the data connection is initiated by the server. So the client sees an incoming connection request to port 1678 (or some other port). Many clients are suspicious about receiving such incoming connections, since under normal circumstances clients establish connections, they don't respond to them. Since incoming TCP connections can potentially be a security risk, many clients are configured to block them using firewall hardware or software.

Why not just make it so the client always accepts connections to the port number one above the ephemeral number used for the control connection? The problem here is that clients often use different port numbers for each transfer by using the *PORT* command. And why is this done? Because of the rules of TCP. As I describe in [the section on TCP](#), after a connection is closed, [a period of time must elapse before the port can be used again](#), to prevent mixing up consecutive sessions. This would cause delays when sending multiple files one after the other, so to avoid this, clients usually use different port numbers for each transfer. This is more efficient, but means a firewall protecting the client would be asked to accept incoming connections that appear to be going to many unpredictable port numbers.

The use of passive connections largely eliminates this problem. Most firewalls have a lot more difficulty dealing with incoming connections to odd ports than outgoing connections. RFC 1579, *Firewall-Friendly FTP*, discusses this issue in detail. It recommends that clients use passive data connections by default instead of using normal connections with the *PORT* command, to avoid the port-blocking problem.

Of course, passive data connections don't really eliminate the problem, they just push it off onto servers. These servers now must face the issue of incoming connections to various ports. Still, it is, generally speaking, easier to deal with security issues on a relatively smaller number of servers than a large number of clients. FTP servers must be able to accept passive mode transfers from clients anyway, so the usual approach is to set aside a block of ports for this purpose, which the server's security provisions allow to accept incoming connections, while blocking incoming connection requests on other ports.

**Note:** As an aside, it is that it is a significant violation of the [layering principle of networks](#) to pass IP addresses and port numbers in FTP commands such as *PORT* and *PASV* and the replies to them. This isn't just a philosophical issue: applications aren't supposed to deal with port numbers, and this creates issues when certain lower-layer technologies are used. For example, consider the use of [Network Address Translation](#), which modifies IP addresses and possibly port numbers. In order to prevent NAT from "breaking" when FTP is used, [special provision](#) must be made to handle the protocol.

---

**Key Concept:** FTP supports two different models for establishing data connections between the client and server. In *normal*, or *active* data connections, the server initiates the connection when the client requests a transfer, and the client responds; in a *passive* data connection, the client tells the server it will initiate the connection, and the server responds. Since TCP is bidirectional, data can flow either way in both cases; the chief difference between the two modes has to do with security. In particular, passive mode is often used because many client devices today are not able to accept incoming connections from servers.

---

## **FTP General Data Communication and Transmission Modes**

Once a [data connection](#) has been established between the Server-DTP and the User-DTP, data is sent directly from the client to the server, or the server to the client, depending on the specific command issued. Since control information is sent using the distinct control channel, the entire data channel can be used for data communication. (Of course, these two logical channels are combined at lower layers along with all other TCP and UDP connections on both devices, so it's not like this represents a performance improvement over a single channel. Just wanted to make that clear.)

FTP defines three different *transmission modes* (also called *transfer modes*) that specify exactly how data is sent from one device to another over an opened data channel: stream mode, block mode, and compressed mode.

### ***Stream Mode***

In this mode, data is sent simply as a continuous stream of unstructured bytes. The sending device simply starts pushing data across the TCP data connection to the recipient. No message format with distinct header fields is used, making this method quite different from the way many other protocols send information in discrete chunks. It relies strongly on the [data streaming](#) and [reliable transport services](#) of TCP. Since there is no header structure, the end of the file is indicated simply by the sending device closing the data connection when it is done.

Of the three methods, stream mode is the one that is by far the most widely used in real FTP implementations. There are likely three reasons for this. First, it is the default and also the simplest method, so it is the easiest to implement and one that is required for compatibility. Second, it is the most general, because it treats all files as simple streams of byte without paying attention to their content. Third, it is the most efficient method because no bytes are wasted on “overhead” such as headers.

---

## Block Mode

This is a more “conventional” data transmission mode in which data is broken into data blocks and encapsulated into individual FTP blocks, or records. Each record has a three-byte header that indicates its length and contains information about the data blocks being sent. A special algorithm is used to keep track of the transmitted data and to detect and restart an interrupted transfer.

## Compressed Mode

A transmission mode where a relatively simple compression technique called *run-length encoding* is used to detect repeated patterns in the data being sent, and then represent them in such a way that the overall message takes fewer bytes. The compressed information is then sent in a way similar to block mode, using a header+payload record format.

Compressed mode seems on the surface to be useful. In practice, however, compression is often implemented in other places in a typical networking software stack, making it unnecessary in FTP. For example, if you are transferring a file over the Internet using an analog modem, your modem normally performs compression down at layer one. Large files on FTP servers are also often already compressed using something like the ZIP format, meaning further compression would serve no purpose.

**Key Concept:** FTP includes three different transmission modes: *stream*, *block* and *compressed*. In stream mode, data is sent as a continuous sequence of bytes; in block mode, data is formatted into blocks with headers; and in compressed mode, bytes are compacted using run-length encoding. Stream mode is the one most commonly used.

---

## FTP Data Representation: Data Types, Data Structures and Format Control

The most general way of designing the File Transfer Protocol would have been to make it treat all files as “black boxes”. The file would be represented as just as a set of bytes. FTP would pay no attention to what the file contained, and would simply move the file, one byte at a time, from one place to another. In this, it would seem to be very similar to the “copy” command that is implemented on most file systems, which likewise creates a copy without looking into the file to see what it contains.

So what would be the problem with that, you may wonder? Well, for some types of files, this is exactly what we want, but for others, it introduces a problem. The reason is that certain types of files use different representations on different systems. If you copy a file from one place to another on the same computer using a “copy” command, there is no problem: the same representation for files is used everywhere within that computer. But when you copy it to a computer that uses a different representation, however, you may encounter difficulties.

---

The most common example of this is a type of file that may surprise you: simple text files. All ASCII text files use the ASCII character set, but they differ in the control characters used to mark the end of a line of text. On UNIX, a line feed (LF) character is used; on Apple computers, a carriage return (CR); and Windows machines used both (CR+LF).

If you move a text file from one type of system to another using regular FTP, the data will all get moved exactly as it was. Moving a text file from a UNIX system to a PC as just a set of bytes would mean programs would not properly recognize end of line markers. Avoiding this predicament requires that FTP move past the idea that “all files are just bytes” and incorporate some intelligence to handle different types of files. The FTP standard recognizes this by allowing the specification of certain details about the file's internal representation prior to transfer.

### ***FTP Data Types***

The first piece of information that can be given about a file is its *data type*, which dictates the overall representation of the file. There are four different data types specified in the FTP standard:

- ☉ **ASCII:** Defines an ASCII text file, with lines marked by some sort of end-of-line marker as described above.
- ☉ **EBCDIC:** Conceptually the same as the ASCII type, but for files using IBM's EBCDIC character set.
- ☉ **Image:** The file has no formal internal structure and is sent one byte at a time without any processing; this is the “black box” mode I mentioned above.
- ☉ **Local:** This data type is used to handle files that may store data in logical bytes containing a number of bits other than 8. Specifying this type along with the way the data is structured allows the data to be stored on the destination system in a manner consistent with its local representation.

**Note:** The term “byte” conventionally refers to 8 bits but strictly speaking, the term for 8 bits is “octet”. A byte may in fact contain a number of bits other than 8 on certain systems. [See the background topic on bits and bytes for the details.](#)

---

In practice, the two data types most often used are *ASCII* and *image*. The *ASCII* type is used for text files, and allows them to be moved between systems with line-end codes converted automatically. The *Image* type is used for generic binary files, such as graphical images, ZIP files and other data that is represented in a universal manner. It is also often called the *binary* type for that reason.

### ***ASCII Data Type Line Delimiting Issues***

When the *ASCII* data type is used, differences in internal representations between systems are handled by using a universal external representation that acts as a “common language”. Lines of the file being transmitted are converted by the sending FTP process from the

---

sender's internal representation to the neutral ASCII representation used by the [Telnet](#) protocol ("NETASCII") with each line ending in "CR+LF". The receiving device then converts from this neutral representation to the internal format used by the recipient file system.

For example, when using FTP to move a text file from a Macintosh to a UNIX system, each line would have the "CR" changed to a "CR+LF" for transmission over the FTP data channel. The receiving UNIX system would change each "CR+LF" to just "LF", so UNIX programs would read it properly.

Note that this actually does mean the resulting file can be bigger or smaller than the original, if it is transferred between systems using *ASCII* mode. Also, since FTP works by converting to a neutral representation for universality, sending an ASCII file from a UNIX system to a UNIX system means each "LF" is changed to "CR+LF" for transmission, then changed back to just "LF" by the recipient. Slightly inefficient, but not that big a deal.

It's very important that when FTP is used, the correct data type be specified with the appropriate user command. Sending a text file between dissimilar systems without setting *ASCII* mode will result in either a file that cannot be properly read on the destination, or one that has stray characters in it. Conversely, binary files **must** be sent in binary mode. If you send something like a ZIP file or a JPG graphic in *ASCII* mode, the FTP software will think it is a text file. It will treat the file as if it were text, and each time it encounters bytes in the file that look like "CR", "LF" or "CR+LF" it will convert them, which you do not want. (Having the wrong data type set is a leading cause of corrupted files when using FTP to move files between PCs and UNIX systems. I know from experience!)

**Key Concept:** FTP defines four data types: *ASCII*, *EBCDIC*, *image* and *local*. *ASCII* and *EBCDIC* are used for text files in the ASCII and EBCDIC character sets, respectively; the *image* type is used for files with no specific structure, and the *local* type for local representation. The *ASCII* type is important because it allows text files to be transferred successfully between file systems that may use different methods of indicating the end of a line of text. The *image* type, also called *binary*, is used for files that must be sent and received byte-for-byte with no transformation, such as executable files, graphics and files with arbitrary formats.

---

## **FTP Format Control**

For the ASCII and EBCDIC types, FTP defines an optional parameter called *format control*. This allows a user to specify a particular representation for how vertical formatting is used to describe a file. The three options are:

- ☉ **Non Print:** The default, indicating no vertical formatting.
- ☉ **Telnet Format:** Indicates that vertical format control characters, as specified in the Telnet protocol, are used in this file.
- ☉ **Carriage Control / FORTRAN:** The file uses format control characters given as the first character of each line, as specified for the FORTRAN programming language.

---

The format control option was created for the particular purpose of properly handling files transferred from host devices to printers. It is not used today, to my knowledge (or if it is used, it is only in special applications.)

### ***FTP Data Structures***

In addition to specifying a file's data type, it is also possible to specify the file's *data structure*. There are three possibilities:

- ☉ **File Structure:** The file is a contiguous stream of bytes with no internal structure.
- ☉ **Record Structure:** The file consists of a set of sequential records, each of which is delimited by an end-of-record marker.
- ☉ **Page Structure:** The file contains a set of special indexed data pages.

The *file* structure is the default and is used for most types of files. The *record* structure can be used for ASCII text files, but these are more commonly sent with the regular *file* structure using the *ASCII* data type. The *page* structure is not commonly used; I believe it was initially created for a now archaic type of computer used in the early ARPAnet.

---

## **FTP Commands and Replies**

In [the previous section](#) I discussed the general operation of the File Transfer Protocol. As part of this description I explained how data transfers are performed, how connections are established and managed, and the various transmission modes and data types that FTP supports. All of these functions are implemented using a special set of *FTP commands* sent [by the User-FTP process to the Server-FTP process](#). The server device acknowledges commands by sending back *replies* using special codes. Understanding FTP commands and reply codes will allow us to see fully how the protocol works.

I begin the section by discussing FTP commands and how they are grouped. I then show the special encoding format used for FTP reply codes, and list some of the more common and important codes. I also discuss the FTP user interface and the commands used by typical FTP implementations to allow a user to communicate with the FTP software. These commands are usually different than the internal FTP commands, to allow the user to operate the protocol in a way more friendly to humans.

### **FTP Internal Protocol Commands and Command Groups**

An FTP session begins with the establishment of a TCP connection from an FTP client (user device) to an FTP server. Once established, the [control channel](#) is logically in place between the Server-PI and the User-PI. All communication to manage the operation of the protocol takes place over this channel. The User-PI sends *protocol commands* to the Server-PI, which processes them and takes appropriate action. The Server-PI responds back with *reply codes* to tell the User-PI the result of the commands it issued and convey other important information.

### ***FTP Command Groups***

Each command is identified by a short three-letter or four-letter *command code* for convenience, and performs a specific task in the overall functionality of FTP. There are several dozen of these protocol commands, and to help organize them, the FTP standard categorizes them into three groups, based on overall function type:

- ☉ **Access Control Commands:** Commands that are part of the [user login and authentication process](#), are used for resource access, or are part of general session control.
- ☉ **Transfer Parameter Commands:** Commands that specify parameters for how data transfers should occur. For example, commands in this group specify the [data type](#) of a file to be sent, indicate whether [passive or active data connections](#) will be used, and so forth.
- ☉ **FTP Service Commands:** This is the largest group, containing all the commands that actually perform file operations, such as sending and receiving files. Commands to implement support functions, such as deleting or renaming files, are also here.

Interestingly, the actual transmission of FTP commands over the control channel is done using specifications based on the [Telnet protocol](#). You may recall from the [FTP overview](#) that Telnet and FTP are two of the very oldest TCP/IP applications, the former being for

---

“direct” network use and the latter for “indirect” resource access. They were developed at around the same time, and setting up the FTP control channel to act as a type of Telnet connection is a good example of how Internet standards try not to “reinvent the wheel”.

**Key Concept:** FTP operation is controlled through the issuing of *protocol commands* from the FTP client to the FTP server. Each command has a three- or four-letter command code that indicates its function. The commands are organized into three groups: *access control commands* used for login and general session control; *transfer parameter commands* that control how transfers are performed; and *FTP service commands*, which are used to perform actual file operations.

---

## FTP Protocol Commands

Since the commands are based on the Telnet specifications, they are just sent as plain text as specified by Telnet's [Network Virtual Terminal \(NVT\)](#) conventions. I have provided below three tables that describe the FTP internal protocol commands in the order that they appear in the FTP standard (RFC 959). [Table 226](#) covers FTP access control commands, [Table 227](#) lists transfer parameter commands, and [Table 228](#) service commands.

**Table 226: FTP Access Control Commands (Page 1 of 2)**

Command Code	Command	Description
<b>USER</b>	<i>User Name</i>	Identifies the user attempting to establish an FTP session.
<b>PASS</b>	<i>Password</i>	Specifies the password for the user given previously by the <i>USER</i> command during login authentication.
<b>ACCT</b>	<i>Account</i>	Specifies an account for an authenticated user during the FTP session. Only used on systems that require this to be separately identified; most select an account automatically based on the name entered in the <i>USER</i> command.
<b>CWD</b>	<i>Change Working Directory</i>	Allows the user to specify a different directory for file transfer during an FTP session.
<b>CDUP</b>	<i>Change To Parent Directory</i> ("Change Directory Up")	A special case of the CWD command that goes to the directory one level up in the server's directory structure. It is implemented separately to abstract out differences in directory structures between file systems; the user can just use CDUP instead of knowing the specific syntax for navigating up the directory tree on the server.
<b>SMNT</b>	<i>Structure Mount</i>	Allows the user to mount a particular file system for access to different resources.

**Table 226: FTP Access Control Commands (Page 2 of 2)**

Command Code	Command	Description
<b>REIN</b>	<i>Reinitialize</i>	Reinitializes the FTP session, flushing all set parameters and user information. This returns the session to the state when the control connection is just established. It is, in essence, the opposite of the <i>USER</i> command. The next command issued is often <i>USER</i> , to log in a different user.
<b>QUIT</b>	<i>Logout</i>	Terminates the FTP session and closes the control connection.  Note that the naming of this command “Logout” was unfortunate; the <i>REIN</i> command is really most similar to a conventional “logout” command, as it terminates a logged-in user and allows another user to log in. In contrast, the <i>QUIT</i> command shuts down the entire session.

**Table 227: FTP Transfer Parameter Commands**

Command Code	Command	Description
<b>PORT</b>	<i>Data Port</i>	Used to tell the FTP server that the client wants to accept an active data connection on a specific port number.
<b>PASV</b>	<i>Passive</i>	Requests that the FTP server allow the User-DTP to initiate passive data connections.
<b>TYPE</b>	<i>Representation Type</i>	Specifies for the file to be transferred the data type (ASCII, EBCDIC, Image or Local), and optionally the format control (Non Print, Telnet or Carriage Control).
<b>STRU</b>	<i>File Structure</i>	Specifies the data structure for the file (File, Record or Page).
<b>MODE</b>	<i>Transfer Mode</i>	Specifies the transmission mode to be used (Stream, Block or Compressed).

**Table 228: FTP Service Commands (Page 1 of 2)**

Command Code	Command	Description
<b>RETR</b>	<i>Retrieve</i>	Tells the server to send the user a file.
<b>STOR</b>	<i>Store</i>	Sends a file to the server.
<b>STOU</b>	<i>Store Unique</i>	Like STOR, but instructs the server to make sure the file has a unique name in the current directory. This is used to prevent overwriting a file that may already exist with the same name. The server replies back with the name used for the file.
<b>APPE</b>	<i>Append (with Create)</i>	Like STOR, but if a file with the name specified already exists, the data being sent is appended to it instead of replacing it.
<b>ALLO</b>	<i>Allocate</i>	An optional command used to reserve storage on the server before a file is sent.
<b>REST</b>	<i>Restart</i>	Restarts a file transfer at a particular server marker. Used only for <i>Block</i> or <i>Compressed</i> transfer modes.

**Table 228: FTP Service Commands (Page 2 of 2)**

Command Code	Command	Description
<b>RNFR</b>	<i>Rename From</i>	Specifies the old name of a file to be renamed. See the <i>RNTO</i> command just below.
<b>RNTO</b>	<i>Rename To</i>	Specifies the new name of a file to be renamed. Used with the <i>RNFR</i> command.
<b>ABOR</b>	<i>Abort</i>	Tells the server to abort the last FTP command and/or the current data transfer.
<b>DELE</b>	<i>Delete</i>	Deletes a specified file on the server.
<b>RMD</b>	<i>Remove Directory</i>	Deletes a directory on the server.
<b>MKD</b>	<i>Make Directory</i>	Creates a directory.
<b>PWD</b>	<i>Print Working Directory</i>	Displays the current server working directory for the FTP session; shows the user “where they are” in the server’s file system.
<b>LIST</b>	<i>List</i>	Requests a list of the contents of the current directory from the server, including both names and other information. Similar in concept to the “DIR” command in DOS/Windows or the “ls” command in UNIX.
<b>NLST</b>	<i>Name List</i>	Like <i>LIST</i> , but returns only the names in a directory.
<b>SITE</b>	<i>Site Parameters</i>	Used to implement site-specific functions.
<b>SYST</b>	<i>System</i>	Requests that the server send to the client information about the server’s operating system.
<b>STAT</b>	<i>Status</i>	Prompts the server to send an indication of the status of a file or the transfer currently in progress.
<b>HELP</b>	<i>Help</i>	Asks the server for any help information that might be useful in allowing the user to determine how the server should be used.
<b>NOOP</b>	<i>No Operation</i>	Does nothing, other than prompting the server to send an “OK” response to verify that the control channel is alive.

**Note:** FTP commands are not case-sensitive, but have been shown in upper case for clarity.

FTP commands are all sent between FTP protocol elements; they are not usually issued directly by users. Instead, a special set of [user commands](#) is employed for this purpose. The FTP user interface implements the link between the user and the User-FTP process, including the translation of user commands into FTP protocol commands.

---

## **FTP Replies, Reply Code Format and Important Reply Codes**

Each time that the User-PI sends a command to the Server-PI over the control connection, the server sends back a *reply*. FTP replies serve three main purposes. First, they serve as confirmation that the server received a command. Second, they tell the user device whether the command was accepted or not, and if an error occurred, what it was. Third, they communicate various types of information to the user of the session, such as the status of a transfer.

### ***The Advantages of Using Both Text and Numeric Replies***

For a human user, a string of reply text would be sufficient to satisfy the requirements above, and FTP replies do include descriptive text. But having only a text string would make it difficult or impossible for FTP software on the client side to interpret results coming from the server. FTP was designed to also allow software applications to interact with each other over the FTP command link. For this reason, the protocol designed its reply system around the use of *reply codes*.

FTP reply codes are three-digit numeric responses that can be easily interpreted by a computer program. They are also useful for human users who are familiar with FTP, because they communicate at a glance the results of various operations. While each FTP server implementation may differ in the text sent for each type of reply, the reply codes are used in a consistent manner based on the specifications of the FTP standard. It is therefore the codes that are examined to determine the results of a command; the text is just descriptive.

### ***Reply Code Structure and Digit Interpretation***

To make reply codes even more useful, the codes are not just assigned in a linear or random order, but a special encoding scheme is used. Each code has three digits that each communicate a particular type of information and to categorize replies. A code can be considered to be of the form “xyz”, where “x” is the first digit, “y” the second and “z” the third.

**Key Concept:** Each command sent by the FTP client results in a reply sent by the FTP server. FTP replies consist of a three-digit numeric *reply code*, along with a line of descriptive text. The reply code serves to standardize FTP replies, both so they can be interpreted by client software, and so experienced users can see at a glance what the results were of a command. The reply code is structured so that the first two digits indicate the type of reply and to what category it belongs.

---

---

## First Reply Code Digit (“x”)

The first digit of the reply code indicates the success or failure of the command in general terms, whether a successful command is complete or incomplete, and whether an unsuccessful one should be tried again or not. [Table 229](#) shows the possible values.

**Table 229: FTP Reply Code Format: First Digit Interpretation**

Reply Code Format	Meaning	Description
1yz	<b>Positive Preliminary Reply</b>	An initial response indicating that the command has been accepted and processing of it is still in progress. The user should expect another reply before a new command may be sent.
2yz	<b>Positive Completion Reply</b>	The command has been successfully processed and completed.
3yz	<b>Positive Intermediate Reply</b>	The command was accepted, but processing of it has been delayed, pending receipt of additional information. This type of reply is used in the middle of command sequences. For example, it is used as part of the authentication sequence after receiving a <i>USER</i> command but before the matching <i>PASS</i> command is sent.
4yz	<b>Transient Negative Completion Reply</b>	The command was not accepted and no action was taken, but the error is temporary and the command may be tried again. This is used for errors that may be a result of temporary glitches or conditions that may change; for example, a file being “busy” due to another resource accessing it at the time a request was made for it.
5yz	<b>Permanent Negative Completion Reply</b>	The command was not accepted and no action was taken. Trying the same command again is likely to result in another error. For example, a request for a file that is not found on the server would fall into this category, or sending an invalid command like “BUGU”. ☺

## Second Reply Code Digit (“y”)

The second digit is used to categorize messages into functional groups. These groups are shown in [Table 230](#).

**Table 230: FTP Reply Code Format: Second Digit Interpretation (Page 1 of 2)**

Reply Code Format	Meaning	Description
x0z	<b>Syntax</b>	Syntax errors or miscellaneous messages.
x1z	<b>Information</b>	Replies to requests for information, such as status requests.
x2z	<b>Connections</b>	Replies related to the control connection or data connection.
x3z	<b>Authentication and Accounting</b>	Replies related to login procedures and accounting.

**Table 230: FTP Reply Code Format: Second Digit Interpretation (Page 2 of 2)**

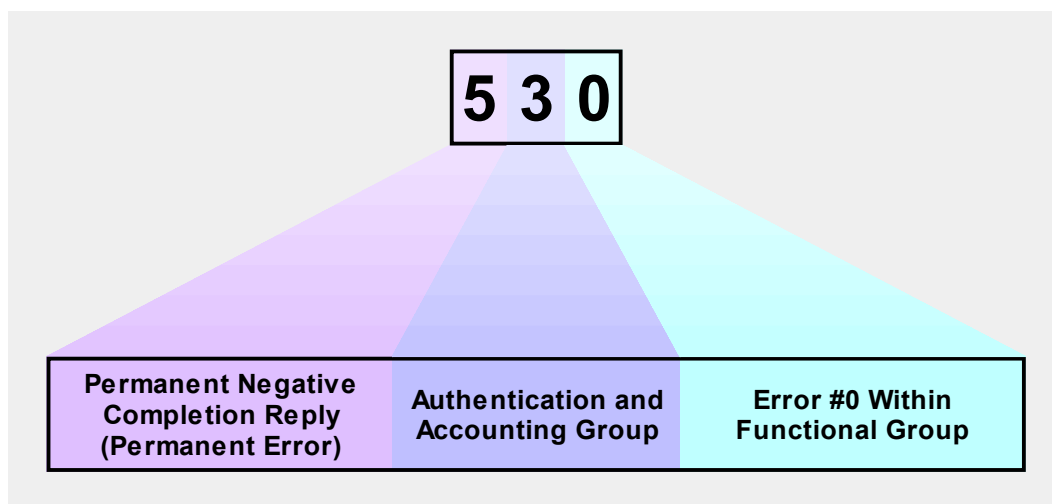

Reply Code Format	Meaning	Description
x4z	Unspecified	Not defined.
x5z	File System	Replies related to the server's file system.

### Third Reply Code Digit (“z”)

The last reply code digit indicates a specific type of message within each of the functional groups described by the second digit. The third digit allows each functional group to have 10 different reply codes for each reply type given by the first code digit (preliminary success, transient failure and so on.)

### Combining Digit Values to Make Specific Reply Codes

These “x”, “y” and “z” digit meanings are combined to make specific reply codes. For example, consider reply code “530”, diagrammed in [Figure 292](#). The first digit tells you that this is a permanent negative reply; the second indicates that it is related to login or accounting. (It is in fact an error message received when a login fails.)

**Figure 292: FTP Reply Code Format**

This diagram shows how the three-digit FTP reply code format is interpreted. In this example, reply code 530, the “5” indicates a permanent error, the “3” specifies that the error is related to authentication or accounting, and the “0” is the specific error type. A similar method is used for reply codes in many other TCP/IP application protocols, including SMTP and HTTP.

Using “encoded” reply codes allows the code itself to immediately communicate information, and provides a way of keeping different types of responses organized. The idea described above was adapted for use by several other application protocols, including SMTP for e-mail, NNTP for network news and HTTP for the World Wide Web.

---

## Common FTP Reply Codes

Table 231 contains a list of some of the more common FTP reply codes taken from RFC 959. They are shown in numerical order, along with the reply text given as typical in that document, and additional descriptive information from myself where needed:

**Table 231: FTP Reply Codes (Page 1 of 2)**

Reply Code	Typical Reply Text	Description
110	Restart marker reply.	Used as part of the marker restart feature when transferring in block mode.
120	Service ready in “nnn” minutes.	“nnn” indicates the number of minutes until the service will be available.
125	Data connection already open; transfer starting.	
150	File status okay; about to open data connection.	
200	Command okay.	Sometimes the text indicates the name of the command that was successful.
202	Command not implemented, or superfluous at this site.	
211	System status, or system help reply.	Will contain system-specific status or help information.
212	Directory status.	
213	File status.	
214	Help message.	Includes help information of use to a human user of this server.
215	“NAME” system type.	“NAME” is the name of a type of operating system. Often sent as a reply to the SYST command.
220	Service ready for new user.	Sent when the command channel is established before the USER command is sent.
221	Service closing control connection.	A “goodbye” message sent when the session is closed.
225	Data connection open; no transfer in progress.	
226	Closing data connection.	Sent after a successful file transfer or a file abort.
227	Entering Passive Mode (h1,h2,h3,h4,p1,p2).	Sent in reply to the PASV command, indicates the IP address and port to use for the data connection.
230	User logged in, proceed.	Sent after successful USER and PASS authentication. Systems often include additional “greeting” or other information with this code after a login.
250	Requested file action okay, completed.	The text description will provide more details about what was successfully done, such as confirming a change of directory or deleted file.

**Table 231: FTP Reply Codes (Page 2 of 2)**

Reply Code	Typical Reply Text	Description
257	"PATHNAME" created.	"PATHNAME" is replaced by the path created.
331	User name okay, need password.	Intermediate result after sending <i>USER</i> but before sending <i>PASS</i> .
332	Need account for login.	
350	Requested file action pending further information.	
421	Service not available, closing control connection.	Sometimes sent if the FTP server is in the process of shutting down.
425	Can't open data connection.	
426	Connection closed; transfer aborted.	
450	Requested file action not taken. File unavailable.	The file is not available; for example, it may be locked by another user. Contrast to reply code 550.
451	Requested action aborted: local error in processing.	
452	Requested action not taken. Insufficient storage space in system.	The file system is full.
500	Syntax error, command unrecognized.	Bad or excessively long command line was sent.
501	Syntax error in parameters or arguments.	
502	Command not implemented.	
503	Bad sequence of commands.	
504	Command not implemented for that parameter.	
530	Not logged in.	Sent if authentication fails due to a bad user name or incorrect password.
550	Requested action not taken. File unavailable.	File was not found or user does not have access to it. This error code may be sent in reply to any file transfer command if the user has not successfully logged in yet. Contrast to reply code 450.
551	Requested action aborted: page type unknown.	
552	Requested file action aborted. Exceeded storage allocation.	
553	Requested action not taken. File name not allowed.	

---

## ***FTP Multiple-Line Text Replies***

It is possible for a reply to contain more than one line of text. In this case, each line starts with the reply code, and all lines but the last have a hyphen between the reply code and the reply text, to indicate that the reply continues. The last line has a space between the reply code and reply text, just like a single-line reply. This facility is often used to provide additional response information after a user logs in, via the 230 reply code. [Table 232](#) contains an example.

**Table 232: FTP Multiple-Line Text Reply Example**

```
230-Welcome user to FTP server jabberwockynocky.  
230-  
230-You are user #17 of 100 simultaneous users allowed.  
230-  
230-  
230-Please see the file "faq.txt" for help using this server.  
230-  
230 Logged in.
```

As mentioned before, the actual text string for each reply code is implementation-specific. You can sometimes find some rather humorous text strings associated with some of these error messages. For example, I tried some commands using the FreeBSD FTP client on one of my Internet accounts. If you try to send or receive a file before you are logged in, it doesn't return an error like "Requested action not taken. File unavailable". It tells me "Login first, then I might let you do that.". Laugh... what an attitude these computers have today! ☺

## **FTP User Interface and User Commands**

The FTP [protocol command set](#) provides a rich, complete set of instructions for implementing the File Transfer Protocol. A human user could employ those commands to perform file transfer functions directly with an FTP server. But to do this requires that the user have an intimate knowledge of how FTP works. The user must know exactly which commands to send at which time, and in what order.

### ***FTP User Interface Benefits***

Memorizing internal FTP commands might be a reasonable assignment for an internet-working expert, but not for a typical TCP/IP application user. For this reason, the FTP protocol defines an additional [protocol component](#) as part of the User-FTP Process: the *FTP user interface*. It provides three main benefits to the FTP user:

- ☉ **User Friendliness:** The FTP user interface presents FTP to the human user in a way that is easier and simpler to use than issuing protocol commands. Instead of requiring the knowledge of all those four-letter codes, the user interface can allow functions to be performed with more intuitive human-language commands. For example, we can say "get" a file instead of knowing to use the command *RETR*.

- 
- ☛ **Customization:** The command used to perform a particular function can be customized based on common parlance in the networking industry, without requiring changes to be made to the FTP protocol itself. For example, the “image” transfer mode is now also commonly called “binary” mode, so a user command called “binary” has been created to set this mode.
  - ☛ **Detail Abstraction and Command Sequence Simplification:** A single user command can be made to issue multiple FTP protocol commands, hiding internal FTP details and making the protocol easier to use. In particular, commands that are related to the maintenance of the connection and other “overhead” issues that users don't want to deal with can be automated. For example, an FTP client normally issues a *PASV* or *PORT* command prior to each data transfer. The user interface can take care of issuing this command automatically prior to a *RETR* or *STOR* command when a user tells FTP to get or send a file.

### ***Command-Line and Graphical FTP Interfaces***

Traditionally, FTP clients have used a *command-line interface*. In this familiar arrangement, an FTP client is invoked and the user is automatically asked for a user name and password to establish an FTP session. Then, the user is presented with a command prompt, at which they can type various FTP commands to perform different functions. Text responses from the server are displayed to the user to indicate the results of various commands. Normally, the internal protocol commands (such as *PASV* and *STOR*) sent by the client are suppressed to avoid “screen clutter” but can be enabled in a debug mode.

Command-line utilities are efficient but some folks don't care for them. They are rather “old school” in the context of modern graphical operating systems and applications. Thus, there are also now many FTP clients that are graphical in nature. They allow actions to be performed arguably even more quickly, by clicking on buttons instead of typing commands. Some allow files to be transferred by “dragging and dropping” from a local file system display to one on a remote server. These make FTP even easier to use.

**Key Concept:** The *FTP user interface* is the component on the FTP client that acts as an intermediary between the human user and the FTP software. The existence of the user interface allows FTP to be used in a friendly manner without requiring knowledge of FTP's internal protocol commands. Most FTP software uses either a *command-line interface* that understands English-like *user commands*, or a *graphical interface*, where mouse clicks and other graphical operations are translated into FTP commands.

---

---

## Typical FTP User Commands

To discover the specific commands supported by an FTP client, consult its documentation. In a command-line client, you can enter the command “?” to get a list of supported commands. [Table 233](#) shows some of the common commands encountered in typical FTP command-line clients, along with the typical parameters they require.

**Table 233: FTP User Commands (Page 1 of 2)**

User Command	Description
<b>account</b> <account-name>	Sends the <i>ACCT</i> command to access a particular account on the server.
<b>append</b> <file-name>	Appends data to a file using <i>APPE</i> .
<b>ascii</b>	Sets the <i>ASCII</i> data type for subsequent transfers.
<b>binary</b>	Sets the <i>Image</i> data type for subsequent transfers. Same as the <i>image</i> command.
<b>bye</b>	Terminates FTP session and exits the FTP client (same as <i>exit</i> and <i>quit</i> ).
<b>cd</b> <directory-path>	Change remote server working directory (using <i>CWD</i> protocol command.)
<b>cdup</b>	Go to parent of current working directory.
<b>chmod</b> <file-name>	On UNIX systems, change file permissions of a file.
<b>close</b>	Closes a particular FTP session but user stays at FTP command line.
<b>debug</b>	Sets debug mode.
<b>delete</b> <file-name>	Deletes a file on the FTP server.
<b>dir</b> [<optional-file-specification>]	Lists contents of current working directory (or files matching the specification).
<b>exit</b>	Another synonym for <i>bye</i> and <i>quit</i> .
<b>form</b> <format>	Set transfer format.
<b>ftp</b> <ftp-server>	Open session to FTP server.
<b>get</b> <file-name> [<dest-file-name>]	Get a file. If the “<dest-file-name>” parameter is specified, it is used for the name of the file retrieved; otherwise, the source file name is used.
<b>help</b> [<optional-command-name>]	Displays FTP client help information. Same as “?”.
<b>image</b>	Set Image data type, like the <i>binary</i> command.
<b>ls</b> [<optional-file-specification>]	Lists contents of current working directory (or files matching the specification). Same as <i>dir</i> .
<b>mget</b> <file-specification>	Gets multiple files from the server.
<b>mkdir</b> <directory-name>	Create directory on remote server.
<b>mode</b> <transfer-mode>	Set file transfer mode.
<b>mput</b> <file-specification>	Sends (“puts”) multiple files to the server.
<b>msend</b> <file-specification>	Same as <i>mput</i> .
<b>open</b> <ftp-server>	Open session to FTP server (same as <i>ftp</i> ).
<b>passive</b>	Turns passive transfer mode on and off.

**Table 233: FTP User Commands (Page 2 of 2)**

User Command	Description
<b>put</b> <file-name> [<dest-file-name>]	Sends a file to the server. If the "<dest-file-name>" parameter is specified, it is used as the name for the file on the destination host; otherwise, the source file name is used.
<b>pwd</b>	Prints current working directory.
<b>quit</b>	Terminates FTP session and exits FTP client (same as <i>bye</i> and <i>exit</i> .)
<b>recv</b> <file-name> [<dest-file-name>]	Receives file (same as <i>get</i> ). If the "<dest-file-name>" parameter is specified, it is used for the name of the file retrieved; otherwise, the source file name is used.
<b>rename</b> <old-file-name> <new-file-name>	Renames a file.
<b>rhelp</b>	Displays remote help information, obtained using FTP <i>HELP</i> command.
<b>rmdir</b> <directory-name>	Removes a directory.
<b>send</b> <file-name> [<dest-file-name>]	Sends a file (same as <i>put</i> ). If the "<dest-file-name>" parameter is specified, it is used as the name for the file on the destination host; otherwise, the source file name is used.
<b>site</b>	Sends a site-specific command to the server.
<b>size</b> <file-name>	Show size of remote file.
<b>status</b>	Displays current session status.
<b>struct</b> <structure-type>	Sets file structure.
<b>system</b>	Shows the server's operating system type.
<b>type</b> <data-type>	Sets data type for transfers.
<b>user</b> <user-name>	Log in to server as a new user. Server will prompt for password.
<b>? [&lt;optional-command-name&gt;]</b>	Displays FTP client help information. Same as <i>help</i> .

Note how many of these commands are actually synonyms, such as *bye*, *exit* and *quit*. Similarly, one can use the command "type ascii" to set the ASCII data type, or just use the *ascii* command. This is all done for the convenience of the user and is one of the benefits of having a flexible user interface that is distinct from the FTP protocol command set.

Finally, an alternative way of using FTP is through the specification of an FTP [Uniform Resource Locator \(URL\)](#). While FTP is at its heart an interactive system, FTP URLs allow simple functions, such as retrieving a single file, to be done quickly and easily. They also allow FTP file references to be integrated with hypertext (World Wide Web) documents. [See the discussion of URL schemes for more on how FTP uses URLs.](#)

---

## FTP Sample User and Internal Command Dialog

The previous two sections have described [how FTP operates](#), and shown the [commands and reply codes](#) used to implement communication between an FTP user and an FTP server. Having now seen all the details of how FTP works, let's tie everything together by looking at a sample FTP session between an FTP client and server, to see FTP commands and replies "in action".

In this example, I will invoke FTP from a client to retrieve a text file from an FTP server, then delete the file from the server and the directory that contained it. In the process, I will issue some additional commands to illustrate more of how FTP works. I will enable "debug" mode in the FTP client so that for each user command we can see the actual FTP protocol commands generated.

[Table 234](#) shows the sample FTP dialog, slightly simplified. The first column contains commands entered by the user (that's me) on the FTP client. The second shows the actual protocol command(s) sent to the FTP server in highlighted text, and the reply returned from the server to the client in plain text. The third contains descriptive comments.

**Table 234: Sample FTP Session (Page 1 of 3)**

User Command	FTP Protocol Command / FTP Server Reply	Comments
<code>ftp -d pcguide.com</code>	Connected to pcguide.com. 220 ftp199.pair.com NcFTPD Server (licensed copy) ready. Name (pcguide.com:ixl):	This is the command to start up FTP. The "-d" enables debug mode. In this initial step the TCP control connection is made, and the server replies with a 220 reply code indicating that it is ready for user identification. The FTP client automatically prompts for the user name.
<code>ixl</code>	<b>USER ixl</b>  331 User ixl okay, need password.	I use "ixl" for user names commonly. Here, the FTP client sends the user name and the server responds back asking for the password.
<code>****</code>	<b>PASS XXXX</b>  230-You are user #1 of 300 simultaneous users allowed. 230- 230- 230-Welcome to (<system name>) 230- 230 Logged in.  <b>SYST</b>  215 UNIX Type: L8 Remote system type is UNIX. Using binary mode to transfer files.	I enter my password, which is sent to the FTP server, and a bunch of stuff happens. ☺ The server authenticates me and sends back a 230 message. This tells me the login was successful. It also provides me with additional information.  The FTP client then automatically sends a <b>SYST</b> command to tell me what type of system the server is using, in this case UNIX. The client also tells me that binary mode has been selected by default; this is often the default when doing FTP from UNIX to UNIX (as I am doing here) since there is no need for ASCII mode when moving text files between similar systems.

**Table 234: Sample FTP Session (Page 2 of 3)**

User Command	FTP Protocol Command / FTP Server Reply	Comments
<code>pwd</code>	<b>PWD</b>  257 "/usr/home/ixl" is cwd.	I check the current working directory ("cwd"), which the server tells me is my own home directory on this system.
<code>cd ftptest</code>	<b>CWD ftptest</b>  550 No such directory.	I try to go to a directory called "ftptest" but that was the wrong name, so I get a 550 error for my trouble. (I wasn't trying to do this, I forgot the directory name but figured I might as well show it to you anyway! ☺)
<code>cd ftpdemo</code>	<b>CWD ftpdemo</b>  250 "/usr/home/ixl/ftpdemo" is new cwd.	I got the name right this time and the server confirms the new working directory.
<code>dir</code>	<b>PASV</b>  227 Entering Passive Mode (ip1,ip2,ip3,ip4,193,224)  <b>LIST</b>  150 Data connection accepted from ip5.ip6.ip7.ip8:4279; transfer starting. -rw-r--r- 1 ixl users 16 May 22 17:47 testfile.txt 226 Listing completed.	I request a list of files from the server. The FTP client automatically issues a <b>PASV</b> command and the server responds with a port number and IP address for it to use (I have not shown the IP here for security reasons.) The directory listing is then transferred from the server to the client.
<code>asc</code>	<b>TYPE A</b>  200 Type okay.	I set ASCII mode. Don't really need to, as I said above, but what the heck. Note that this client allowed me to abbreviate the <code>ascii</code> command as "asc".
<code>get testfile.txt</code>	<b>PASV</b>  227 Entering Passive Mode (ip1,ip2,ip3,ip4,193,226)  <b>RETR testfile.txt</b>  150 Data connection accepted from ip5.ip6.ip7.ip8:4283; transfer starting for testfile.txt (16 bytes).  226 Transfer completed. 17 bytes received in 0.10 seconds (0.17 KB/s)	I get the file in this demo directory using a <code>get</code> command. The server accepts the <b>PASV</b> command and sends the file. It initially sends a 150 reply as the transfer starts (initial positive reply) then sends 226 when it is done.  Note that the port numbers used here are different (for both server and client) than they were for the directory listing I did earlier.
<code>del testfile.txt</code>	<b>DELE testfile.txt</b>  250 Deleted.	I delete the original file on the server.

---

**Table 234: Sample FTP Session (Page 3 of 3)**

User Command	FTP Protocol Command / FTP Server Reply	Comments
<code>cdup</code>	<code>CDUP</code> 250 "/usr/home/ixl" is new cwd.	I go up to the parent directory.
<code>rmdir ftpdemo</code>	<code>RMD ftpdemo</code> 250 Directory removed.	I remove the directory that the file was in.
<code>quit</code>	<code>QUIT</code> 221 Goodbye.	I end the FTP session. The quit command also automatically closes the FTP client and returns me to the UNIX shell.

---

## **Trivial File Transfer Protocol (TFTP)**

The File [Transfer Protocol \(FTP\)](#) implements a full set of command and reply functionality that enables a user to perform a wide range of file movement and manipulation tasks between two TCP/IP machines. It is ideal as a general purpose protocol for file transfer between computers, but on certain types of hardware, it is too complex to easily implement, and provides more capabilities than are really needed. In cases where only the most basic file transfer functions are needed and simplicity and small program size is of paramount importance, a companion to FTP was created called the *Trivial File Transfer Protocol (TFTP)*.

In this section I provide a description of the operation of TFTP. I begin with an overview description of the protocol, its history and motivation, and the relevant standards that describe it. I discuss its operation in general terms and how TFTP clients and server communicate, and explain TFTP messaging in detail. I then discuss TFTP options and the TFTP option negotiation mechanism, and conclude by showing the various TFTP message formats.

**Background Information:** While TFTP is a distinct protocol from FTP, explaining the former is easier when the reader is familiar with the latter. I assume that the reader has some understanding of FTP, since it is the more commonly-used protocol. If you have come to this section prior to reading [the section on FTP](#), I'd recommend at least reading the [FTP overview topic](#) before proceeding.

---

### **TFTP Overview, History and Standards**

The [File Transfer Protocol \(FTP\)](#) is the main protocol used for the majority of general file transfers in TCP/IP internetworks. One of the objectives of the designers of FTP was to keep the protocol relatively simple, but that was really only possible to a limited extent. To enable the protocol to be useful in a variety of cases and between many kinds of devices, FTP needed a fairly large set of features and capabilities. As a result, while FTP is not as complex as certain other protocols, it is still fairly complicated in a number of respects.

#### ***The Need for TFTP***

The complexity of FTP is partially due to the protocol itself, with its dozens of commands and reply codes, and partly due to the need to use of the [Transmission Control Protocol \(TCP\)](#) for connections and data transport. The reliance on TCP means that any device wanting to use FTP needs not only the FTP program, but also a full TCP implementation as well. It must handle FTP's need for simultaneous data and control channel connections and other requirements.

For a conventional computer, like a regular PC, Macintosh or UNIX workstation, none of this is really an issue, especially with today's large hard disks and fast, cheap memory. But remember that FTP was developed over three decades ago, when hardware was slow and

---

memory was expensive. Furthermore, even today, regular computers are not the only devices used on networks. There are some networked devices that do not have the capabilities of “true” computers, but still need to be able to do file transfers. For these devices, a full FTP and TCP implementation is a non-trivial matter.

One of the most notable examples of devices where this is an issue are *diskless workstations*. These are computers that have no permanent storage, so when they start up, they cannot read a whole TCP/IP implementation from a hard disk like most computers do easily. They start with only a small amount of built-in software, and must obtain configuration information from a server and then download the rest of their software from another network device. The same issue arises for certain other hardware devices with no hard disks.

The process of starting up these devices is commonly called *bootstrapping* and occurs in two phases. First, the workstation is provided with an IP address and other parameters, through the use of a [host configuration protocol](#) such as [BOOTP](#) or [DHCP](#). Second, the client downloads software, such as an operating system and drivers, that let it function on the network like any other device. This requires the ability to transfer files quickly and easily. The instructions to perform this bootstrapping must fit onto a read-only memory (ROM) chip and this makes the size of the software an important issue—again, especially many years ago.

The solution to this need was to create a “light” version of FTP that would emphasize small program size and simplicity over functionality. This new protocol, called the *Trivial File Transfer Protocol (TFTP)*, was initially developed in the late 1970s, and first standardized in 1980. The modern version, called *TFTP version 2*, was documented in RFC 783 in 1981, which was revised and published as RFC 1350, *The TFTP Protocol (Revision 2)*, in 1992. This is the current version of the standard.

### **Comparing FTP and TFTP**

Probably the best way of understanding the relationship between TFTP and FTP is to compare it to [the relationship between TCP and UDP at the transport layer](#). UDP is a simplified, “stripped-down” alternative to TCP, used when simplicity is more important than rich functionality. Similarly, TFTP is a greatly simplified version of FTP that allows only basic operations and lacks some of FTP's fancy capabilities, in order to keep its implementation easy (even “trivial”!) and its program size small.

Some of the more significant specific differences between FTP and TFTP:

- ☉ **Transport:** The comparison to TCP and UDP is apt not only based on the features/simplicity trade-off, but because FTP uses [TCP](#) for transport while TFTP uses [UDP](#). Like TFTP, UDP is simple and this makes the two ideal for embedding together as a hardware program set in a network device.
- ☉ **Limited Command Set:** FTP includes a rich set of commands to allow files to be sent, received, renamed, deleted and so forth. TFTP only allows files to be sent and received.
- ☉ **Limited Data Representations:** TFTP does not include some of FTP's fancy data representation options; it allows only simple ASCII or binary file transfers.

- 
- ☉ **Lack of Authentication:** UDP uses no login mechanism or other means of authentication. This is again a simplification, though it means the operators of TFTP servers must severely restrict the files they make available for access. (It is also part of why TFTP specifically does not allow the client to perform “dangerous” file operations such as deletion.)

Due to its limitations, TFTP is a complement to the regular File Transfer Protocol, not a replacement for it. It is used only when its simplicity is important and its lack of features is not. Its most common application is bootstrapping, as described above, though it can be used for other purposes. One specific application that the TFTP standard describes for the protocol is the transport of electronic mail. While the protocol supports this explicitly, TFTP is not generally used today for this purpose.

### **Overview of TFTP Operation**

Communication and messaging in TFTP is very different than it is in FTP because of the different transport layer protocols used by each. FTP makes use of TCP's rich functionality, including its stream data orientation, to allow it to send bytes of data directly over the FTP data connection. TCP also takes care of reliable delivery of data for FTP, ensuring files are received correctly. In contrast, since TFTP uses UDP, it must package data into individual messages for both protocol control and data communication. TFTP must also take care of timing transmissions to detect lost datagrams and then retransmitting as needed.

TFTP servers allow connections from TFTP clients to perform file send and receive operations. Many hosts that run FTP servers will also run a separate TFTP server module as well. TFTP users initiate connections by starting a TFTP client program, which generally uses a command-line interface similar to that of many FTP clients; the main difference is the much smaller number of commands in TFTP.

**Key Concept:** For situations where the full File Transfer Protocol (FTP) is either unnecessary or impractical, the simpler *Trivial File Transfer Protocol (TFTP)* was developed. TFTP is like FTP in that it is used for general file transfer between a client and server device, but it is stripped down in its capabilities. Rather than including a full command set and using TCP for communication like FTP, TFTP can only be used for reading or writing a single file, and uses the fast but unreliable UDP for transport. It is often preferred in situations where small files must be transferred quickly and simply, such as bootstrapping diskless workstations.

---

### **TFTP Option Extension and TFTP Options**

The basic operation of TFTP has not changed since RFC 1350 was published, but a new feature was added to the protocol in 1995. RFC 1782, *TFTP Option Extension*, defines a mechanism by which a TFTP client and TFTP server can negotiate certain parameters that will control a file transfer prior to the transfer commencing. This allows more flexibility in how TFTP is used, adding a slight amount of complexity to TFTP, but not a great deal.

---

The option extension is backwards-compatible with regular TFTP, and is only used if both server and client support it. Two subsequent RFCs define the actual options that can be negotiated: RFC 1783, *TFTP Blocksize Option* and RFC 1784, *TFTP Timeout Interval and Transfer Size Options*. This set of three RFCs (1782, 1783 and 1784) was replaced in 1998 by updated versions in RFCs 2347, 2348 and 2349.

## **TFTP General Operation, Connection Establishment and Client/Server Communication**

Since the “T” in “TFTP” stands for “trivial”, and the protocol was specifically designed to be simple, you would think that describing how it works would, in fact, be simple, wouldn't you? Well, actually, it pretty much is. Sorry, I couldn't resist setting you up there. ☺

TFTP communication is client/server based, as discussed in the overview. The process of transferring a file consists of three main phases. In highly generalized terms, these are:

1. **Initial Connection:** The TFTP client establishes the connection by sending an initial request to the server. The server responds back to the client and the connection is effectively opened.
2. **Data Transfer:** Once the connection is established, the client and server exchange TFTP messages. One device sends data and the other sends acknowledgments.
3. **Connection Termination:** When the last TFTP message containing data has been sent and acknowledged, the connection is terminated.

### ***Connection Establishment and Identification***

The concept of a “connection” is somewhat different in TFTP than it is with a protocol like FTP that uses TCP. FTP must establish a connection at the TCP level before anything can be done by FTP itself. TFTP, however, uses the [connectionless](#) UDP for transport, so there is no connection in the sense that one exists in TCP. In TFTP, the connection is more in a “logical sense”, meaning that the client and server are participating in the protocol and exchanging TFTP messages.

The TFTP server listens continuously for requests on [well-known](#) UDP port number 69, which is reserved for TFTP. The client chooses for its initial communication an [ephemeral port number](#), as is usually the case in TCP/IP. This port number actually identifies the data transfer, and is called a *transfer identifier (TID)*.

What's different about TFTP, however, is that the server also selects a pseudo-random TID that it uses for sending responses back to the client; it doesn't send them from port number 69. The reason this is done is that by using unique client port number and source port number, multiple TFTP exchanges can be conducted simultaneously by a server. Each transfer is identified automatically by the source and destination port number, so there is no need to identify in data messages the transfer to which each block data belongs. This keeps the TFTP header size down, allowing more of each UDP message to contain actual data.

---

For example, suppose the TFTP client selects a TID of 3,145 for its initial message. It would send a UDP transmission from its port 3,145 to the server's port 69. Say the server selects a TID of 1,114. It would send its reply from its port 1,114 to the client's port 3,145. From then on, the client would send messages back to server port 1,114 until the TFTP session was completed.

### ***"Lock-Step" Client/Server Messaging***

After the initial exchange, the client and server exchange data and acknowledgment messages in "lock-step" fashion. Each device sends a message for each message it receives: one device sends data messages and waits for acknowledgments, the other sends acknowledgments and waits for data messages. This form of rigid communication is less efficient than allowing the transmitter to "fire away" with one data message after another, but is important because it keeps TFTP simple when it comes to an important issue: retransmissions.

Like all protocols using the unreliable UDP, TFTP has no assurances that any messages sent will in fact arrive at their destination, so it must use timers to detect lost transmissions and resend them. What is different about TFTP is that both clients and servers perform retransmission. The device that is sending data messages will resend the data message if it doesn't receive an acknowledgment in a reasonable period of time; the device sending the acknowledgments will resend the acknowledgment if it doesn't receive the next data message promptly. The "lock-step" communication discussed above greatly simplifies this process, since each device only needs to keep track of one "outstanding" message at a time. It also eliminates the need to deal with complications such as reorganizing blocks received out of order (which protocols like FTP rely on TCP to manage.)

**Key Concept:** Since TFTP uses UDP rather than TCP, there is no explicit concept of a connection as in FTP. A TFTP session instead uses the concept of a "logical connection", which is opened when a client sends a request to a server to read or write a file. Communication between the client and server is performed in "lock-step" fashion: one device sends data messages and receives acknowledgments so it knows the data messages were received; the other sends acknowledgments and receives data messages so it knows the acknowledgments were received.

---

### ***Difficulties With TFTP's Simplified Messaging Mechanism***

One of the most important drawbacks with this technique is that while it simplifies communication, it does so at the cost of **performance**. Since only one message can be in transit at a time, this limits throughput to a maximum of 512 bytes for exchange of messages between the client and server. In contrast, when using FTP, large amounts of data can be pipelined; there is no need to wait for an acknowledgment for the first piece of data before sending the second.

---

Another complication is that if a data or acknowledgment message is re-sent and the original was not lost but rather just delayed, two copies will show up. The original TFTP protocol rules stated that upon receipt of a duplicate datagram, the device receiving it may re-send the current datagram again. So, receipt of a duplicate block #2 by a client doing a read would result in the client sending a duplicate acknowledgment for block #2. This would mean two acknowledgments received by the server, which would in turn send block #3 twice. Then there would be two acknowledgments for block #3, and so on.

The end result of this is that once the initial duplication occurs, every message thereafter is sent twice. This has been affectionately dubbed the *Sorcerer's Apprentice Bug*, after the story used as the basis of the famous scene in Disney's *Fantasia* where Mickey Mouse cuts animated brooms in half only to find that in turn, each half comes to life. This problem was fixed by changing the rules so that only the device receiving a duplicate **data** message may send a duplicate acknowledgment. Receipt of a duplicate **acknowledgment** does not result in sending a duplicate data message. Since only one of the two devices can send duplicates, this fixes the problem.

It's also worth emphasizing that TFTP includes absolutely no security, so there is no login or authentication process. As mentioned in [the overview](#), administrators must use caution in deciding what files to make available via TFTP, and in allowing write access to TFTP servers.

## **TFTP Detailed Operation and Messaging**

TFTP operation consists of [three general steps](#): initial connection, data transfer, and connection termination. All operations are performed through the exchange of specific TFTP messages. Let's take a more detailed look now at these three phases of operation and the specifics of TFTP messaging functions.

### ***Initial Message Exchange***

The first message sent by the client to initiate TFTP is either a *read request (RRQ)* message or a *write request (WRQ)* message. This message serves to implicitly establish the logical TFTP connection, and to indicate if the file is to be sent from the server to the client (read request) or the client to the server (write request). The message also specifies the type of file transfer to be performed. TFTP supports two transfer modes: *netascii* mode (ASCII text files as used by the [Telnet Protocol](#)) and *octet* mode (binary files).

**Note:** There was originally a third file type option—*mail* mode—but TFTP was never really designed for transmitting mail and this option is now obsolete.

---

---

Assuming there was no problem with the request (such as a server problem, inability to find the file, etc.) the server will respond with a positive reply. In the case of a read request, the server will immediately send the first data message back to the client. In the case of a write request, the server will send an acknowledgment message to the client, telling it that it may proceed to send the first data message.

After the initial exchange, the client and server exchange data and acknowledgment messages in “lock-step” fashion as described in [the previous topic](#). For a read, the server sends one data message and waits for an acknowledgment from the client before sending the next one. For a write, the client sends one data message and the server sends an acknowledgment for it, before the client sends the next data message.

If there is a problem at any stage of the connection establishment or transfer process, a device may reply with an error message instead of a data or acknowledgment message, as appropriate. An error message normally results in the failure of the data transfer; this is one of the prices paid for the simplicity of TFTP.

Each TFTP file transfer proceeds using one of the processes described below, which either reads or writes a single file. If another file needs to be sent or received, a new logical communication is established, in a manner analogous to how FTP creates [data connections](#). The main difference is that TFTP has no [persistent control connection](#) like FTP does.

### ***Data Block Numbering***

Each data message contains a block of between 0 and 512 bytes of data. The blocks are numbered sequentially, starting with 1. The number of each block is placed in the header of the data message carrying that block, and then used in the acknowledgment for that block so the original sender knows it was received. The device sending the data will always send 512 bytes of data at a time for as long as it has enough data to fill the message. When it gets to the end of the file and has fewer than 512 bytes to send, it will send only as many bytes as remain. Interestingly, this means that if the size of the file is an exact multiple of 512, the last message sent will have zero bytes of data!

The receipt of a data message with between 0 and 511 bytes of data signals that this is the last data message. Once this is acknowledged, this automatically signals the end of the data transfer. There is no need to explicitly terminate the “connection”, just as it was not necessary to explicitly establish it.

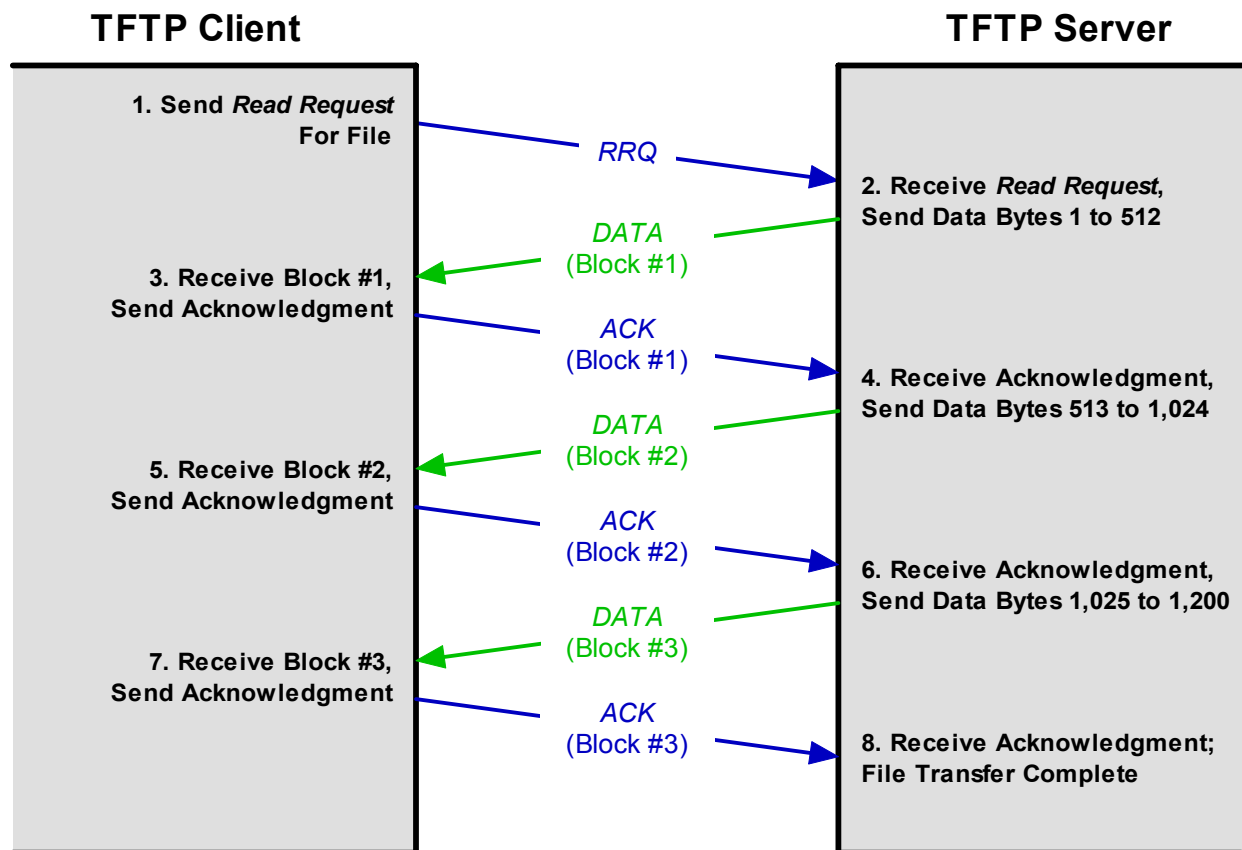

### ***TFTP Read Process Steps***

Let's use an example to see how TFTP messaging works. Suppose the client wants to read a particular file that is 1,200 bytes long. Here are the steps in simplified form (also displayed in [Figure 293](#)):

1. The client sends a read request to the server, specifying the name of the file.
2. The server sends back a data message containing block #1, carrying 512 bytes of data.
3. The client receives the data, and sends back an acknowledgment for block #1.

4. The server sends block #2, with 512 bytes of data.
5. The client receives block #2, and sends back an acknowledgment for it.
6. The server sends block #3, containing 176 bytes of data. It waits for an acknowledgment before terminating the logical connection.
7. The client receives the data, sends an acknowledgment for block #3. Since this data message had fewer than 512 bytes, it knows the file is complete.
8. The server receives the acknowledgment, and knows the file was received successfully.

**Figure 293: TFTP Read Process**

In this example, the client starts the process of reading a file by sending a request for it to the server. The server acknowledges this request by immediately sending a *DATA* message carrying block #1, containing the first 512 bytes of the file. The client acknowledges this with an *ACK* message for block #1. The server then sends block #2, containing bytes 513 to 1,024, which the client acknowledges. When the client receives block #3, it realizes it has only 176 bytes, which marks it as the last block of the file.

### **TFTP Write Process Steps**

Here are the steps in the same process, but where the client is writing the file (see [Figure 294](#)):

1. The client sends a write request to the server, specifying the name of the file.

- 
2. The server sends back an acknowledgment. Since this acknowledgment is prior to the receipt of any data, it uses block number zero in the acknowledgment.
  3. The client sends a data message containing block #1, 512 bytes of data.
  4. The server receives the data, sends back an acknowledgment for block #1.
  5. The client sends block #2, 512 bytes of data.
  6. The server receives the data, sends back an acknowledgment for block #2.
  7. The client sends block #3, containing 176 bytes of data. It waits for an acknowledgment before terminating the logical connection.
  8. The server receives block #3 and sends an acknowledgment for it. Since this data message had fewer than 512 bytes, the transfer is done.
  9. The client receives the acknowledgment for block #3 and knows the file write was completed successfully.

**Key Concept:** A TFTP *read operation* begins with the client sending a *Read Request* message to the TFTP server; the server then sends the file in 512-byte *Data* messages, waiting after each one for the client to acknowledge receipt before sending the next. A TFTP *write operation* starts with a *Write Request* sent by the client to the server, which the server acknowledges. The client then sends the file in 512-byte *Data* blocks, waiting after each for the server to acknowledge receipt. In both cases there is no explicit means by which the end of a transfer is marked; the device receiving the file simply knows the transfer is complete when it receives a *Data* message containing fewer than 512 bytes.

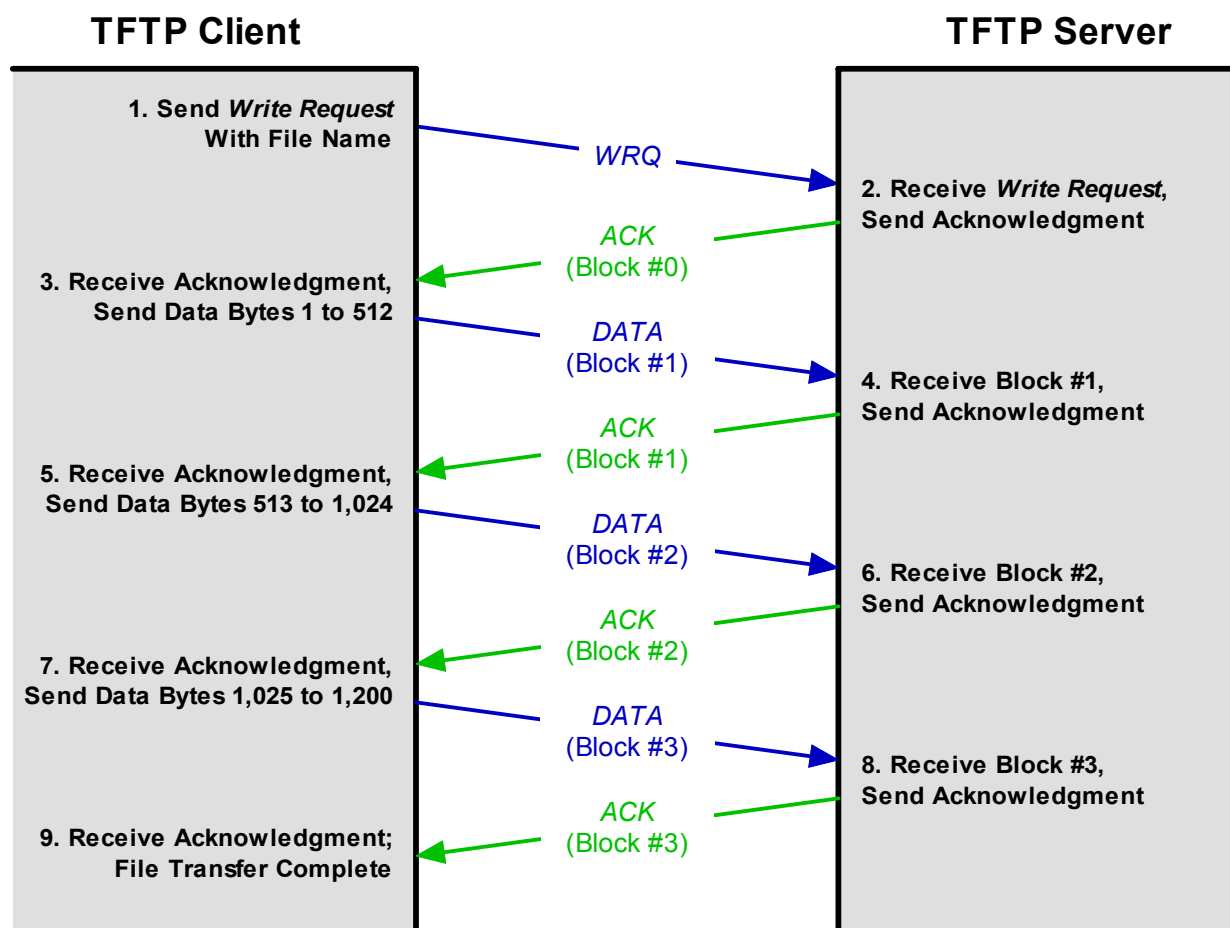

---

## **TFTP Options and Option Negotiation**

One of the difficulties that designers of simple protocols and applications seem to have is **keeping** them simple. Many protocols start out small but over time, well-intentioned users suggest improvements that are added slowly but surely. Eventually, the program that was once “lean and mean” has become, well, shall we say, “well-marbled”. ☺ In the software industry, this is called “feature creep” and it has happened to many protocols and applications.

The temptation to add features is especially strong when the program or protocol has few to begin with. Given this, the maintainers of the TFTP protocol have done a good job over the years of avoiding this pitfall. However, they did allow one new feature to be added to the protocol in 1995: the *TFTP Option Extension*, which describes how a TFTP client and server can negotiate *options* before transferring a file.

The reason for adding this capability is that the original TFTP protocol provided no way at all for the client and server to exchange important control information prior to sending a file. This limited the flexibility of the protocol to deal with special cases, such as the transfer of data over unusual network types. The TFTP option negotiation feature allows additional parameters to be exchanged between the client and server which govern how data is trans-

**Figure 294: TFTP Write Process**

This example shows the client sending the same 1,200-byte file to the server that it read in [Figure 293](#). The client sends a write request to the server, which acknowledges it; it uses block #0 to represent acknowledgment of the request prior to receipt of any data. The client then sends blocks of data one at a time, each of which is acknowledged by the server. When the server receives block #3 containing fewer than 512 bytes of data, it knows it has received the whole file.

ferred. It does this without significantly complicating the protocol, and is backward-compatible with normal TFTP. It is only used if both client and server support it, and one device trying to use the feature will not cause problems if the other doesn't support it.

### ***TFTP Option Negotiation Process***

The client begins the negotiation by sending a modified TFTP *Read Request* or *Write Request* message. In addition to the normal information that appears in this message (see the next topic), a list of options may also be included. Each is specified with an *Option Code* and an *Option Value*. The names and values are expressed as ASCII strings, terminated by a null character (zero byte). Multiple options may be specified in the request message.

---

The server receives the request containing the options, and if it supports the option extension, processes them. It then returns a special *Option Acknowledgment (OACK)* message to the client, where it lists all the options that the client specified that the server recognizes and accepts. Any options that the client requested but the server rejects, it does not include in this option acknowledgment. The client may only use the options that the server accepts. If the client rejects the server's response, it may send back an error message (with error code 8) upon receipt of the unacceptable *OACK* message.

The server may specify an alternative value in its response for certain options, if it recognizes the option but doesn't like the client's suggested value. Obviously, if the server doesn't support options at all, it will ignore the client's option requests, and respond back with a data message (for a read) or a regular acknowledgment (for a write) as in normal TFTP.

If the server did send an *OACK*, the client then proceeds to send messages using the regular messaging exchange described in the previous section. In the case of a write, the option acknowledgment replaces the regular acknowledgment in the message dialog. In the case of a read, the option acknowledgment is the server's first message instead of the first data block that it would normally send. TFTP doesn't allow the same device to send two datagrams in a row, so there needs to be a reply from the client before that first block can be sent. The client does this by sending a regular acknowledgment with a block number of 0 in it — the same form of acknowledgment a server normally sends for a write.

**Key Concept:** TFTP is supposed to be a small and simple protocol, so it includes few “extra” features. One that it does support is *option negotiation*, where a TFTP client and server attempt to come to agreement on additional parameters that they will use in transferring a file. The TFTP client includes one or more options in its *Read Request* or *Write Request* message; the TFTP server then sends an *Option Acknowledgment (OACK)* message listing each option the server agrees to use. The use of options when reading a file means that an extra acknowledgment must be sent by the client--to acknowledge the *OACK*--before the server sends the first block of the file.

---

Phew, that's confusing. For review, let's take a look at each of the four possible cases (read and write, with and without options).

### ***TFTP Read Process With and Without Option Negotiation***

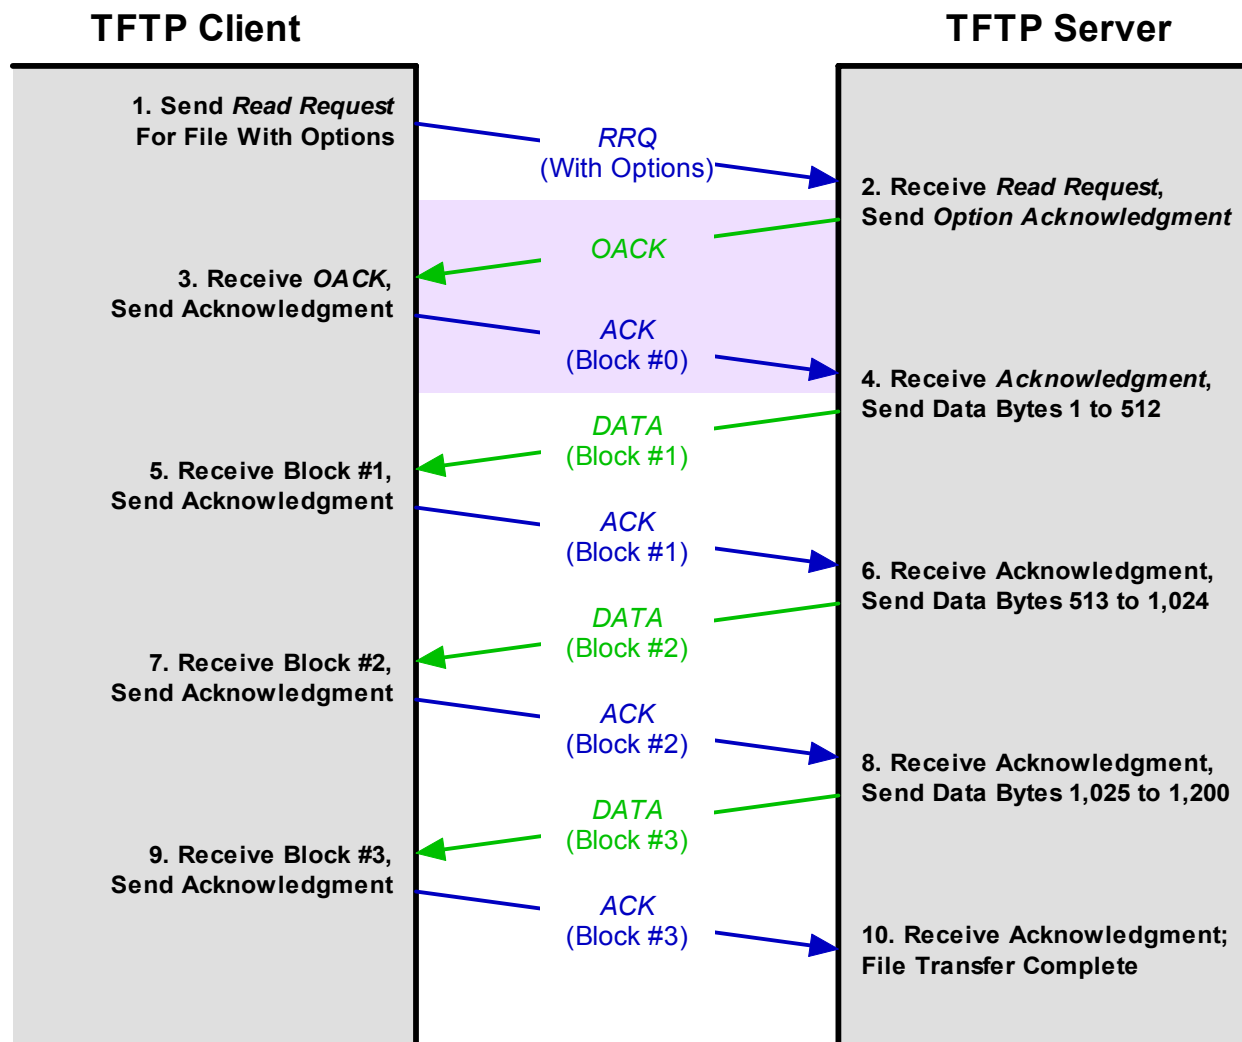

The initial message exchange for a normal read (without option negotiation), as shown in [Figure 293](#):

1. Client sends *Read Request*.
2. Server sends *Data* block #1.
3. Client acknowledges data block #1.

And so on...

And now, a read with option negotiation ([Figure 295](#)):

1. Client sends *Read Request* with options.
2. Server sends *Option Acknowledgment*.
3. Client sends regular acknowledgment for “block #0”, that is, it acknowledges the OACK.
4. Server sends data block #1.
5. Client acknowledges data block #1.
- Etc...

**Figure 295: TFTP Read Process With Option Negotiation**

This diagram shows the same example illustrated in [Figure 293](#), but with one added message exchange used for option negotiation (purple background). The client's initial *Read Request* here includes options that it wants to use for this transfer. The server responds not immediately with the first data block, but with an *Option Acknowledgment*. The client indicates receipt of the OACK by sending an acknowledgment using block #0. The server sends data block #1 and the rest of the exchange proceeds as normal.

---

## TFTP Write Process With and Without Option Negotiation

The initial message exchange for a normal write (without option negotiation):

1. Client sends write request.
2. Server sends acknowledgment.
3. Client sends data block #1.
4. Server acknowledges data block #1.

...

And a write with option negotiation:

1. Client sends write request with options.
2. Server sends option acknowledgment (instead of regular acknowledgment).
3. Client sends data block #1.
4. Server acknowledges data block #1.

...

### TFTP Options

[Table 235](#) contains a summary of the three TFTP options currently defined.

**Table 235: TFTP Options**

TFTP Option Name	TFTP Option Code (Used in Request Messages)	Defining RFC	Description
<b>Block Size</b>	<i>blksize</i>	2348	Allows the client and server to send data blocks of a size different than 512 bytes, to improve efficiency or address limitations of a particular type of network.
<b>Timeout Interval</b>	<i>interval</i>	2349	Permits the client and server to agree on a specified number of seconds to use for their retransmission timers. Again, may be of value on certain networks with high latency or other special requirements.
<b>Transfer Size</b>	<i>tsize</i>	2349	Lets the device sending the file (client on a write, server on a read) tell the other device the size of the file before the transfer commences. This allows the receiving device to allocate space for it in advance.

### TFTP Message Formats

Unlike FTP, all communication in TFTP is accomplished in the form of discrete messages that follow a particular message format. The reason why TFTP and FTP are so different in this regard is the different transport protocols they use. FTP uses TCP, which allows data to be streamed a byte at a time; FTP also makes use of a dedicated channel for commands. TFTP runs on UDP, which uses a conventional “header/data” formatting scheme.

The original TFTP standard defines five different types of messages: *Read Request (RRQ)*, *Write Request (WRQ)*, *Data (DATA)*, *Acknowledgment (ACK)* and *Error (ERROR)*. The [TFTP option extension](#) feature defines a sixth message: *Option Acknowledgment (OACK)*. Of these six messages, the first two share the same message format. The others all have their own unique format. The only common field in every TFTP message is the *Operation Code (Opcode)*, which tells the recipient of the message what type it is.

TFTP's message formats are different than those used for certain other protocols because many of the fields are variable in length. Usually, variable-length fields in messages are expressed using a preceding length field that specifies the length of the variable-sized field. Instead, TFTP sends such fields as strings of ASCII characters using *netascii*, the [Telnet](#) version of ASCII. The end of the string is marked by a zero byte. The exception to this is the data field in *Data* messages, the content of which depends on the transfer mode.

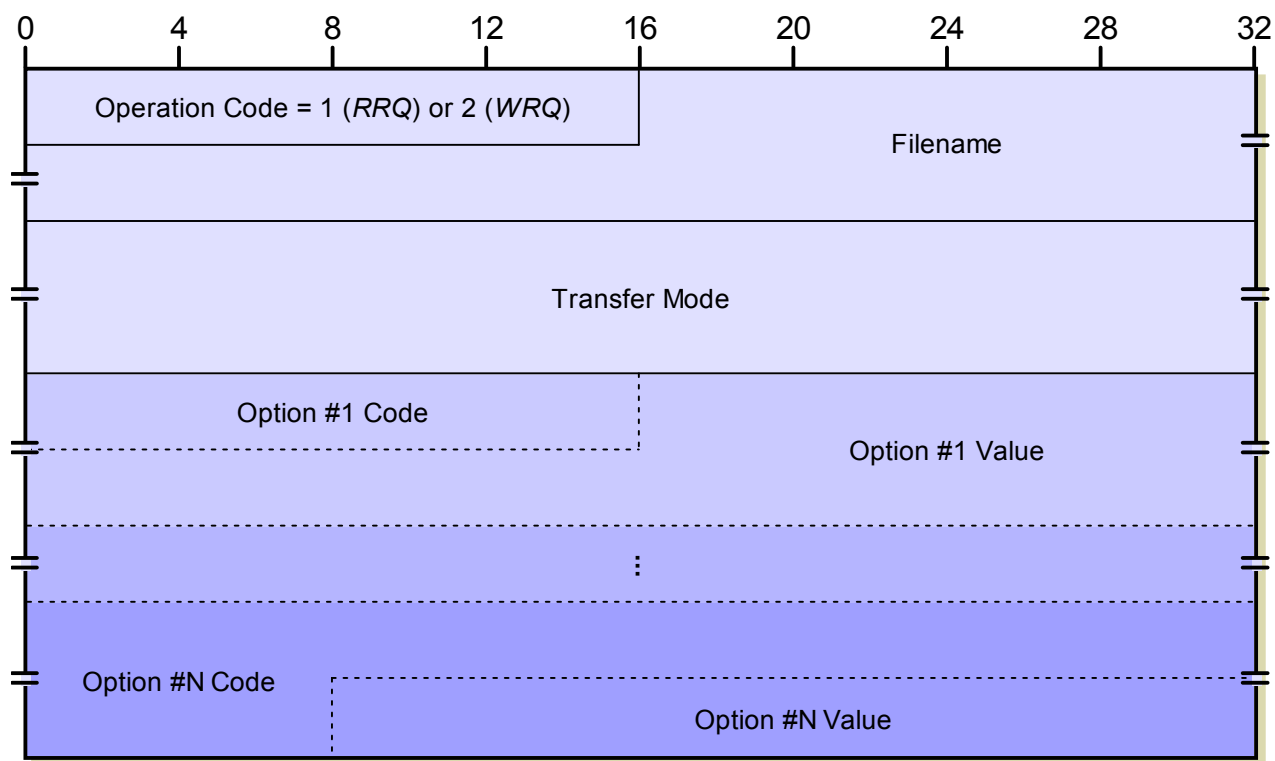

You will find below the details of each TFTP message type.

### ***Read Request and Write Request Messages***

These messages use a common message format, described in [Table 236](#) and shown graphically in [Figure 296](#).

**Table 236: TFTP Read Request / Write Request Message Format**

Field Name	Size (bytes)	Description									
<b>Opcode</b>	2	<b>Operation Code:</b> Specifies the TFTP message type. A value of 1 indicates a <i>Read Request</i> message, while a value of 2 is a <i>Write Request</i> message.									
<b>Filename</b>	Variable	<b>Filename:</b> The name of the file to be read or written.									
<b>Mode</b>	Variable	<b>Transfer Mode:</b> The string “netascii” or “octet”, zero-terminated. (Why not just use one byte set to 0 for netascii and 1 for octet? Don't ask <i>me!</i> ☺)									
<b>Options</b>	Variable	<b>Options:</b> When the client supports TFTP options, it will encode them in sequence following the <i>Mode</i> field. Each option consists of these subfields:									
		<table><tr><th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr><tr><td><b>optN</b></td><td>Variable</td><td><b>Option Code for Option #N:</b> A string specifying the name of the option; currently, “blksize”, “interval” and “tsize” are supported.</td></tr><tr><td><b>valueN</b></td><td>Variable</td><td><b>Option Value for Option #N:</b> The value the client is requesting for this option. Note that this is a zero-terminated string just like other TFTP variable-length fields, even for a numeric value.</td></tr></table>	Subfield Name	Size (bytes)	Description	<b>optN</b>	Variable	<b>Option Code for Option #N:</b> A string specifying the name of the option; currently, “blksize”, “interval” and “tsize” are supported.	<b>valueN</b>	Variable	<b>Option Value for Option #N:</b> The value the client is requesting for this option. Note that this is a zero-terminated string just like other TFTP variable-length fields, even for a numeric value.
		Subfield Name	Size (bytes)	Description							
<b>optN</b>	Variable	<b>Option Code for Option #N:</b> A string specifying the name of the option; currently, “blksize”, “interval” and “tsize” are supported.									
<b>valueN</b>	Variable	<b>Option Value for Option #N:</b> The value the client is requesting for this option. Note that this is a zero-terminated string just like other TFTP variable-length fields, even for a numeric value.									

**Figure 296: TFTP Read Request / Write Request Message Format**

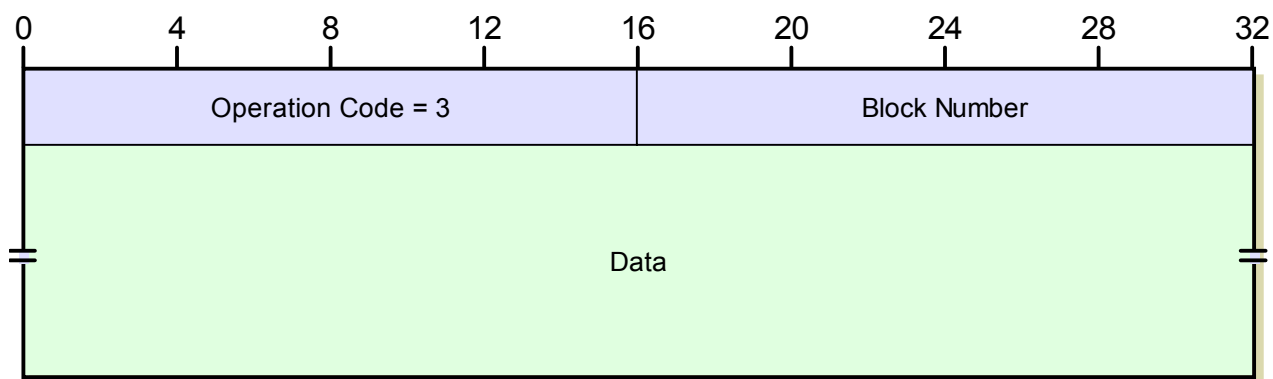

### Data Messages

Data blocks are sent using the simplified format shown in [Table 237](#) and [Figure 297](#).

**Table 237: TFTP Data Message Format**

Field Name	Size (bytes)	Description
<b>Opcode</b>	2	<b>Operation Code:</b> Specifies the TFTP message type. A value of 3 indicates a <i>Data</i> message.
<b>Block #</b>	2	<b>Block Number:</b> The number of the data block being sent.
<b>Data</b>	Variable	<b>Data:</b> 0 to 512 bytes of data.

**Figure 297: TFTP *Data* Message Format**

### ***Acknowledgment Messages***

Acknowledgments have the simplest format of any TFTP message, as you can see in [Table 238](#) and [Figure 298](#).

**Table 238: TFTP *Acknowledgment* Message Format**

Field Name	Size (bytes)	Description
<b><i>Opcode</i></b>	2	<b><i>Operation Code</i></b> : Specifies the TFTP message type. A value of 4 indicates an <i>Acknowledgment</i> message.
<b><i>Block #</i></b>	2	<b><i>Block Number</i></b> : The number of the data block being acknowledged; a value of 0 is used to acknowledge receipt of a write request without options, or to acknowledge receipt of an option acknowledgment.

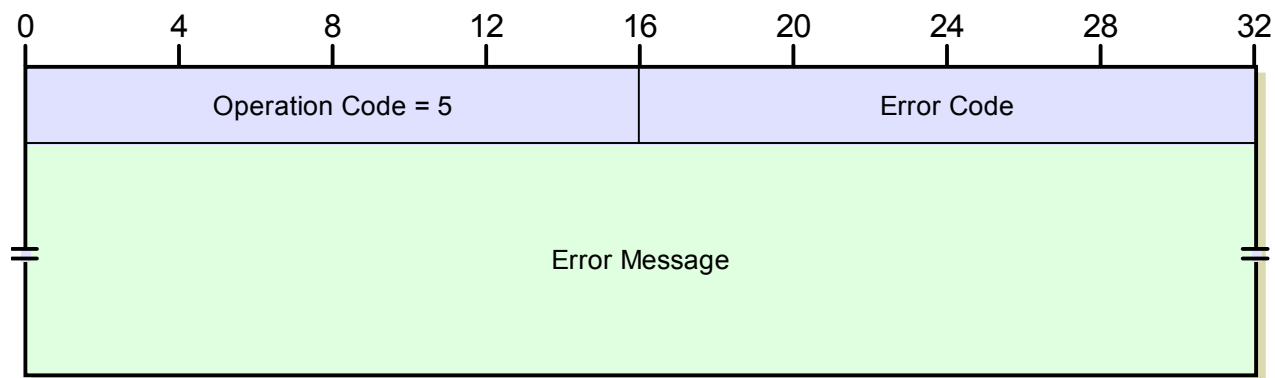

**Figure 298: TFTP *Acknowledgment* Message Format**

## Error Messages

Error messages can be sent by either client or server in cases where a problem is detected in the communication. They have the format indicated in [Table 239](#) and [Figure 299](#).

**Table 239: TFTP Error Message Format**

Field Name	Size (bytes)	Description																				
Opcode	2	<b>Operation Code:</b> Specifies the TFTP message type. A value of 5 indicates an <i>Error</i> message.																				
Error Code	2	<b>Error Code:</b> A numeric code indicating the type of message being communicated. Values 0 to 7 are defined by the TFTP standard, while value 8 was added by the TFTP option extension: <table><tr><th>Error Code Value</th><th>Error Type</th></tr><tr><td>0</td><td>Not defined; see error message field for details.</td></tr><tr><td>1</td><td>File not found.</td></tr><tr><td>2</td><td>Access violation.</td></tr><tr><td>3</td><td>Disk full or allocation exceeded.</td></tr><tr><td>4</td><td>Illegal TFTP operation.</td></tr><tr><td>5</td><td>Unknown transfer ID.</td></tr><tr><td>6</td><td>File already exists.</td></tr><tr><td>7</td><td>No such user.</td></tr><tr><td>8</td><td>Client transfer termination due to unacceptable option negotiation.</td></tr></table>	Error Code Value	Error Type	0	Not defined; see error message field for details.	1	File not found.	2	Access violation.	3	Disk full or allocation exceeded.	4	Illegal TFTP operation.	5	Unknown transfer ID.	6	File already exists.	7	No such user.	8	Client transfer termination due to unacceptable option negotiation.
Error Code Value	Error Type																					
0	Not defined; see error message field for details.																					
1	File not found.																					
2	Access violation.																					
3	Disk full or allocation exceeded.																					
4	Illegal TFTP operation.																					
5	Unknown transfer ID.																					
6	File already exists.																					
7	No such user.																					
8	Client transfer termination due to unacceptable option negotiation.																					
Error Msg	Variable	<b>Error Message:</b> A descriptive text error message string, intended for “human consumption”, as the standard puts it. ☺																				

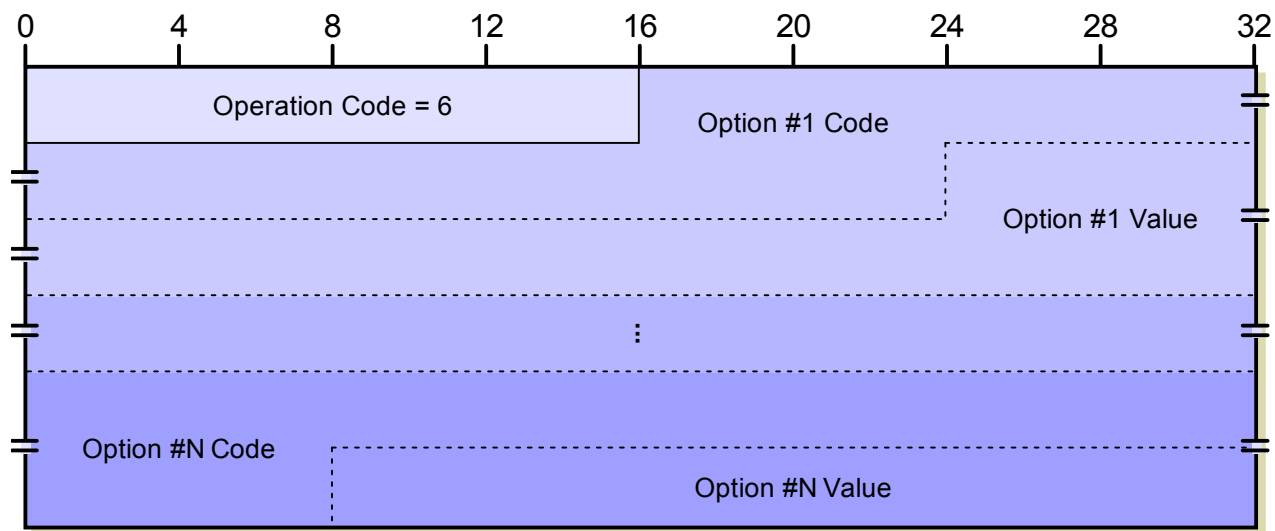

**Figure 299: TFTP Error Message Format**

## Option Acknowledgment Messages

OACK messages are used to acknowledge receipt of TFTP options. They are structured as shown in [Table 240](#) and [Figure 300](#).

**Table 240: TFTP Option Acknowledgment Message Format**

Field Name	Size (bytes)	Description									
<b>Opcode</b>	2	Operation Code: Specifies the TFTP message type. A value of 6 indicates an <i>Option Acknowledgment</i> message.									
<b>Options</b>	Variable	<b>Options:</b> A list of options being acknowledged by the server. Each option consists of these two subfields: <table><tr><th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr><tr><td><b>optN</b></td><td>Variable</td><td><b>Option Code for Option #N:</b> A string specifying the name of the option, copied from the <i>Read Request</i> or <i>Write Request</i> message.</td></tr><tr><td><b>valueN</b></td><td>Variable</td><td><b>Option Value for Option #N:</b> The acknowledged value for the option, which may be the value that the client specified, or an alternative value, depending on the type of option.</td></tr></table>	Subfield Name	Size (bytes)	Description	<b>optN</b>	Variable	<b>Option Code for Option #N:</b> A string specifying the name of the option, copied from the <i>Read Request</i> or <i>Write Request</i> message.	<b>valueN</b>	Variable	<b>Option Value for Option #N:</b> The acknowledged value for the option, which may be the value that the client specified, or an alternative value, depending on the type of option.
Subfield Name	Size (bytes)	Description									
<b>optN</b>	Variable	<b>Option Code for Option #N:</b> A string specifying the name of the option, copied from the <i>Read Request</i> or <i>Write Request</i> message.									
<b>valueN</b>	Variable	<b>Option Value for Option #N:</b> The acknowledged value for the option, which may be the value that the client specified, or an alternative value, depending on the type of option.

---

## **TCP/IP Electronic Mail System: Concepts and Protocols (RFC 822, MIME, SMTP, POP3, IMAP)**

It is common for human beings to create systems that are reminiscent of ones to which they are already accustomed. We are all accustomed to using the regular mail system to send letters and other documents from our location to recipients anywhere that the postal system serves. Naturally, one of the first applications of internetworks was to create an electronic version of this conventional mail system that would allow messages to be sent in a similar manner, but more quickly and easily. Over the course of many years, an *electronic mail system* for TCP/IP was created and refined. It is now the most widely used means of electronic messaging in the world.

In this section I describe TCP/IP electronic mail in detail, in five sections that discuss electronic mail concepts and the various components and protocols that comprise the overall TCP/IP e-mail system. The first subsection provides an overview of TCP/IP electronic mail and discusses the way that it is used and the different protocols and methods that comprise the system. The second discusses how e-mail messages are addressed, and the third covers standard and special formats for e-mail messages. The fourth and fifth subsections describe the TCP/IP protocols that implement electronic mail functionality. This includes an examination of the Simple Mail Transfer Protocol (SMTP), which is responsible for the delivery of e-mail, and several protocols and methods used for mailbox access and mail retrieval, including POP3 and IMAP.

**Note:** This discussion focuses primarily on the mechanisms used for electronic mail composition, delivery and access in modern internetworks. In the e-mail overview topic I make mention of some techniques used in the past for TCP/IP electronic mail, but only briefly for historical completeness, and to contrast these methods to the ones presently used.

---

---

## **TCP/IP Electronic Mail System Overview and Concepts**

Electronic mail in the TCP/IP protocol suite is not implemented as just a single protocol or technology. Rather, it is a complete **system** that contains a number of related components that work together. These include standards defining methods for addressing and message formatting, and a number of protocols that play different functions in implementing electronic mail messaging. Before proceeding to examine each of these pieces, it makes sense to start with an overview of the system as a whole.

In this section I provide an introductory look at TCP/IP electronic mail, to help you understand the system, how it works, and how different components fit into it. I begin with an overview and history of e-mail and its implementation in TCP/IP. I provide a general overview of the steps involved in the e-mail communication process. I conclude with a more specific discussion of the communication model used in TCP/IP and the roles played by various TCP/IP devices and protocols in the sending and receiving of electronic mail.

### **TCP/IP Electronic Mail System Overview and History**

The need to communicate is as old as humanity itself. Thousands of years ago, communication was, of necessity, almost exclusively local. Messages were primarily oral, and even when in writing, rarely delivered a great distance. Most people never travelled far from their homes, and rarely communicated with those distant from themselves. But even in ancient times, messengers were used by leaders to send short pieces of critical information from place to place. It was slow and unreliable, but some messages were important enough that an effort to communicate often had to be made in spite of the difficulties.

Advances in transportation led to advances in communication capability, eventually resulting in the creation of physical mail systems. Today, these systems have evolved to the point where anyone in the developed world can send a letter to just about anyone else. Reliability has vastly improved, despite all the jokes people make about the postal service. ☺ Speed is also much better than it was in the olden times, with messages now taking days to reach their destination instead of weeks or months.

Waiting even days for a message to get from one place to another is pretty slow by the standards of our modern world. For this reason, one of the most natural applications of networks was to use them as a replacement for the physical transportation of messages from one place to another. Transforming mail from a physical process to an electronic one yields enormous benefits, chief among them greatly increased communication speed, the ability to instantly send one message to multiple recipients, and the ability to get nearly instantaneous feedback upon receipt of a message.

### ***The Early Days of Electronic Mail***

The idea behind *electronic mail* (*e-mail* or *email*) is not only as old as computer networks, it actually predates internetworking. The first electronic mail systems were implemented on traditional mainframe computers. These are single large computers accessed by many users simultaneously through connected terminals. An e-mail system on a mainframe consisted of a set of software running on the mainframe that implemented the entire

---

electronic mail system. Each user simply had a mailbox that resided on this machine, and mail was “delivered” by moving messages from one mailbox to the next. Users sent and received mail through a user interface program.

Such an early electronic mail system was useful for local communication, but not for sending messages to a person in another organization. Mainframe e-mail is somewhat analogous to “local mail” being sent by one resident of a town to another. There is no way to send mail to a person in a distant town without more infrastructure for delivery.

The power of internetworking is what really enables electronic mail to become a universal method of communication. Internetworks link together systems the way the postal service's fleet of airplanes and vehicles link together post offices. Mail is sent from user to user over the underlying technology of the internetwork. TCP/IP is of course the most commonly used internetworking protocol suite, and the modern Internet uses TCP/IP to tie together systems across the globe. It is thus “the vehicle” for sending electronic mail.

### ***The History of TCP/IP Electronic Mail***

Like some other file and message transfer protocols, e-mail on TCP/IP actually goes back to [before TCP/IP and the Internet formally existed](#). The first protocols for e-mail were developed during the days of the ARPAnet. Prior to the creation of e-mail, several Internet RFCs, such as RFC 95 (yes 95, two digits, we are going back a long way here!) and RFC 155 describe physical mailing lists that were used for distributing documents in the early 1970s. It was this need to send documents that likely made TCP/IP pioneers realize how useful an electronic messaging system would be using the technology they were themselves creating.

The first Internet document describing electronic mail was probably RFC 196, published in 1971. It describes something called *A Mail Box Protocol*, a very rudimentary message transfer method using the predecessors of TCP/IP. This protocol was designed for the specific purpose of sending documents for remote printing. In those days it was not as common for people to use computers at interactive terminals as it is today, but the idea of electronically mailing documents was the same. The Mail Box Protocol was revised several times in 1971.

In the mid-1970s, work began to develop a more comprehensive method of implementing electronic mail on the fledgling Internet. The technique was originally described using a number of then-existing application-layer transfer protocols, including the [File Transfer Protocol \(FTP\)](#). In 1980 the *Mail Transfer Protocol (MTP)* was published in RFC 772. This was the first precursor of today's TCP/IP e-mail, and was defined using principles from the [Telnet](#) remote access protocol as well as FTP.

During the time that e-mail protocols were being developed in the 1970s, mail was being exchanged between host systems using a variety of different techniques. One of the most common used the *Unix-to-Unix Copy Protocol (UUCP)*, which was designed to allow files to be transferred between UNIX systems, moving them from one connected system to the next. UUCP was also used for communicating [Usenet](#) newsgroup articles and other files.

---

In 1981, the modern TCP/IP electronic mail era came into being with the definition of the *Simple Mail Transfer Protocol (SMTP)*. SMTP described in detail how mail could be moved directly or indirectly from one TCP/IP host to another without the need to use FTP or another file transfer method. [It has its own detailed history and discussion in this Guide](#). Other complementary specifications were created at around the same time, which formalized or defined other components and elements of the system. We'll explore these pieces of the puzzle in the next two topics.

## **Overview of the TCP/IP Electronic Mail System**

One of the most important general concepts in the modern electronic mail system is that a distinction is made between protocols that deliver electronic mail between SMTP hosts on the internetwork, and those that let users access received mail on their local hosts. To continue our analogy, different protocols are used for sending mail between post offices, and for “home delivery”. As we'll see, this was done intentionally, to make it possible to send mail to users even if they are not connected to the Internet at the time mail was sent. This decoupling is critical as it enables *delayed* communication, where mail can be sent when the sender wants to transmit it, and received when the recipient wants to read it.

Over the years, the basic components defined in the early 1980s have not changed substantially, but how they are used has evolved and been improved. Early electronic mail delivery involved the use of route specifications by one SMTP host to dictate how mail was to be delivered through intermediate systems; today, the [Domain Name System](#) makes much of that obsolete, facilitating nearly immediate direct mail delivery in most cases. Early electronic mail supported only simple text, where we can now send graphical images, programs and other files in e-mail. Modern high-speed Internet connections and updated access protocols allow modern e-mail to be the realization of the ultimate goal of nearly instantaneous communication even across continents.

**Key Concept:** One of the most important TCP/IP applications is the internetworking equivalent of the real-world postal delivery system, commonly called *electronic mail* or *e-mail*. The history of e-mail goes back to the very earliest days of TCP/IP's development; today it is used by millions of people every day to send both simple and complex messages around the world. TCP/IP e-mail is not a single application, but rather a complete system that includes several protocols, software elements and components.

---

## **TCP/IP Electronic Mail Communication Overview: Message Composition, Submission, Delivery, Receipt, Processing and Access**

TCP/IP electronic mail is implemented as a [complete system](#), with a number of different elements that perform different portions of the complete job of electronic mail communication. These included a standard message format, a specific syntax for recipient addressing, and protocols to both deliver mail and allow access to mailboxes from intermittently-connected TCP/IP clients.

---

To help set the groundwork for examining these components, I want to provide an overview of the complete end-to-end process of e-mail communication, so you can see how everything works. I will show the basic steps in simplified form, and continue the analogy to the regular mail system for comparison.

## ***E-Mail Communication Process Steps***

The modern TCP/IP e-mail communication process consists of the following five basic steps.

### **1. Mail Composition**

A user begins the e-mail journey by creating an electronic mail message. The message contains two sections: the *header* and the *body*. The body of the message is the actual information to be communicated; the header contains data that describes the message and controls how it is delivered and processed. The message must be created so that it matches the [standard message format](#) for the e-mail system so that it can be processed. It must also specify the [e-mail addresses](#) of the intended recipients for the message.

By way of analogy to real mail, the body of the message is like a letter, and the header is like the envelope into which the letter is placed.

### **2. Mail Submission**

As we'll see in greater detail in [the next topic](#), electronic mail is different from many other internetworking applications in that the sender and receiver of a message do not necessarily need to be connected to the network simultaneously, nor even continuously, to use it. The system is designed so that after composing the message, the user decides when to submit it to the electronic mail system so it can be delivered. This is done using the [Simple Mail Transfer Protocol \(SMTP\)](#).

This is analogous to dropping off an envelope at the post office, or to a postal worker picking up an envelope from a mailbox and carrying it to the local post office to insert into the mail delivery stream.

### **3. Mail Delivery**

The electronic mail message is accepted by the sender's local SMTP system for delivery through the mail system to the destination user. Today, this is accomplished by performing a [Domain Name System \(DNS\)](#) lookup of the intended recipient's host system and establishing an SMTP connection to that system. SMTP also supports the ability to specify a sequence of SMTP servers through which a message must be passed to reach a destination. One way or the other, eventually the message arrives at the recipient's local SMTP system.

This is like the transportation of the envelope through the postal system's internal "inter-network" of trucks, airplanes and other equipment to the intended recipient's local post office.

---

#### 4. Mail Receipt and Processing

The local SMTP server accepts the e-mail message and processes it. It places the mail into the intended recipient's mail box, where it waits for the user to retrieve it.

In our physical analogy, this is the step where the recipient's local post office sorts mail coming in from the postal delivery system and puts the mail into individual post office boxes or bins for delivery.

#### 5. Mail Access and Retrieval

The intended recipient periodically checks with its local SMTP server to see if any mail has arrived. If so, the recipient retrieves the mail, opens it and reads its content. This is done using not SMTP but a special [mail access protocol or method](#). To save time, the access protocol and client e-mail software may allow the user to scan the headers of received mail (such as the subject and sender's identity) to decide which mail messages to download.

This is the step where mail is physically picked up at the post office or delivered to the home.

#### ***Modifications to the General Communication Process***

In some cases not all of these steps are performed. If a user is sending e-mail from a device that is already an SMTP server, then step #2 can be omitted; if the recipient is logged in to a device that is also an SMTP server, step #5 will be skipped, as the user can read mail directly on the server. Thus, in the simplest case all that occurs is composition, delivery and receipt; this occurs when one user of a dial-up UNIX host sends mail to another. In most cases, today, however, all five steps occur.

**Key Concept:** TCP/IP electronic mail communication normally involves a sequence of five steps, each of which is analogous to a portion of the journey taken by a regular letter through the postal system. First, e-mail is *composed* (written); second, it is *submitted* to the e-mail system; third, it is *delivered* to recipient's server; fourth, it is *received and processed*; and finally, fifth, it is *accessed and retrieved* by its recipient.

---

Again, this is simplified. I have, for example, omitted the step where the recipient notices that the mail is in fact an advertisement from a spammer for how he can "make money fast", eliminate debt or lose weight overnight, then mutters under his breath and deletes the message. Hey, I never said there were no **disadvantages** to electronic mail being fast and nearly free. ☺

---

## **TCP/IP Electronic Mail Message Communication Model and Device and Protocol Roles**

The purpose of the electronic mail system as a whole is to accomplish the transmission of electronic mail messages from a user of a TCP/IP internetwork to one or more recipients. In order to accomplish this, a special method of communication is required that makes the electronic mail system quite different from that used by most other protocols. To understand what I mean by this, you need only recognize the difference in communication between sending a letter and making a phone call.

Most TCP/IP protocols are analogous to making a phone call in this respect: the sender and the receiver must both be on the network at the same time. You can't call someone and talk to them if they aren't around to answer the phone. (Yeah, yeah, answering machines and voice mail. Stop interrupting, will you? ☺) Most TCP/IP protocols are like this: to send a file using [FTP](#), for example, you must make a direct connection from the sender's machine to the recipient's machine. If the recipient's machine is not on the network at the exact time that sender's is, no communication is possible.

For electronic mail, this type of communication is simply unacceptable. Electronic mail is like its real-world counterpart; Joe wants to be able to put a message into the system at a time that is convenient for him, and Ellen wants to be able to receive Joe's mail at a time that works for her. For this to work, e-mail must use a “send and forget” model, just like real mail, where Joe drops the “envelope” into the e-mail system and it eventually gets to its destination.

This *decoupling* of the sender and receiver is critical to the design of the electronic mail system. This is especially true because many of the users of Internet electronic mail are not on the Internet all the time. Just as you wouldn't want real mail to be rejected if it arrived when you are not home, you don't want electronic mail to not be delivered if you are not on the Internet when it arrives. Similarly, you may not want to be connected to the Internet for the entire time it takes to write a message, especially if you have access to the Internet for only a limited amount of time each day.

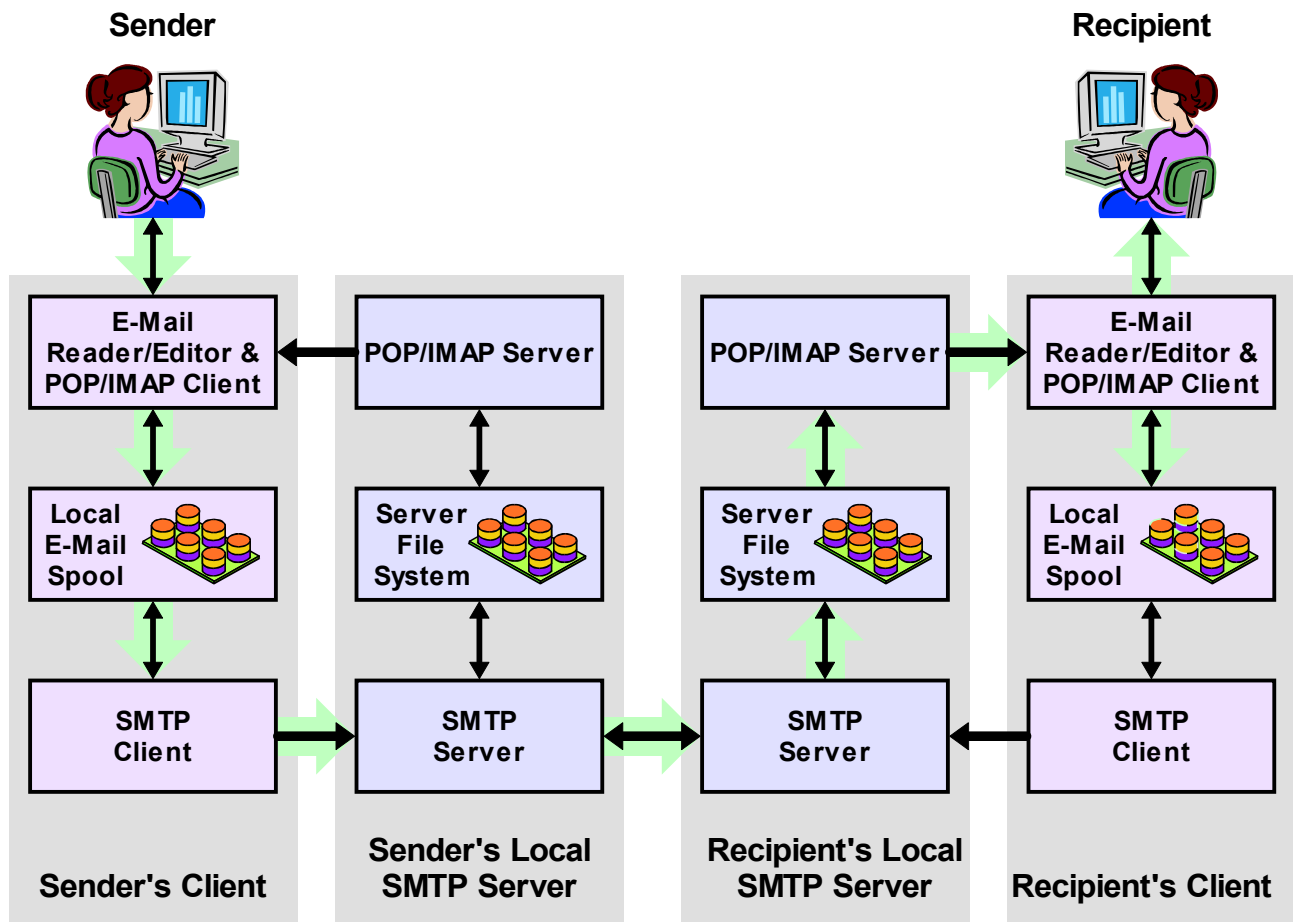

Also critical to the entire electronic mail system is that idea that communication is between specific **users**, and not between particular machines. This makes e-mail inherently different than many other types of communication on TCP/IP internetworks. We'll see more of why this is important when we look at [e-mail addressing](#).

### ***The Delayed Delivery Model and Device Roles***

To allow the type of communication needed for electronic mail, the entire system is designed to facilitate the *delayed delivery* of e-mail messages from one user to another. To see how this works, let's look again at the example communication we discussed in [the previous topic](#), but this time, considering the roles of the different **devices** in the exchange (as shown in [Figure 301](#)):

- 
- ☛ **Sender's Client Host:** The sender of the mail composes an electronic mail message, generally using a mail client program on his or her local machine. The mail, once composed, is not immediately sent out over the Internet; it is held in a buffer area called a *spool*. This allows the user to be “detached” for the entire time that a number of outgoing messages are created. When the user is done, all of the messages can be sent at once.
  - ☛ **Sender's Local SMTP Server:** When the user's mail is ready to be sent, he or she connects to the internetwork. The messages are then communicated to the user's designated local **SMTP** server, normally run by the user's Internet Service Provider (ISP). The mail is sent from the client machine to the local SMTP server using SMTP. (It is possible in some cases for the sender to be working directly on a device with a local SMTP server, in which case sending is simplified.)
  - ☛ **Recipient's Local SMTP Server:** The sender's SMTP server sends the e-mail using SMTP to the recipient's local SMTP server over the Internetwork. There, the e-mail is placed into the recipient's incoming mailbox (*inbox*). This is comparable to the outgoing spool that existed on the sender's client machine. It allows the recipient to accumulate mail from many sources over a period of time, and retrieve them when it is convenient.

- ☉ **Recipient's Client Host:** In certain cases the recipient may access his or her mailboxes directly on the local SMTP server. More often, however, a mail access and retrieval protocol, such as POP3 or IMAP, is used to read the mail from the SMTP server and display it on the recipient's local machine. There, it is displayed using an e-mail client program, similar to the one the sender used to compose the message in the first place.

**Figure 301: Electronic Mail (E-Mail) Communication Model**

This diagram shows the four devices that are involved in a typical e-mail communication between two users. (Yes, they *are* identical twins, imagine that! ☺) Each device consists of a number of different elements, which communicate as indicated by the black arrows. Note the inherent asymmetry, because the method used to send an e-mail from a user is not the same as that used to retrieve it from the server. The large green arrows show a typical transaction: the sender composes mail and it goes to her local e-mail spool. It is sent to the sender's local SMTP server using SMTP, and then to the recipient's SMTP server, where it goes into that user's inbox. It is then retrieved, usually using a protocol such as POP or IMAP.

### **Protocol Roles In Electronic Mail Communication**

You may have noticed that SMTP is used for most of this communication process. In fact, if the recipient uses a machine that runs SMTP software, which is common for those using dialup UNIX shell Internet access, the process of sending e-mail uses SMTP exclusively.

---

SMTP servers must, however, always be available on the Internet and ready to accept mail. Most people access the internetwork using devices that aren't always online or that don't run SMTP software. That is why the last step, mail access and retrieval, is usually required.

It might have been possible to define the electronic mail system so that this last step of communication was carried out using SMTP as well, which would mean the entire system used the same protocol. However, SMTP was tailored for the specific purpose of transporting and delivering e-mail, not for remote mailbox access. It made more sense to leave the function of mailbox access to dedicated, separate protocols. This not only allows these protocols to be tailored to the needs of e-mail recipients, but provides flexibility by giving users more than one option for how e-mail is retrieved. I discuss mail access protocols and methods in a [separate section of the Guide](#), highlighting the two most common protocols: the [Post Office Protocol \(POP\)](#) and the [Internet Message Access Protocol \(IMAP\)](#).

The three protocols discussed above—SMTP, POP3 and IMAP—get the “lead billing” on the TCP/IP electronic mail stage, but they rely on two other elements to play “supporting roles”. The first is a [method of addressing e-mail messages](#) to ensure that they arrive at their destinations. The second is the set of [message formats](#) used to encode messages and control how they are delivered and used. These don't usually get as much attention as they deserve, but they do here, as I have devoted the next two sections to them.

**Key Concept:** One of the critical requirements of an electronic mail system is that the sender and receiver of a message not be required to both be on the system at the time mail is sent. TCP/IP therefore uses a communication model with several devices that allow the sender and recipient to be *decoupled*. The sender's client device spools mail and moves it to the sender's local SMTP server when it is ready for transmission; the e-mail is then transmitted to the receiver's SMTP server using SMTP. The e-mail can remain on the recipient's server for an indefinite period of time. When the recipient is ready to read it, he or she retrieves it using one or more of a set of mail access protocols and methods, the two most popular of which are POP and IMAP.

---

---

## **TCP/IP Electronic Mail Addresses and Addressing**

The entire concept of electronic mail is based on an analogy: the comparison of sending electronic messages to the sending of paper messages. The analogy works well because e-mail was indeed intended to be like regular mail, only with the advantages of the electronic era: speed and flexibility.

One of the many similarities between electronic and regular mail is the need for *addressing*. In order for a message to be delivered, it is necessary that the sender specify who the recipient is, and provide a reasonable amount of information to indicate how the recipient can be reached. In TCP/IP electronic mail, a standard *electronic mail address* format is used for this, and support is also provided for alternative addressing schemes that may be used in special cases.

In this section I describe how electronic mail messages are addressed. I begin with a discussion of standard electronic mail addressing in TCP/IP, and how those addresses are used to determine where e-mail should be sent. I then provide a brief discussion of historical and special e-mail addresses that you may encounter from time to time. I also discuss the use of e-mail address books (aliases) and how multiple recipients may be addressed, as well as providing an overview of electronic mailing lists, one of the earliest ways in which electronic group communication was implemented.

### **TCP/IP Electronic Mail Addressing and Address Resolution**

All communication on an internetwork requires some way of specifying the identity of the intended recipient of the communication. Most application protocols, such as [FTP](#) and [HTTP](#) for example, use conventional TCP/IP constructs—[IP addresses](#) and [port numbers](#)—to specify the destination of information to be sent. The IP address normally identifies a particular host computer, and the port number a software process or application running on that computer.

Electronic mail, however, uses a very different model for communication than most applications. As we saw in our [discussion of the e-mail model](#), one element that sets e-mail apart from many other systems is that communication is *user-oriented*. E-mail is not sent from one machine to another the way a file is transferred using FTP. It is sent from one user to another. This is critical to the operation of the entire system; for one thing, it is what allows someone to retrieve e-mail that has been sent from any number of different client computers. This allows e-mail to be received even when traveling, for example.

Since e-mail messaging is user-based, it is necessary that the addressing scheme be user-based as well. We cannot use conventional IP addresses and ports, but need a distinct system that specifies two primary pieces of information: **who** the user is, and **where** the user is located. These are, of course, analogous to a name and address on a regular mail envelope.

The idea of a user name is relatively straight-forward, but identifying the location of the user is not. In regular mail, an address refers to a physical place. It would have been possible to define e-mail addresses in the same way: have it refer to the user's client machine.

---

However, recall the other important characteristic of e-mail delivery: it is *indirect*, and based on the concept of a user's local SMTP server holding received messages until they can be retrieved. The machine that the user employs to access his or her e-mail may not even routinely be on the Internet, and it may thus not be easy to identify it. And again, we want a user to be able to access mail from multiple machines.

For all of these reasons, we want addresses to identify **not** the user's specific location at any particular time, but the place where the user's permanent mailbox lives. This is on the user's SMTP server, which is permanently connected to the Internet.

### **Standard DNS-Based E-Mail Addresses**

In TCP/IP, the system used for identifying servers (and other machines) is the *Domain Name System (DNS)*. DNS is a big system and is described in [its own large section in this Guide](#); I would refer you to it if you want to learn more. For our purposes, what is important is that in DNS, all devices on the Internet are arranged into a [device naming hierarchy](#), and any device can be identified using a *domain name* consisting of a series of text labels separated by dots.

So, the complete TCP/IP address consists of two components: a user name specification and a domain name specification. The two are connected together using the special “at” symbol (“@”) to form the TCP/IP e-mail address syntax that almost all of us are familiar with today:

`<username>@<domainname>`

The format of `<domainname>` follows the [syntax rules of DNS](#), containing only numbers and digits for each label, and periods to separate the labels. The format of `<username>` is slightly less restrictive, allowing the use of special characters such as the underscore (“\_”). Other special characters and spaces are also allowed in the `<username>` if they are surrounded by quotes (or otherwise marked as being part the name, such as through the use of an escape character.) Domain names are case-insensitive; user names may be case-sensitive, depending on the system.

So, an example of a valid e-mail address might be the following address I used when I was in school many years ago:

`cmk@athena.mit.edu`

Where “cmk” is my user name (my initials) and the “athena.mit.edu” is the name of the host where I was receiving mail. “athena” is a particular system at MIT (“mit”), which is an educational institution, and so uses the “.edu” [top-level domain](#).

---

## URL E-Mail Address Specification

It is also possible to specify an e-mail address using an Internet-standard [Uniform Resource Locator \(URL\)](#). This allows a link to be embedded in a hypertext (Web) document that when clicked, invokes an e-mail client to send mail to a user. E-mail URLs are created by preceding the address by the special [URL scheme](#) string “mailto:”, like this:

mailto:cmk@athena.mit.edu

## The Special Requirements of E-Mail Addresses

Having e-mail addressing refer to the user's local SMTP server provides a great deal of flexibility compared to having addresses mention a specific client computer. But it doesn't provide enough flexibility to handle various situations:

- ☉ An organization may want to use “generic” addresses that do not specify the name of the SMTP server to handle mail. The reason is that this requires people sending them mail to know the name of that server. For example, if someone knew my real name and that I was at MIT, it would be easier for them to remember my old e-mail address as “cmk@mit.edu” than “cmk@athena.mit.edu”.
- ☉ An administrator may change which machines handle mail over a period of time. This would mean all the users's e-mail addresses would have to change— and most of us know what a pain *that* is. For example, if I moved from the “athena” machine to the “jabberwocky” machine, my old address would have needed to change to “cmk@jabberwocky.mit.edu”. But if it were just “cmk@mit.edu” the change would not affect me.
- ☉ In larger organizations, it might be desirable to have multiple servers share the load of handling incoming mail.

## The Mail Exchange (MX) DNS Record

To address all of these requirements, the DNS system includes a feature that was specifically designed to support electronic mail addressing. A special *mail exchange (MX)* record can be set up that specifies which SMTP server should be used for mail coming in to a particular domain name. If properly configured, this allows considerable flexibility to handle the cases I described above and more. For more details, [please see the description of the MX record and DNS electronic mail support](#).

For example, I am the owner of the “pcguide.com” domain name. E-mail can be sent to me at “pcguide.com”, but it is not actually stored on any server by that name. It is redirected to the real server where my inbox is located. This allows me to handle all incoming mail to “pcguide.com” regardless of where my mailbox is actually located.

DNS is also significant in that its “MX” resource records eliminated the need to “relay” e-mail from one SMTP server to the next to deliver it. In modern TCP/IP it is possible to send e-mail directly from the sender's SMTP server to the recipient's, making communication faster and more efficient. [See the section devoted to SMTP for details](#).

**Key Concept:** Some form of addressing is required for all network communication; since electronic mail is *user-oriented*, e-mail addresses are based on users as well. In modern TCP/IP e-mail, standard addresses consist of a *user name*, which specifies who the recipient is, and a *domain name*, which specifies the DNS domain where the user is located. A special DNS *mail exchange (MX)* record is set up for each domain that accepts e-mail, so a sending SMTP server can determine what SMTP server it should use to send mail to a particular recipient.

---

## **TCP/IP Historical and Special Electronic Mail Addressing**

TCP/IP electronic mail has been so successful that it is arguably the most important worldwide standard for electronic messaging. The widespread acceptance of e-mail is tied inextricably to that of TCP/IP and the Internet as a whole. Since most organizations want to be part of the Internet, they connect to it and use its technologies, including the [Domain Name System](#) that is the basis for TCP/IP e-mail addresses. In turn, the use of simple DNS-style e-mail addresses (“user@domain”) encourages further use of e-mail because people find it conceptually easy to decide how to send messages.

TCP/IP is not, however, the only electronic mail system around. Over the years several other networks have developed e-mail systems. Due to the fact that the Internet is the largest internetwork in the world, TCP/IP e-mail has often been used as a “clearing house” of sorts to link together some of these different e-mail mechanism. This is called *gatewaying*, and allows someone using a non-SMTP e-mail system to interact with someone using TCP/IP, and vice-versa. Gatewaying is complex, and one of the reasons is that e-mail systems use different ways of addressing mail. Let's take a look at a couple of these systems and how they interact with TCP/IP.

### ***FidoNet Addressing***

One of the earliest independent e-mail systems was the *FidoNet*, which has been around for a long time and is still in use today. FidoNet is a worldwide network connected using modems and proprietary protocols; it is in essence, a “competitor” to the global TCP/IP Internet. I put “competitor” in quotes because the two are not really comparable in terms of number of users and the kinds of applications they support, but they are similar in overall objectives: worldwide electronic communication.

FidoNet users are identified using four numbers that specify the FidoNet *zone*, *net*, *node* and *point (connection point)*. These addressing elements are used for sending mail on this system, which again is completely distinct from TCP/IP. However, to allow communication between TCP/IP and FidoNet, the FidoNet administrators have set up a gateway system that allows mail to be sent to FidoNet using TCP/IP style domain names. This style of mapping was also used by other systems with proprietary mail address formats to allow them to interface with the Internet.

---

For example, if a user was on machine 4, node 205, net 141, zone 1 (North America), the FidoNet address would be 1:141/205:4. The equivalent domain name would be p4.f205.n141.z1.fidonet.org, and could be used for TCP/IP-style “user@domain” addressing.

### ***UUCP-Style Addressing***

An older address style commonly associated with e-mail was the “UUCP style” address. The *Unix-to-Unix Copy Protocol (UUCP)* was commonly used years ago to route mail before SMTP became widely deployed (again, it is still used, just not as much as before). The addresses in this system are specified as a path of hosts separated by exclamation marks (“!”). The path dictates the route that mail takes to get to a particular user, passing through a series of intermediate machines running UUCP. For example, if mail to “joe” at the host “joesplace” had to go through three hosts “host1”, “host2” and “host3”, the address would be:

host1!host2!host3!joesplace!joe

Since the slang term for an exclamation mark is “bang”, this came to be called *bang path* notation.

The use of UUCP style notation was sometimes mixed with TCP/IP style domain name address notation when DNS came into use. So you might have seen something like “host1!user@domain”. There was some confusion in how exactly to interpret such an address: does it mean to send mail first to “host1” and then to “user@domain”? Or does it mean to first send it to the “domain” which then goes to “user” at “host1”? There was no universal answer to this. The problem was mostly resolved both by the decrease in use of UUCP and the move on the part of UUCP systems to TCP/IP style domain name addressing.

### ***Addressing for Gatewaying***

Finally, you may encounter e-mail addresses that appear like multiple TCP/IP addresses that have been nested using unusual punctuation. For example, you may see something that looks like this:

user%domain1.com@subdomain.domain2.edu

This is a way of addressing sometimes seen when e-mail gateways are used; it will cause the mail to be sent to “user%domain1.com” at “subdomain.domain2.edu”. The address then is interpreted as “user@domain1.com”. However, again, not all systems are guaranteed to interpret this the same way.

E-mail gatewaying is not a simple matter in general, and as you can see, one reason is the use of different e-mail address styles and the problems of consistency in how complex “hybrid” addresses are interpreted, as discussed above. However, as the Internet expands

---

and TCP/IP becomes more widespread, it is becoming less and less common to see these older, special address formats in use. They are becoming more and more a “historical curiosity” (unless you happen to use one of them!)

## **TCP/IP Electronic Mail Aliases / Address Books, Multiple Recipient Addressing and Electronic Mailing Lists**

Electronic mail is analogous to regular mail, but superior to it due to two main advantages of digital and electronic communication. One of these is *speed*, which is why modern Internet users have come up with the slang term “snail mail” to refer to the regular postal service. ☺ But the other is also essential: *flexibility*. E-mail allows you to send messages easily in ways that would be cumbersome with regular mail. And one of the ways this flexibility can be seen is in addressing.

The first way that e-mail addressing is flexible is that most e-mail clients support advanced features that allow users to specify the identity of recipients in convenient ways. While TCP/IP addressing really is fairly straight-forward, remembering the addresses of everyone you know is difficult. In the real world we use address books to help us remember addresses. With e-mail, we can do the same, by allowing e-mail software to associate a name with an e-mail address. This is usually done in one of two ways.

### ***E-Mail Address Aliases***

In “old-fashioned” text-based e-mail such as that used on many UNIX systems, name and address association is performed using *aliases*. These are short forms for e-mail addresses that save typing. For example, my wife's name is Robyn and I often send her e-mail, but I'm too lazy to type in her address all the time. So I have defined an alias for her in my e-mail program called simply “r”. I enter the mail command and specify the alias “r” as the intended recipient, and it expands it for me. (Yeah, I could have used “robyn” but hey, I'm *really* lazy. ☺)

### ***Electronic Address Books***

In modern graphical e-mail systems, aliases aren't used. Instead, an *electronic address book* is usually implemented, which is of course the equivalent of the paper address book. The difference is that there is no manual copying; you just choose the name from the list using your mouse; nothing could be simpler unless the system could somehow read your mind.

### ***Specifying Multiple Recipients***

Another advantage of electronic mail addressing is that it allows the easy specification of multiple recipients. With paper mail, sending a message to ten people means you need ten copies of the message, ten envelopes and also—ten stamps. With e-mail, you just list the recipient addresses separated by a comma in the recipient list:

<user1@domain1>,<user2@domain2>,<user3@domain3>...

---

A separate copy is mailed to each recipient, easy as can be. Of course, aliases and/or address books can be used to specify each recipient here as well, making this even simpler.

Since e-mail makes it so easy for one person to send information to a set of others, so-called *one-to-many* messaging, it was also one of the first ways in which electronic group communication was implemented. Prior to e-mail, sharing information in a group setting either required a face-to-face meeting, or a telephone conference call. In both cases, all parties have to be present simultaneously, and there is a cost involved, especially when the parties are geographically distant.

With e-mail, a group of individuals can share information without needing to meet or even be available at the same time. Suppose there is a group with four individuals: persons *A*, *B*, *C* and *D*. Person *A* has a proposal that he wants discussed. He sends it to *B*, *C* and *D*. Each recipient will read it at a time convenient for him or her. Each can then reply back to the group. For example, *D* might have a comment on the proposal, so she just sends it to *A*, *B* and *C*. Most e-mail clients include a *group reply* feature for this purpose.

## **Mailing Lists**

In larger groups, communication by simply writing out the addresses of each recipient becomes cumbersome. Instead, a *mailing list* is used. The list is created by an individual termed the *list owner* and contains the electronic mail addresses of all the members of the group. Then, a special *list address* is created. This address looks and functions just like a regular e-mail address. However, when anyone sends mail to this special address, it is not simply deposited into a mailbox. It is instead intercepted by special software that processes the message and sends it out automatically to all recipients on the list. Any recipient can reply back to the list address and all members will receive the reply.

There are many thousands of mailing lists on the Internet, covering every subject imaginable. Each list differs in a number of regards, including the following:

- ☉ **Implementation:** Usually some sort of special software is used to allow the list owner to manage it, add and remove users and set parameters that control how the list operates. These programs are commonly called *robots* or *listservs* (*list servers*). One of the more common ones is named *Majordomo*. There are also now mailing lists that are actually implemented and managed using the [World Wide Web](#). (The line between Internet applications continues to get more and more blurry...)
- ☉ **Subscription Rules and Technique:** Some mailing lists are open to anyone who wishes to join, while others are “by invitation only”. Most allow a new subscriber to join automatically using software, others require the list owner to add new members.
- ☉ **Management Method and Style:** The list owner decides what is acceptable for discussion on the list. Some lists are *moderated*, meaning that all submissions to the list must be approved by the list owner before they are sent to list members. Some lists allow mail to the list from non-members, some do not.
- ☉ **“Culture”:** Like all groups, groups of people on mailing lists have their own “culture”, interesting “personalities” and so forth. New members of a list are often encouraged to read the list and not send to it for a while until they become accustomed to it and how it works. This is similar to the acclimation process for Usenet “newbies”.

- 
- ☛ **Special Features:** Some lists support special features, such as the ability to subscribe in *digest mode* (where messages are collected into large digests to cut down on the number of individual messages sent) or to access messages on the Web.

**Key Concept:** One of the many benefits of electronic mail is that it is easy to send a message to many people at once, simply by specifying several recipient addresses. This permits easy and simple *group communication*, because each recipient can then do a group reply to send a response to each of the people who were sent the original message. Electronic *mailing lists* provide a more formalized way for groups to exchange ideas and information; there are many thousands of such lists in existence on the Internet.

---

There are many other ways for groups to share information today, such as World Wide Web bulletin boards, [Usenet newsgroups](#), [Internet Relay Chat](#) and so forth. Some of these have a lot of features that make mailing lists seem “unsophisticated” by comparison. Despite this, electronic mailing lists are still very popular, largely because e-mail is the most universal Internet communication method, and one of the easiest to use.

---

## **TCP/IP Electronic Mail Message Formats and Message Processing: RFC 822 and MIME**

The advantages of using computers for communication are obvious, but there are also some limitations that are imposed by the use of computer technology. When I compare electronic mail to regular mail, I always point out that e-mail is much faster and more flexible in how it can be delivered, and this is true. An electronic mail message can reach its destination in seconds, where a conventional letter would take days.

But one drawback computers have is that they are not very *adaptable* in figuring out how to understand messages. Consider that anyone can put any type of letter, memorandum or other communication in an envelope and send it to you, and assuming you know the language it is written in, you can open the envelope and understand it. You can automatically figure out how to deal with the date being in an unusual place in the letter, or your name appearing at the top compared to the bottom, or the body of the message being structured in different ways. You can read notes that are typed or hand-written; in pen, pencil or crayon; as long as the letters are decipherable, you can understand what is being said.

Computers are not very good at this at all. And it is for that reason that e-mail systems must rely on standard *message formats* to ensure that all messages have the same form and structure. This then makes it possible for all devices in the electronic mail system are able to read and understand each others' messages, to enable TCP/IP e-mail to work on many different types of computers.

In this section, I describe the two formats used for TCP/IP electronic mail messages, in two subsections. The first describes the main TCP/IP electronic mail standard, which is called the RFC 822 format after the standard that defines it. The second describes the Multi-purpose Internet Mail Extensions (MIME) standard, which greatly expands the ability of electronic mail to support the communication of different types of information, by defining methods of encoding various media and non-English language text into the standard RFC 822 format.

---

## **TCP/IP Electronic Mail Standard Message Format: RFC 822**

One of the most astute observations I have read about internetworking applications is that their usefulness is proportional to the number of people who use them. TCP/IP e-mail is a great example: it is a powerful communication method in large part because almost everyone with a computer today participates in the system. The more people who sign on to use e-mail, the more powerful it becomes.

The creators of TCP/IP email realized that people who use the system would employ many different types of hardware and software. To ensure that everyone was able to understand all e-mail messages, regardless of who sent them, they specified a common message format for electronic mail messages. This format doesn't have an official fancy name; it is simply known by the name of the standard that defines it: the *RFC 822* message format.

In this section I describe the RFC 822 message format, which forms the basis for electronic mail message transfer in TCP/IP. I begin with an overview of the format and the general structure of messages, and some of the overall rules used to format RFC 822 messages. I then describe the many headers used in RFC 822 e-mail messages, and how they are arranged into groups. I conclude with a brief look at how RFC 822 messages are processed and their contents interpreted.

**Related Information:** This section may make certain references to [the one on SMTP](#), but was designed so that you could read it prior to reading about SMTP without getting confused. Well, I tried, anyway. ☺

---

### **TCP/IP Electronic Mail RFC 822 Standard Message Format Overview, Structure and General Formatting Rules**

The primary protocol for delivering electronic mail is the [Simple Mail Transfer Protocol \(SMTP\)](#). For this reason, the message format used for TCP/IP e-mail could be considered SMTP's "protocol message format", not unlike the special message formats discussed for other protocols, such as IP and TCP. However, the TCP/IP e-mail message format is used not only by SMTP but by all protocols and applications that deal with electronic mail. This includes the [mail access protocols](#) POP3 and IMAP, as well as others. It was also intended to potentially be usable by other non-TCP/IP mail delivery protocols.

Perhaps for this reason, the TCP/IP e-mail format was not specified as part of the SMTP itself, RFC 821, but rather in a companion document: RFC 822. Both were published in 1982. No official fancy name was given to this message format, and as a result the format became known by the name of the standard itself: the *RFC 822 message format*.

### ***Development of the RFC 822 Message Format Standard***

The history of the message format used in TCP/IP goes back long before 1982, of course. It was originally defined as the format for passing text messages on the Internet's precursor, the ARPAnet, in the early 1970s. Over time the format was refined several times, leading to

---

the publication, in 1977, of the important e-mail standard RFC 733 (*Standard for the Format of ARPA Network Text Messages*). RFC 822 later streamlined the contents of RFC 733, removing some of the features described in the earlier standard that failed to gain acceptance, and simplifying the specification.

In 2001, both SMTP and the RFC 822 message format were revised; SMTP is now described in RFC 2821 and the message format in RFC 2822. This newer standard makes relatively small changes to the RFC 822 message format to reflect modern use of TCP/IP e-mail. Even though RFC 2822 is the current standard, the original name is still the one most commonly used. I will respect that convention in this discussion, describing the message format based on RFC 2822 while still calling it the “RFC 822” message format.

The RFC 822 format describes the form, structure and content of TCP/IP electronic mail messages. It is, as I said, analogous to the message formats used for other protocols in TCP/IP. Like those other formats, the RFC 822 format can be logically divided into two main sections: the *message header*, which contains important control and descriptive information, and the *message body* or *payload*, which carries the data.

### **Overview of RFC 822 Messages**

Where RFC 822 differs from the field formats of other protocols is in expression. Most TCP/IP protocols encode header information into a compact set of bytes that are read and understood based on their location in the message and the semantic meaning assigned to them. Consider the Internet Protocol, for example. The 9th byte of every [IP datagram](#) is the *Time To Live (TTL)* field, which is encoded as a value from 0 to 255. A device reading an IP datagram simply knows that byte number 9 contains the *TTL* value. If it sees the binary value “00010011” there, it knows the *TTL* value for this datagram is the decimal value 19.

In contrast, RFC 822 messages do not use a binary format. They are entirely comprised of lines of regular ASCII text (as used in the United States, called *US-ASCII* by the standard), even the headers. Each line ends with an ASCII *carriage return (CR)* character, followed by a *line feed (LF)* character; the combination is collectively termed “CRLF”. Each line of text should be 78 characters or less (not including the terminating “CRLF”) and must not be more than 998 characters (again, excluding the “CRLF”). Also, the characters CR and LF must not appear by themselves within the text.

The RFC 822 message begins with a set of lines of text that collectively comprise the message header. Each *header field* is expressed in the following form, in text:

<header name>: <header value>

So, for example, if there were a *Time To Live* field in RFC 822 messages (there isn't, of course, as that concept has no meaning to e-mail) and a value of 19 needed to be expressed, the header field would appear like this:

Time To Live: 19

---

This expressing of all fields as simple text means each header takes up more space in each message; the string “Time To Live: 19” takes up 18 bytes including the terminating “CRLF”, where the binary-encoded *Time To Live* field in the IP header takes only a single byte. What we gain from this are two important benefits. First, any user can easily check the headers and immediately understand what headers are present and what their values are, which makes RFC 822 messages very *readable*. Second, since each header is explicitly labeled, RFC 822 messages can vary in terms of the number of headers they contain, and even in what order they appear, making them *flexible*.

## General Structure

The RFC 822 message always starts with a set of header fields as described above; [the next topic](#) describes them in more detail. After all the headers, an empty line must occur. This consists simply of the characters “CRLF” by themselves, immediately following the “CRLF” at the end of the final header field line. Seeing two “CRLF” character pairs in sequence tells the device reading the message that the end of the headers have been reached. All the remaining lines are considered the body of the message. Like the header lines, body lines are comprised of ASCII text and must be no more than 998 characters, with 78 characters or less recommended (for easier reading on standard 80-character terminal displays).

Since both the header and body of e-mail messages are simply ASCII text, this means the entire message is just a text file. This makes these messages very readable, as I said above, and also quite easy to create. One can use a simple text editor to create a complete electronic mail message, including headers, and can read it with a simple text display utility. This contributes to e-mail's universal appeal.

The drawback is that the decision to make messages entirely ASCII means there is no native support in RFC 822 messages for anything that requires more complex structuring, or that cannot be expressed using the small number of ASCII characters. One cannot express pictures, or binary files, spreadsheets, sound clips and so forth directly using ASCII. Also, the use of ASCII makes RFC 822 well-suited to expressing messages in English, but not in many other languages, which use characters that ASCII cannot represent. All of these limitations eventually prompted the creation of the enhanced [MIME message format](#).

**Key Concept:** To ensure that every device on a TCP/IP internetwork can read e-mail sent by every other device, all messages are required to adhere to a specific structure. The standard that first specified the form of modern TCP/IP e-mail messages was RFC 822, and as a result, this is now called the *RFC 822 message format*. An RFC 822 message consists of a set of *message headers* and a *message body*, which are separated by a blank line. RFC 822 messages must contain only plain ASCII text characters; each line must be no more than 1000 characters in length, and the last two characters must be the ASCII characters “CR” and “LF” to mark the end of the line.

---

---

## **TCP/IP Electronic Mail RFC 822 Standard Message Format Header Field Definitions and Groups**

The [RFC 822 message format](#) describes the structure and content of TCP/IP e-mail messages. The structure is intentionally designed to be very simple and easy to both create and understand. Each message begins with a set of headers that describe the message and its contents. An empty line marks the end of the headers, and then the message body follows.

The message body contains the actual text that the sender is trying to communicate to the recipient(s), while the message header contains various types of information that serve various purposes. The headers help control how the message is processed, by specifying who the recipients are, describing the contents of the message, and providing information to a recipient of a message about processing done on the message as it was delivered.

### ***Header Field Structure***

Each header field follows the simple text structure we saw in the preceding topic:

```
<header name>: <header value>
```

The <header name> is of course the name of the header, and the <header value> is the value associated with that header, which depends on the header type. Like all RFC 822 lines, headers must be no more than 998 characters long and are recommended to be no more than 78 characters in length, for easier readability. The RFC 822 and 2822 standards support a special syntax for allowing headers to be “folded” onto multiple lines if they are very lengthy. This is done by simply continuing a header value onto a new line, which *must* begin with at least one “white space” character, such as a space or <Tab> character, like this:

```
<header name>: <header value part 1>
<white space> <header value part 2>
<white space> <header value part 3>
...
```

The <Tab> character is most often used for this purpose. So, for example, if we wanted to specify a large number of recipients for a message, we could do it as follows:

```
To: person1@domain1.org, person2@domain2.com,
    person3@domain3.net, person4@domain4.edu
```

### ***Header Field Groups***

The RFC 822 message format specifies many types of headers that can be included in e-mail messages. A small number of headers are *mandatory*, meaning they must be included in all messages. Some are not mandatory but are usually present, because they are fundamental to describing the message. Others are optional and are included only when needed.

---

To help organize the many headers, the RFC 2822 standard categorizes them into header field groups (as did RFC 822, though the groups are a little different in the older standard):

- ☉ **Origination Date Field:** Specifies the date and time that the message was made ready for delivery; see below for details. (This field is in its own group for reasons that are unclear to me; perhaps just because it is important.)
- ☉ **Originator Fields:** Contain information about the sender of the message.
- ☉ **Destination Address Fields:** Specify the recipient(s) of the message, which may be in one of three different recipient classes.
- ☉ **Identification Fields:** Contain information to help identify the message.
- ☉ **Informational Fields:** Contain optional information to help make more clear to the recipient what the message is about.
- ☉ **Resent Fields:** Used to preserve the original originator, destination and other fields when a message is resent.
- ☉ **Trace Fields:** Used to show the path taken by mail as it was transported.

In addition, the format allows other, user-defined fields to be specified, as long as they correspond to the standard “<header name>: <header value>” syntax. This can be used to provide additional information of various sorts. For example, sometimes the e-mail client software will include a header line indicating the name and version of the software used to compose and send the message. We'll also see that [MIME uses new header lines](#) to encode information about MIME messages.

**Key Concept:** Each RFC 822 message begins with a set of *headers* that carry essential information about the message. These headers are used to manage how the message is processed and interpreted, and also describe the contents of the message body. Each header consists of a *header name* and a *header value*. There are over a dozen different standard RFC 822 headers, which are organized into groups; it is also possible for customized user headers to be defined.

---

---

## Common Header Field Groups and Header Fields

Table 241 describes the header fields in TCP/IP e-mail messages and how they are used:

**Table 241: RFC 822 Electronic Mail Header Field Groups and Fields (Page 1 of 3)**

Field Group	Field Name	Appearance	Number of Occurrences Per Message	Description
Origination Date	<b>Date:</b>	Mandatory	1	Indicates the date and time that the message was made available for delivery by the mail transport system. This is commonly the date/time that the user tells his or her e-mail client to send the message.
Originator Fields	<b>From:</b>	Mandatory	1	The e-mail address of the user sending the message. This should be the person who was the source of the message itself.
	<b>Sender:</b>	Optional	1	The e-mail address of the person who is sending the electronic mail, if different from the message originator. For example, if person <i>B</i> is sending an e-mail containing a message from person <i>A</i> on <i>A</i> 's behalf, person <i>A</i> 's address goes in the <i>From:</i> header and person <i>B</i> 's in the <i>Sender:</i> header. If the originator and the sender are the same (which is commonly the case), this field is not present.
	<b>Reply-To:</b>	Optional	1	Used to tell the recipient of this message the address the originator would like the recipient to use for replies. If absent, replies are normally sent back to the <i>From:</i> address.

**Table 241: RFC 822 Electronic Mail Header Field Groups and Fields (Page 2 of 3)**

Field Group	Field Name	Appearance	Number of Occurrences Per Message	Description
Destination Address Field	<b>To:</b>	Normally present	1	A list of primary recipients of the message.
	<b>Cc:</b>	Optional	1	A list of recipients to receive a “copy” of the message (“cc” stands for “carbon copy”, as used in old typewriters). There is no technical difference between how a message is sent to someone listed in the Cc: header and someone in the To: header. The difference is only semantic, in how the recipient interprets the message. Someone in the To: list is usually the person who is the direct object of the message, while someone in the Cc: list is being copied on the message for informational purposes.
	<b>Bcc:</b>	Optional	1	Contains a list of recipients to receive a “blind carbon copy”. These people receive a copy of the message without other recipients knowing they have received it. For example, if X is specified in the To: line, Y is in the Cc: line, and Z is in the Bcc: line, all three would get a copy of the message, but X and Y would not know Z had received a copy. This is done either by removing the Bcc: line before message delivery or altering its contents.
Identification Fields	<b>Message-ID:</b>	Should be present	1	Provides a unique code for identifying a message; normally generated when a message is sent.
	<b>In-Reply-To:</b>	Optional, normally present for replies	1	When a message is sent in reply to another, the <i>Message-ID:</i> field of the original message is specified in this field, to tell the recipient of the reply what original message the reply pertains to.
	<b>References:</b>	Optional	1	Identifies other documents related to this message, such as other e-mail messages.

**Table 241: RFC 822 Electronic Mail Header Field Groups and Fields (Page 3 of 3)**

Field Group	Field Name	Appearance	Number of Occurrences Per Message	Description
Informa- tional Fields	<b>Subject:</b>	Normally present	1	Describes the subject or topic of the message.
	<b>Comments:</b>	Optional	Unlimited	Contains summarized comments about the message.
	<b>Keywords:</b>	Optional	Unlimited	Contains a list of comma-separated keywords that may be of use to the recipient. This may be used optionally when searching for messages on a particular subject matter.
Resent Fields	<b>Resent-Date:</b> <b>Resent-From:</b> <b>Resent-Sender:</b> <b>Resent-To:</b> <b>Resent-Cc:</b> <b>Resent-Bcc:</b> <b>Resent-Message-ID:</b>	Each time a message is resent, a resent block is required	For each resent block, Resent-Date: and Resent-Sender: are required; the others are optional	These are special fields used only when a message is re-sent by the original recipient to someone else, a process called <i>forwarding</i> . For example, person X may send a message to Y, who forwards it to Z. In that case, the original <i>Date:</i> , <i>From:</i> and other headers are as they were when X sent the message. The <i>Resent-Date:</i> , <i>Resent-From:</i> and other “resent” headers are used to indicate the date, originator, recipient and other characteristics of the re-sent message.
Trace Fields	<b>Received:</b> <b>Return-Path:</b>	Inserted by e-mail system	Unlimited	These fields are inserted by computers as they process a message and transport it from the originator to the recipient. They can be used to trace the path a message took through the electronic mail system.

### **TCP/IP Electronic Mail RFC 822 Standard Message Format Processing and Interpretation**

The standards that define SMTP describe the protocol as being responsible for transporting *mail objects*. A mail object is described as consisting of two components: a *message* and an *envelope*. The envelope contains all the information necessary to accomplish transport of the message; the message is everything in the e-mail message we have seen in the last two topics, including both message header and body.

The distinction between these is important technically. Just as the postal service only looks at the envelope and not its contents in determining what to do with a letter—no wise-cracks, please! ☺—SMTP likewise only looks at the envelope in deciding how to send a message. It does not rely on the information in the actual message itself for basic transport purposes.

---

So technically, the envelope is not the same as the message headers. However, as you can tell by looking at [the list of e-mail headers](#), each message includes the recipients and other information needed for mail transport anyway. For this reason, it is typical for an e-mail message to be specified with sufficient header information that it can be considered enough by itself to accomplish its own delivery. E-mail software can process and interpret the message to construct the necessary “envelope” for SMTP to transport the message to its destination mailbox(es). The distinction between an e-mail message and its envelope is discussed in more detail in [the topic describing SMTP mail transfers](#).

## ***RFC 822 Message Processing Sequence***

The processing of RFC 822 messages is relatively straight-forward, due again to the simple RFC 822 message format. The creation of the complete e-mail message begins with the creation of a message body and certain headers by the user creating the message. Whenever a message is “handled” by a software program, the headers are examined so the program can determine what to do with it. Additional headers are also added and changed as needed.

The following is the sequence of events that occur in the “lifetime” of a message's headers.

### **Composition**

The human composer of the message writes the message body, and also tells the e-mail client program the values to use for certain important header fields. These include the intended recipients, the message subject and other informational fields, and certain optional headers such as the *Reply-To* field.

### **Sender Client Processing**

The e-mail client processes the message, puts the information the human provided into the appropriate header form and creates the initial e-mail message. At this time, it inserts certain headers into the message, such as the origination date. The client also parses the intended recipient list to create the envelope for transmission of the message using SMTP.

### **SMTP Server Processing**

SMTP servers do not pay attention to most of the fields in a message as they forward it. They will, however, add certain headers, especially trace headers such as *Received* and *Return-Path*, as they transport the message. These are generally prepended to the beginning of the message in order to ensure that existing headers are not rearranged or modified.

Note however that when [gatewaying](#) is done between e-mail systems, certain headers must actually be changed, to ensure that the message is compatible with non-TCP/IP e-mail software.

---

## Recipient Client Processing

When the message arrives at its destination, the recipient's SMTP server may add headers to indicate the date and time the message was received.

## Recipient Access

When the recipient of a message uses client software, optionally via a mail access protocol such as POP3 or IMAP, the software analyzes each message in the mailbox. This enables the software to display the messages in a way meaningful to the human user, and may also permit the selection of particular messages to be retrieved.

For example, most of us like to see a summary list of newly-received mail, showing the originator, message subject and the date and time the message was received, so we can decide which mail we want to read first, what mail to defer to a later time, and what to just delete without reading (spam spam spam ... ☺)

---

## **TCP/IP Enhanced Electronic Mail Message Format: Multipurpose Internet Mail Extensions (MIME)**

The [RFC 822 e-mail message format](#) is the standard for the exchange of electronic mail in TCP/IP internetworks. Its use of simple ASCII text makes it easy to create, process and read e-mail messages, which has contributed to the success of e-mail as a worldwide communication method.

Unfortunately, while ASCII text is great for writing simple memorandums and other short messages, it provides no flexibility to support other types of communication. To allow e-mail to carry multimedia information, arbitrary files, and messages in languages using character sets other than ASCII, the *Multipurpose Internet Mail Extensions (MIME)* standard was created.

In this section I describe MIME and how it is used for modern e-mail messaging. I begin with an overview of MIME and discussion of its history and the standards that define it. I describe the two overall MIME message structures and provide a summary of the important MIME-specific headers. I then explain the important MIME *Content-Type* header in more detail, and discuss MIME discrete media types, subtypes and parameters. I discuss the more complex MIME multipart and encapsulated message structures, and then the different methods by which data can be encoded into MIME message bodies. I conclude with the special MIME extension to allow support for non-ASCII characters in ordinary e-mail headers.

**Background Information:** MIME is a message format that augments the basic RFC 822 message format, rather than replacing it. This section assumes that you have basic familiarity with [the RFC 822 format](#) and the more important [e-mail message headers](#).

---

**Note:** While MIME was developed specifically for mail, its encoding and data representation methods have proven so useful that it has been adopted by other application protocols as well. One of the best known of these is the [HyperText Transfer Protocol \(HTTP\)](#), which uses MIME headers for indicating the characteristics of data being transferred. Some elements of MIME were in fact developed not for e-mail but for use by HTTP or other protocols, and I indicate this where appropriate. Be aware, however, that HTTP only uses **elements** of MIME; there are important differences, and HTTP messages are not MIME-compliant.

---

### **MIME Message Format Overview, Motivation, History and Standards**

I describe [the reasons why universal standards are important](#) in the [Networking Fundamentals chapter](#) of this Guide, and re-emphasize the point in many other places as well. Most protocols become successful for the specific reason that they are based on open

---

standards that are widely accepted. The [RFC 822 e-mail message format standard](#) is an excellent example; it is used by millions of people every day to send and receive TCP/IP e-mail.

However, success of standards comes at a price: *reliance* on those standards. Once a standard is in wide use, it is very difficult to modify it, even when times change and those standards are no longer sufficient for the requirements of modern computing. Again here, unfortunately, the RFC 822 e-mail message format is an excellent example.

### ***The Motivation for MIME***

TCP/IP e-mail was developed in the 1960s and 1970s. Compared to the way the world of computers and networking is today, almost everything back then was *small*. The networks were small; the number of users was small; the computing capabilities of networked hosts was small; the capacity of network connections was small; the number of network applications was small. (The only thing that wasn't small back then was the size of the computers themselves!)

As a result of this, the requirements for electronic mail messaging were also rather... small. Most computer input and output back then was text-based, and it was therefore natural that the creators of [SMTP](#) and the RFC 822 standard would have envisioned e-mail as being strictly a text medium. Accordingly, they specified RFC 822 to carry text messages.

The fledgling Internet was also developed within the United States, and at first, the entire internetwork was within American borders. Most people in the United States speak English, a language that as you may know uses a relatively small number of characters that is well-represented using the ASCII character set. Defining the e-mail message format to support United States ASCII (US-ASCII) also made sense at the time.

However, as computers developed, they moved away from a strict text model towards graphical operating systems. And predictably, users became interested in sending more than just text. They wanted to be able to transmit diagrams, non-ASCII text documents (such as Microsoft Word files), binary program files, and eventually multimedia information: digital photographs, MP3 audio clips, slide presentations, movie files and much more. Also, as the Internet grew and became global, other countries came “online”, some of which used languages that simply could not be expressed with the US-ASCII character set.

Unfortunately, by this point, the die was cast. RFC 822 was in wide use and changing it would have also meant changes to how protocols such as SMTP, [POP](#) and [IMAP](#) worked, protocols that ran on millions of machines. Yet by the late 1980s, it was quite clear that the limitations of plain ASCII e-mail were a big problem that had to be resolved. A solution was needed, and it came in the form of the *Multipurpose Internet Mail Extensions (MIME)*.

**Note:** MIME is usually referred to in the singular, as I will do from here forward, even though it is an abbreviation of a plural term.

---

---

## MIME Capabilities

The idea behind MIME is both clever and elegant—which means I like it! RFC 822 restricts e-mail messages to be ASCII text, but that doesn't mean that we cannot define a more specific structure for how that ASCII text is created. Instead of just letting the user type an ASCII text message, we can use ASCII text characters to actually encode non-text information (commonly called *attachments*). Using this technique, MIME allows regular RFC 822 e-mail messages to carry the following:

- Non-text information, including graphic files, multimedia clips and all the other non-text data examples I listed earlier;
- Arbitrary binary files, including executable programs and files stored in proprietary formats (for example, AutoCAD files, Adobe Acrobat PDF files and so forth);
- Text messages that use character sets other than ASCII. This even includes the ability to [use non-ASCII characters in the headers](#) of RFC 822 e-mail messages.

MIME even goes one step beyond this, by actually defining a structure that allows [multiple files to be encoded into a single e-mail message](#), including files of different types. For example, someone working on a budget analysis could send one e-mail message that includes a text message, a Powerpoint presentation, and a spreadsheet containing the budget figures. This capability has greatly expanded e-mail's usefulness in TCP/IP.

All of this is accomplished through special encoding rules that transform non-ASCII files and information into an ASCII form. Headers are added to the message to indicate how the information is encoded. The encoded message can then be sent through the system like any other message. SMTP and the other protocols that handle mail pay no attention to the message body, so they don't even know MIME has been used.

The only changes required to the e-mail software is adding support for MIME to e-mail client programs: both the sender and receiver must support MIME to encode and decode the messages. Support for MIME was not widespread when MIME was first developed, but the value of the technique is so significant that it is present in nearly all e-mail client software today. Furthermore, most clients today can also use the information in MIME headers to not only decode non-text information but pass it to the appropriate application for presentation to the user.

**Key Concept:** The use of the RFC 822 message format ensures that all devices are able to read each other's e-mail messages, but it has a critical limitation: it only supports plain, ASCII text. This is insufficient for the needs of modern internetworks, yet reliance on the RFC 822 standard would have made replacing it difficult. Instead, a new standard called the *Multipurpose Internet Mail Extensions (MIME)* was defined. MIME specifies several methods that allow e-mail messages to contain multimedia content, binary files, and text files using non-ASCII character sets, all while still adhering to the RFC 822 message format. MIME also further expands e-mail's flexibility by allowing multiple files or pieces of content to be sent in a single message.

---

---

## MIME Standards

MIME was first described in a set of two standards, RFC 1341 and RFC 1342, published in June 1992. These were updated by RFCs 1521 and 1522 in September 1993. In March 1994, a supplemental standard was published, RFC 1590, which specified the procedure for defining new MIME media types.

Work continued on MIME through the mid-1990s, and in November 1996 the standards were revised again. This time, the documents were completely restructured and published as a set of 5 individual standards. This was done to improve the readability of the information. These standards are shown in [Table 242](#).

**Table 242: Multipurpose Internet Mail Extensions (MIME) Standards**

RFC Number	Name	Description
2045	<u><i>Multipurpose Internet Mail Extensions (MIME) Part One: Format of Internet Message Bodies</i></u>	Describes the fundamental concepts behind MIME and the structure of MIME messages.
2046	<u><i>Multipurpose Internet Mail Extensions (MIME) Part Two: Media Types</i></u>	Explains the concept of MIME media types and subtypes and describes some of the kinds of media whose encoding is defined in the MIME standards.
2047	<u><i>MIME (Multipurpose Internet Mail Extensions) Part Three: Message Header Extensions for Non-ASCII Text</i></u>	Describes how RFC 822 headers can be modified to carry non-ASCII text.
2048	<u><i>Multipurpose Internet Mail Extensions (MIME) Part Four: Registration Procedures</i></u>	Discusses how organizations can register additional media types for use with MIME.
2049	<u><i>Multipurpose Internet Mail Extensions (MIME) Part Five: Conformance Criteria and Examples</i></u>	Provides additional implementation information and examples of how MIME can be used.

Since the time that these five “primary” MIME standards came out, numerous additional RFCs have been published. These have defined various extensions to MIME itself, including additional MIME header types and new media types. Notable examples are RFCs 2183 and 2557, which define the MIME *Content-Disposition* and *Content-Location* headers, respectively. Some other MIME capabilities are actually defined as part of other technologies that use MIME; for example, the first [HTTP](#) standard, RFC 1945 defines the *Content-Length* header. Numerous other RFCs define new media types/subtypes, too many to list here.

## MIME Basic Structures and Headers

The creators of the Multipurpose Internet Mail Extensions (MIME) standard had a difficult challenge on their hands: how to bring flexibility in the types of data contained in e-mail messages, when RFC 822 said that they had to be comprised of only ASCII text. To accomplish this, they had to exploit the areas of flexibility that had already been put into the existing RFC 822.

---

There were two such “opportunities” available. The first was the fact that RFC 822 message bodies are allowed to contain any type of ASCII text, as long as lines don't exceed 998 text characters and each line ends with a “CRLF” control code combination. Even though the creators of RFC 822 naturally assumed this ASCII text would be human-readable, there was nothing stopping it from being machine-readable code. The second was the facility built into RFC 822 (and the protocols that use it, such as SMTP) to allow custom “user-defined” header fields to be added to any e-mail message.

The non-specific nature of RFC 822 message bodies forms the basis for how MIME itself works. An e-mail client that supports the MIME standard uses special encoding algorithms that transform non-ASCII information into ASCII form. It then places this set of encoded ASCII characters into the body of the message, as if it had been typed by a user, using one of two special structures.

The ability to add new headers to RFC 822 is used to communicate information about the use of MIME from the sender to the recipient. The devices transporting a MIME message don't care that MIME was used, because they don't pay attention to the contents of the message body. However, when the message reaches its destination, the recipient's e-mail client program must have some way of knowing that MIME was used, and must also be told how the information in the message was encoded. Otherwise, it might just present the encoded non-ASCII data to the user as ASCII text (which would look like random gibberish!)

### ***Basic Structure Types***

The exact method by which data is encoded in the message body and MIME headers are included depends on the overall structure of the MIME message. There are two basic structure types, which are described based on the kind of media the message carries:

- ☉ **Simple Structure (Discrete Media):** MIME messages carrying a single *discrete* media type, such as a text message or a graphical image, use a simple structure. Only one encoding of information is present in the body of the message.
- ☉ **Complex (Composite Media) Structure:** Some MIME messages carry a *composite* media type, which allows multiple different media to be contained in a single message, such as a text message **and** a graphical image, or to encapsulate another e-mail message in its entirety. Many of these use a more complex structure where the body of the message contains several *MIME body parts*.

### ***MIME Entities***

Collectively, both whole MIME messages and individual body parts are called *MIME entities*. Each set of MIME headers provides information about either type of MIME entity: a MIME message as a whole, or a body part in a composite message. When a MIME message is received, the recipient first examines the headers in the message as a whole (the RFC 822 headers) to determine the overall message type. This then indicates if the message uses a simple or complex structure. If the latter, the body of the message is

---

parsed and each individual body part is individually interpreted, including its individualized headers. [The topic on composite media types](#) has more details on how these body parts are formatted.

### **Primary MIME Headers**

The first of the five main MIME standards, RFC 2045, describes a set of five primary MIME headers that communicate basic information about the content of each MIME entity (message or body part).

#### ***MIME-Version***

Each MIME message is required to have a *MIME-Version* header, which serves two purposes. First, it identifies the e-mail message as being MIME-encoded. Second, even though only one version of MIME has been defined so far, having a version number header provides “future-proofing” in case a new version is created later that may have some incompatibilities with the present one. Right now, all MIME messages use version 1.0.

This is the only MIME header that applies only to an entire message; it is not used to label individual MIME body parts. This is easy to remember as it is the only header whose name does not begin with “Content-”.

#### ***Content-Type***

Describes the nature of the data that is encoded in the MIME entity. This header specifies a content *type* and a content *subtype*, which are separated by a slash character. It may optionally also contain certain *parameters*, that convey additional information about the type and subtype. In a message body, this header is what tells the recipient of the e-mail message what sort of media it contains, and whether the body uses a simple or complex structure. In a body part, it describes the media type the body part contains.

For example, a message containing an HTML document might have a *Content-Type* header of “text/html”, where a message containing a JPEG graphical file might be specified as “image/jpeg”. For a composite MIME type, the *Content-Type* header of the whole message will contain something like “multipart/mixed” or “multipart/alternative”, and each body part will contain individual *Content-Type* headers such as “text/html” or “image/jpeg”. These are all discussed in detail in the next two topics.

This header is optional. When not present, the default of a regular US-ASCII text message is assumed (the media type of regular RFC 822 messages).

#### ***Content-Transfer-Encoding***

For a message using simple structure, specifies the specific method that was used to encode the data in the message body; for a composite message, identifies the encoding method for each MIME body part. For data that is already in ASCII form, no special

---

encoding is needed, but other types of data must be converted to ASCII for transmission. This header tells the recipient how to decode the data back into its normal representation. [MIME encoding methods are described later in this section.](#)

This header is optional; the default value if it is not present is “7bit” encoding, which again is the encoding of regular ASCII.

### ***Content-ID***

Allows the MIME content to be assigned a specific identification code. This header is analogous to the RFC 822 *Message-ID* header field, but is specific to the MIME content itself. It is optional, and is most often used for body parts in multipart MIME messages.

### ***Content-Description***

This is an optional header that allows an arbitrary additional text description to be associated with the MIME entity. In a multipart message, each body part might be given a description header to make clear to the recipient what the parts represent.

### ***Additional MIME Headers***

In addition to the five basic headers above, the MIME standard allows additional ones to be defined. The only restriction is that they all must start with the word “Content-”, which again, clearly labels them as describing content of a MIME entity (message or body part). Obviously, both sender and recipient must support a custom header for it to be useful.

Several new MIME headers have in fact been created and documented in various Internet RFCs. Some are actually designed not specifically for use by e-mail messages, but for use by other protocols that make use of MIME technology, such as the [HyperText Transfer Protocol \(HTTP\)](#). Here are three notable ones.

### ***Content-Disposition***

In multipart MIME messages, this header may be given to MIME body parts to control how information is presented to the user. The two most common values are “inline”, which says the content is intended to be displayed automatically along with other body parts, and “attachment”, which indicates that the content is separate from the main document. This header is defined in RFC 2183.

### ***Content-Location***

Allows the location of a MIME body part to be identified using a [uniform resource identifier \(URI\)](#). This is sometimes used when encoding HTML and other multimedia-enabled document formats into e-mail using MIME multipart messages. It is defined in RFC 2557.

---

## Content-Length

Specifies the length of a MIME entity in bytes. This header is not commonly used in e-mail applications of MIME, but [is an important header in HTTP](#). It is described in the HTTP standards, first appearing in RFC 1945.

**Key Concept:** MIME provides flexibility in the information that can be carried in e-mail messages, by encoding non-ASCII data in ASCII form, and by adding special headers that describe this data and how it is to be interpreted. The most important MIME headers are *Content-Type*, which describes what sort of data is in the message, and *Content-Transfer-Encoding*, which specifies how the data is encoded. MIME supports two basic overall formats: *simple structure*, in which a single type of *discrete media* is encoded in a message; and *complex structure*, which encodes a *composite media* type that can carry multiple kinds of information.

---

## MIME Content-Type Header and Discrete Media: Types, Subtypes and Parameters

MIME transforms TCP/IP e-mail from the drab, text-only world of [RFC 822](#), to a rich communication method that can carry many types of data. It accomplishes this by using special techniques to encode various kinds of information into ASCII text form, such as graphical images, sound files, video clips, application programs, compressed data files, and many others. We commonly refer to these as different types of *media*, and MIME uses the same term to describe them.

Since MIME supports so many kinds of media, it is necessary that each message contain information that describes what it contains, to permit accurate decoding of message contents. This is the function of the important MIME *Content-Type* header.

### **Content-Type Header Syntax**

The syntax of the header is as follows:

Content-Type: <type>/<subtype> [; parameter1 ; parameter2 .. ; parameterN ]

The purpose of these different elements is to describe the media in the MIME entity in a way that proceeds from the general to the specific. The first element, “<type>”, is called the *top-level media type* and describes the overall form of the data. For example, it indicates if the MIME entity contains text, an image, audio and so forth. The second element, “<subtype>”, provides specific information about the form or format of the data. For example, a JPEG image and a GIF image are both images, but they are in a different format. Both “<type>” and “<subtype>” are mandatory in the *Content-Type* header.

---

Following these elements may appear one or more *parameters*, which are usually optional but may be required for some media types. These provide still more detailed specification of the nature of the data, when it is required. Each parameter is preceded by a semi-colon and is expressed as an attribute/value pair, separated by an “=” sign, like this:

; attribute=value

One example of how parameters may be used is in specifying the character set in a text message. The representation of “regular” RFC 822 ASCII text is as follows:

Content-type: text/plain; charset=“us-ascii”

The top-level media type is “text”, and the subtype is “plain”, so this indicates a plain text message. The parameter “charset” specifies that the message uses the US ASCII character set. Another common use for parameters is to specify the name of an attached file, like this:

Content-type: image/jpeg; name=“ryanpicture.jpg”

### ***Discrete Media Types and Subtypes***

As I mentioned in [the preceding topic](#), MIME supports two basic structures: simple or complex. A simple message carries only one media type, such as a piece of text, a picture or an executable file. These are called *discrete media types* in MIME. A complex message carries a *composite media type*, which may incorporate multiple body parts. Each body part in turn carries data corresponding to one of the discrete media types. The top-level media type indicates whether the whole message carries a discrete media type or a composite type; I will describe the discrete media types here; the composite types are discussed in [the next topic](#).

The RFC 2046 standard (part two of the [set of five standards that describes MIME](#)) defines five discrete top-level media types: *text*, *image*, *audio*, *video* and *application*; they each represent one of the major classes of data commonly transmitted over TCP/IP. Each of these has one or more subtypes, and some also have parameters that are used to provide more information about them.

The creators of MIME recognized that the standard could not describe every media type, and that new ones would be created in the future. RFC 2048 (part four of the five-standard MIME set) describes the process by which new media types, subtypes and parameters can be described and registered with the [Internet Assigned Numbers Authority \(IANA\)](#).

Thus far, only one new top-level media type has been created; this is the *model* top-level type, defined for CAD modeling files and similar uses, as described in RFC 2077. However, many dozens of new *subtypes* have been created over the years, some specified in RFCs and others just registered directly with IANA. This includes many “vendor-specific” subtypes, which are usually identified by either the prefix “x-” or “vnd.” in the subtype name.

---

**On The Web:** You can find a complete list of MIME media organized by top-level media type, on IANA's web site: <http://www.iana.org/assignments/media-types/index.html>

---

---

**Key Concept:** The MIME *Content-Type* header specifies what sort of data is encoded in a MIME message. The header indicates the general form of the message's content through a *top-level media type*, and the more specific nature of the data through the specification of a *subtype*. It may also contain optional *parameters* that provide still more information about the content.

---

### ***Common Discrete Media Types and Subtypes***

There are literally hundreds of type/subtype combinations now, and I will not try to list them all, but will briefly describes the six MIME discrete top-level media types. For each, a table has been provided showing some of the more commonly-encountered MIME subtypes, to give you an idea of what is "out there". This includes a description of each subtype and a reference to the place where it is defined.

#### **Text Media Type (*text*)**

This type is used for sending data that is primarily in textual form ([Table 243](#)).

**Table 243: MIME *text* Media Type Subtypes**

type/subtype	Description	Defining Source
<b><i>text/plain</i></b>	Plain text, used for regular messages such as those corresponding to the initial RFC 822 standard.	RFC 2046
<b><i>text/enriched</i></b>	Text that includes formatting information or other "enrichment" that makes it no longer "plain".	RFC 1896
<b><i>text/html</i></b>	A document expressed in <a href="#">Hypertext Markup Language (HTML)</a> , commonly used for the <a href="#">World Wide Web</a> .	RFC 2854
<b><i>text/css</i></b>	Cascading style sheet information for the World Wide Web.	RFC 2318

---

## Image Media Type (*image*)

The *image* type indicates graphical image files, such as pictures. The subtype normally indicates the specific format to allow the recipient to properly decode and present the file, with some of the more common subtypes given in [Table 244](#).

**Table 244: MIME *image* Media Type Subtypes**

type/subtype	Description	Defining Source
<i>image/jpeg</i>	An image in JPEG format.	RFC 2046
<i>image/gif</i>	A Graphical Interchange Format (GIF).image.	(IANA says RFC 2046 but it's not there...)
<i>image/tiff</i>	Tagged Image File Format (TIFF) image.	RFC 2302
<i>image/vnd.dwg</i> , <i>image/vnd.dxf</i> , <i>image/vnd.svf</i>	Vector images used in AutoCAD.	Registration with IANA

## Audio Media Type (*audio*)

This media type is used for sending audio information. The subtype normally indicates the specific format, with [Table 245](#) showing a couple of common values.

**Table 245: MIME *audio* Media Type Subtypes**

type/subtype	Description	Defining Source
<i>audio/basic</i>	A “basic” audio type defined in the main MIME standards. It describes single-channel audio encoded using 8-bit ISDN mu-law PCM at 8000 Hz.	RFC 2046
<i>audio/mpeg</i>	MPEG standard audio (including the popular MP3 file format).	RFC 3003

## Video Media Type (*video*)

This type is used for sending video information. Again, the subtype normally indicates the specific format ([Table 246](#)).

**Table 246: MIME *video* Media Type Subtypes (Page 1 of 2)**

type/subtype	Description	Defining Source
<i>video/mpeg</i>	Video encoded to the MPEG digital video standard.	RFC 2046

---

**Table 246: MIME *video* Media Type Subtypes (Page 2 of 2)**

type/subtype	Description	Defining Source
<i>video/dv</i>	Digital video corresponding to several popular standards including SD-VCR, HD-VCR, and DVB, as used by various types of video equipment.	RFC 3189
<i>video/quicktime</i>	Apple's Quicktime movie format.	Registration with IANA

**Model Media Type (*model*)**

This type describes a model representation, such as a two-dimensional or three-dimension physical model ([Table 247](#)).

**Table 247: MIME *model* Media Type Subtypes**

type/subtype	Description	Defining Source
<i>model/mesh</i>	A mesh, as used in modeling.	RFC 2077
<i>model/vrml</i>	A Virtual Reality Modeling Language (VRML) model.	RFC 2077
<i>model/iges</i>	A model file corresponding to the Initial Graphics Exchange Specification (IGES).	Registration with IANA

**Application Media Type (*application*)**

This media type is a “catch all” for any kind of data that doesn't fit into one of the categories above, or that is inherently application-specific. The subtype describes the data by indicating the kind of application that uses it. This can be used to guide the recipient's e-mail program in choosing an appropriate application program to display it, just like how a file extension in Windows tells the operating system how to open different kinds of files.

For example, if you have Microsoft Excel installed on your PC, clicking a file ending with “.XLS” will launch Excel automatically. Similarly, an Excel spreadsheet will normally be sent using MIME with a media type of *application/vnd.ms-excel*. This tells the recipient's e-mail program to launch Excel to read this file.

---

Since there are so many applications out there, there are over a hundred different subtypes within this top-level type. [Table 248](#) contains a few representative samples.

**Table 248: MIME *application* Media Type Subtypes**

type/subtype	Description	Defining Source
<b><i>application/octet-stream</i></b>	An arbitrary set of binary data octets. See below for more details.	RFC 2046
<b><i>application/postscript</i></b>	A Postscript file, used for printing and for generating Adobe Acrobat (PDF) files.	RFC 2046
<b><i>application/applefile</i></b>	Resource file information for representing Apple Macintosh files.	Registration with IANA
<b><i>application/msword</i></b>	Microsoft Word document. Note that this does not have the “vnd” prefix like most other Microsoft file types.	Registration with IANA
<b><i>application/pdf</i></b>	A Portable Document Format (PDF) file, as created by Adobe Acrobat.	Registration with IANA
<b><i>application/vnd.framemaker</i></b>	An Adobe FrameMaker file.	Registration with IANA
<b><i>application/vnd.lotus-1-2-3</i></b>	A Lotus 1-2-3 file.	Registration with IANA
<b><i>application/vnd.lotus-notes</i></b>	A Lotus Notes file.	Registration with IANA
<b><i>application/vnd.ms-excel</i></b>	A Microsoft Excel spreadsheet file.	Registration with IANA
<b><i>application/vnd.ms-powerpoint</i></b>	A Microsoft Powerpoint presentation file.	Registration with IANA
<b><i>application/vnd.ms-project</i></b>	A Microsoft Project file.	Registration with IANA
<b><i>application/zip</i></b>	A compressed archive file containing one or more other files, using the ZIP/PKZIP compression format.	Registration with IANA

Of these, there is one special subtype that is worth further mention: the *application/octet-stream* subtype. This is a “catch all” within the “catch all” of the *application* type, and just means the file is a sequence of arbitrary binary data. It is usually used when the sender is unsure of what form the data takes, or cannot identify it as belonging to a particular application. When this type is used, the recipient will usually be prompted to just save the data to a file. He or she must then figure out what application to use to read it.

The *application/octet-stream* MIME type/subtype may even be used for images, audio or video in unknown formats. If you try to send a multimedia document that your sending program does not understand, it will generally encode it as *application/octet-stream* for transmission. This is your e-mail program's way of saying to the recipient “I am sending you this file as-is, you figure out what to do with it”.

---

This *application/octet-stream* type is also very often used for transmitting executable files (programs) especially on Windows systems. Unfortunately, while convenient, this can be a serious security hazard. In recent years, the Internet has been subject to a steady stream of viruses and worms that spread by sending themselves to other users through executable file attachments in e-mail. This makes opening and running any unknown *application/octet-stream* attachment potentially dangerous.

## **MIME Composite Media Types: Multipart and Encapsulated Message Structures**

MIME **discrete media types** allow MIME to represent hundreds of different kinds of data in e-mail messages. This alone would make MIME an incredibly useful technology, but the MIME standard goes one step further, by defining *composite* media types. These allow MIME to perform even more “spectacular feats”, such as sending many types of data at once, or encapsulating other messages or information into e-mail.

The use of a MIME composite media type is indicated via the *Content-Type* header of an RFC 822 message. Instead of one of the six discrete media types (*text*, *image*, *audio*, *video*, *model* and *application*), one of these two composite media types is used:

- ☛ **Multipart Media Type (*multipart*):** Allows one or more sets of data to be sent in a single MIME message. Each piece of data is represented as an individual discrete media type.
- ☛ **Message Media Type (*message*):** Allows a message to encapsulate another message. This may be another e-mail message previously sent, or a message of some other kind. This media type also provides flexibility for sending partial messages and other special types of communication.

**Key Concept:** There are two MIME composite media types: *message*, which allows one message to encapsulate another, and *multipart*, which allows multiple individual media types to be encoded into a single e-mail message.

---

## ***MIME Multipart Message Type***

The *multipart* media type is the more common of the two, and for good reason: it is an ***incredibly*** powerful mechanism. It allows one message to contain many different kinds of information that can be used in different ways. Each piece of data is encoded separately as a MIME *body part* and the parts are combined into a single e-mail message. How these parts are used depends on the semantics of the message, which is indicated by the MIME subtype. RFC 2046 describes several of these, and a few new ones have also been defined by the IANA registration scheme described in the previous topic.

## **MIME Multipart Message Subtypes**

The following are the most common multipart media subtypes, and how they are used. The first four are defined in RFC 2046, and the others as indicated:

- 
- ☉ ***multipart/mixed***: Indicates that the body parts are not really related, but have just been bundled for transport in a single message for convenience. For example, this might be used by someone to send an office memo along with a vacation snapshot just for fun. This subtype is also used sometimes when the parts are related but the relationship is communicated to the recipient in some other way (such as a description in a distinct body part).
  - ☉ ***multipart/alternative***: Specifies that the body parts are alternative representations of the same information. The recipient decodes the parts and chooses the one that is best suited to his or her needs. A common use of this is in sending [HTML](#)-encoded e-mail. Some e-mail clients can't display HTML, so it is courteous to send a *multipart/alternative* message containing the message in both HTML and plain text forms.

The alternatives should be placed in the message in increasing order of preference, meaning that the preferred format goes last. In the case of a document that includes plain text and rich text alternatives—such as the example above with plain text and HTML versions of a document—the plainest format should go first and the “fanciest” last.

- ☉ ***multipart/parallel***: Tells the recipient that the body parts should all be displayed at the same time (“in parallel”). One example of how this might be used would be if someone sent an audio clip along with explanatory text to be displayed alongside it as it played.
- ☉ ***multipart/digest***: This is used to allow a message to carry a digest, such as a collection of other e-mail messages.
- ☉ ***multipart/related***: Indicates specifically that the body parts are related to each other. Special parameters are used to provide more information on how they are to be interpreted. This subtype was defined in RFC 2387.
- ☉ ***multipart/encrypted***: Used for encrypted data. The first body part contains information on how the data is to be decrypted, and the second contains the data itself. This subtype was defined in RFC 1847.

## Multipart Message Encoding

You can see just from these different subtypes how much flexibility the *multipart* type provides to MIME, and there are others. In all cases, the same syntax is used to encode the constituent body parts into a single message. The basic process is as follows:

1. Each individual piece of data is processed as if it were to be transmitted as the body of a discrete media type MIME message. This includes the specification of appropriate headers, such as *Content-Type*, *Content-ID* and *Content-Transfer-Encoding*, as needed.
2. A special *boundary delimiter* is chosen to separate the body parts. It must be selected so that it will not appear in any of the body parts; a random string is sometimes used. It is prepended with two dashes (“--”) when placed in the message to reduce the chance of it being mistaken for data.
3. The multipart message is assembled. It consists of a *preamble* text area, then a boundary line, followed by the first body part. Each subsequent body part is separated from the previous one with another boundary line. After the last body part, another boundary line appears, followed by an *epilogue* text area.

- 
4. The special parameter *boundary* is included in the *Content-Type* header of the message as a whole, to tell the recipient what pattern separates the body parts.

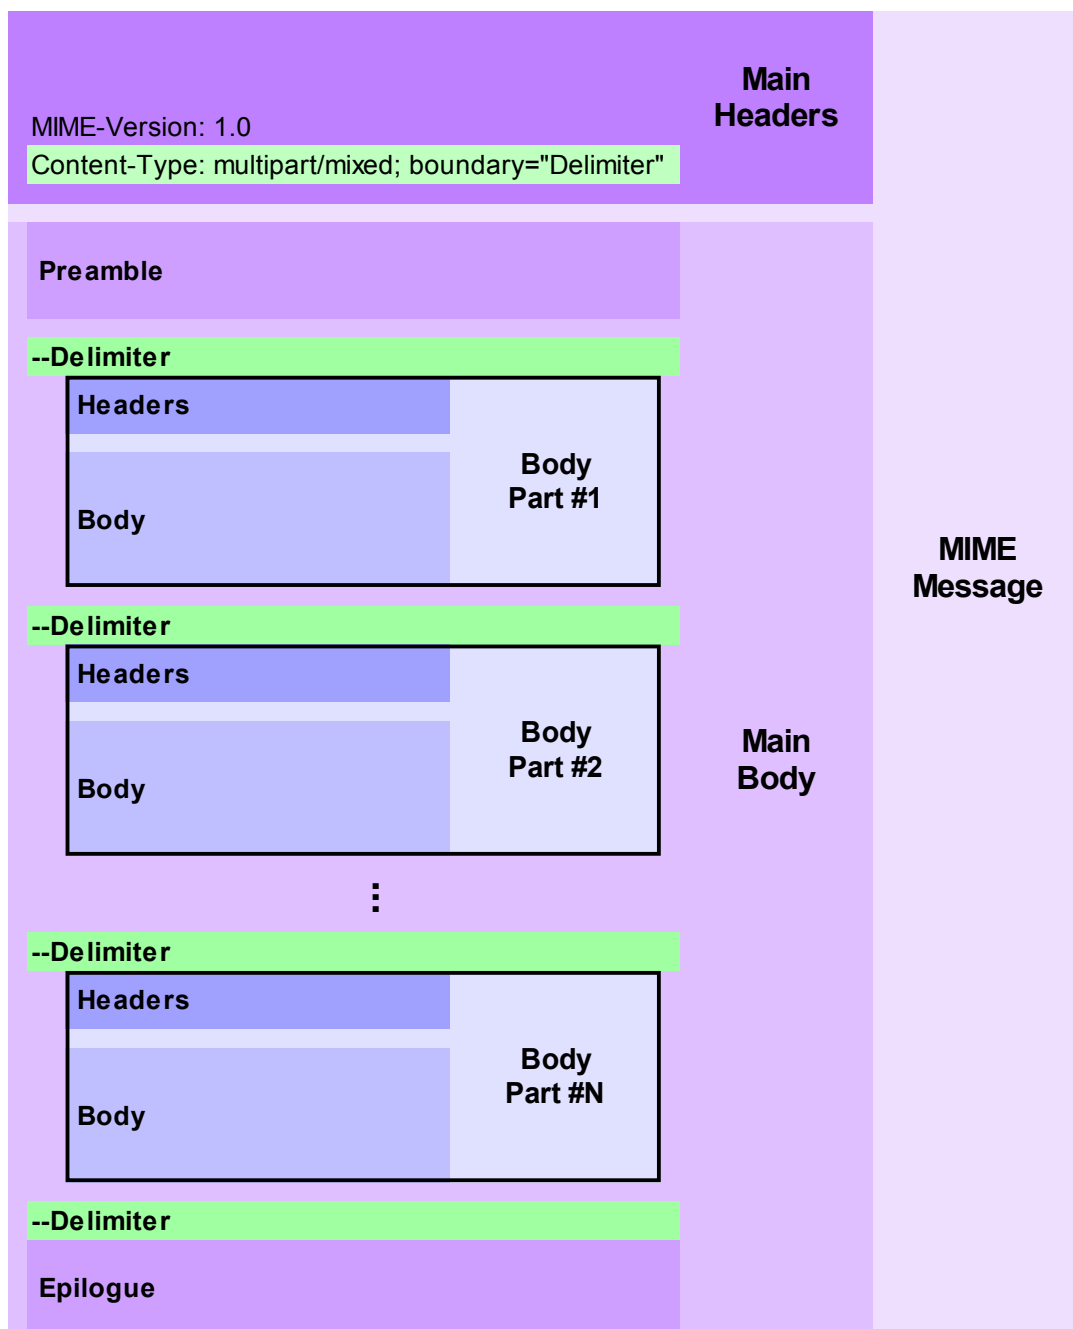

**Key Concept:** MIME multipart messages are formed by first processing each individual data component to create a MIME *body part*. Each can have a distinct encoding method and set of headers, as if it were a separate MIME message. These body parts are then combined into a single multipart message, and separated with a *boundary delimiter*. The identity of the delimiter is inserted into the *boundary* parameter of the *Content-Type* header, so the recipient can easily separate the individual body parts upon receipt of the message.

---

### Multipart Message Structure

These rules seem rather complicated, but they really aren't that bad; once you've seen a couple of multipart messages the structure will make sense. To help clarify, I have provided [Figure 302](#), which shows graphically the overall structure of a multipart MIME message.

**Figure 302: MIME Multipart Message Structure**

A MIME multipart message consists of a set of main headers and a main body portion, like all messages. Within the main body are one or more body parts, each of which has its own body-part-specific headers followed by the body part itself; each body part is shown in blue. The *Content-Type* header of the message as a whole (highlighted in green) indicates that the message type is multipart, and the *boundary* parameter specifies the name of the delimiter, in this case just called “Delimiter” (how boring.) This delimiter is used to separate the body parts from each other and from the preamble and epilogue that begin and end the message body, respectively.

---

## Example Multipart Message

Table 249 contains a specific example of a multipart message (with portions abbreviated to keep length down), so you can see what one looks like in text form. (If you want to see more, you probably have several in your own e-mail inbox right now!)

**Table 249: Example MIME Multipart Message**

```
From: Joe Sender <joe@someplace.org>
To: Jane Receiver <jane@somewhereelse.com>
Date: Sun, 1 Jun 2003 13:28:19 -0800
Subject: Photo and discussion
MIME-Version: 1.0
Content-Type: multipart/mixed; boundary="exampledelimtext123"

This is a multipart message in MIME format

--exampledelimtext123
Content-Type: text/plain

Jane, here is the photo you wanted me for the new client.
Here are some notes on how it was processed.
(Blah blah blah...)
Talk to you soon,
Joe.

--exampledelimtext123

Content-Type: image/jpeg; name="clientphoto.jpg"
Content-Transfer-Encoding: base64

SDc9Pjv/2wBDAQoLCw4NDhwQEBw7KCIoOzs7Ozs7Ozs
...
zv/wAARCADIARoDASIAAhEBAxEB/8QAHAAAAQUBA

--exampledelimtext123

(Epilogue)
```

In this example, Joe is sending Jane a multipart message containing a JPEG photograph and some explanatory text. The main header of the message specifies the *multipart/mixed* type and a boundary string of “exampledelimtext123”. The message begins with the *preamble*, which is ignored by the recipient e-mail client but can be seen by the human reader. It is common to put a string here such as the one given in this example. That way, if a person using a client that does not support MIME receives the message, the recipient will know what it is.

---

The first delimiter string is then placed in the message, followed by the first body part, the text Joe is sending Jane. This is preceded by whatever headers are needed by the body part, in this case *Content-Type: text/plain*. (Note, however, that this is the default in MIME, so it could be omitted here.) After the text message is another delimiter and then the encoded JPEG photo in the second body part, with its own headers. Finally, one more delimiter and then a space for the *epilogue*. This is ignored if present, and is often not used at all.

It is possible to send a “multipart” message that has only a single body part. This is sometimes done to take advantage of the preamble area to provide information about how to decode a non-text media type. Of course, this can also be done by including such text decoding instructions as a body part.

### ***MIME Encapsulated Message Type***

The other composite media type is the *message* type, which is devoted to the special purpose of encapsulating existing e-mail messages within the body of a new message, or for encapsulating other types of messages. The following are the subtypes defined in RFC 2046:

- ☉ ***message/rfc822***: Indicates that the body contains an encapsulated e-mail itself formatted according to the RFC 822 standard. Note that this doesn't necessarily mean it is a plain text e-mail message; it could be a MIME message (though encapsulating MIME within MIME must be done carefully...)
- ☉ ***message/partial***: Used to allow the fragmentation of larger messages into pieces that can later be reassembled. This is described in detail in RFC 2046.
- ☉ ***message/external-body***: Indicates that the body of the message is not actually contained in the message itself; instead, a reference is provided to where the actual body is located. Sufficient information to locate the real message body must be provided. Again, this “out of body experience” is described in RFC 2046. (Sorry, couldn't resist! ☺)

### **MIME Content-Transfer-Encoding Header and Encoding Methods**

One of the main reasons why MIME was created was the [significant restrictions](#) that the RFC 822 standard places on how data in e-mail messages must be formatted. To follow the rules, messages must be encoded in US ASCII, a 7-bit data representation. This means that even though each byte can theoretically have any of 256 values, in ASCII only 128 values are valid. Furthermore, lines can be no longer than 1000 characters including the carriage return and line feed (“CRLF”) characters at the end, and those two characters cannot appear elsewhere.

For some types of data, such as text files, this is no big deal, but for others it is a serious problem. This is especially the case with binary data. If you look at the data in a video clip or MP3 file or executable program, it will appear to be “random gibberish”. In fact, such data is not random but is represented using specific rules, but the data is expressed in raw binary

---

form, where any 8-bit byte can contain any value from 0 to 255, which is why it looks like “junk” to humans. More importantly, this means that this data does not follow the rules for RFC 822 files and cannot be sent directly in this form.

## **MIME Encoding Methods**

To send non-ASCII data in MIME, it is necessary that it be encoded. The *Content-Transfer-Encoding* header is used to specify how a MIME message or body part has been encoded, so that it can be decoded by its recipient. The following types of encoding are defined:

- ☉ **7bit:** This indicates that the message is already in ASCII form compatible with RFC 822. It is the default and is what is assumed if no *Content-Transfer-Encoding* header is present.
- ☉ **8bit / binary:** These synonymous values mean the message has been encoded directly in 8-bit binary form. Yes, I did just say that this would violate the rules of RFC 822. These options appear to have been included to support future mechanisms for transporting binary data directly. RFC 1652 describes an SMTP extension that discusses this in part: *SMTP Service Extension for 8bit-MIMEtransport* (sic, there is no space between “MIME” and “transport”). However, the standard is clear that this still does not allow the transfer of raw binary data using SMTP and RFC 822.
- ☉ **quoted-printable:** This is a special encoding that is used when most of the data is ASCII text, but when it contains certain violations of the rules of RFC 822. These illegal sections are converted using special encoding rules so the data as a whole is consistent with RFC 822.
- ☉ **base64:** An encoding used to allow arbitrary binary data to be represented in ASCII form. The data is then sent as ASCII and decoded back into binary form by the recipient.

The *quoted-printable* and *base64* encodings are the most interesting ones, because they are what allow non-RFC-822 data to be sent using RFC 822.

**Key Concept:** MIME supports four encoding methods: *7bit*, *8bit (binary)*, *quoted-printable* and *base64*. *7bit* encoding is standard ASCII and is used for text; *quoted-printable* encoding is for output that is mostly text but has some special characters that must be encoded; *base64* is used for arbitrary binary files. (The *8bit* encoding method is defined in MIME but not used for RFC 822 messages.)

---

## ***quoted-printable* Encoding**

This encoding method is used when the message is “mostly” ASCII; only the problem bytes are encoded. The result is that RFC 822 compatibility is achieved while maintaining most of the data as regular text so it can still be easily understood by a human.

An example of where this would be letters with tildes or accents, such as those used in French or Spanish. Another would be a text message formed using an editor that inserts carriage return characters in the middle of a line. Most of the message is still text. The

---

*quoted-printable* encoding can be used here, with the carriage return characters represented as “=0D” (the hexadecimal value of the character prepended by an equal sign). RFC 2046 contains more details on how this is done.

### **base64 Encoding**

In contrast, the *base64* encoding is more often used for raw binary data that is not in human-readable form anyway, such as graphical images, audio, video and application files. The idea behind it is simple: the data that needs to be sent can have any value for each 8-bit byte, which is not allowed. So, why not rearrange the bits so the data “fits” into the 7-bit ASCII limits of RFC 822?

This is done by processing the data to be sent three bytes at a time. There are 24 bits in each three-byte block, which are carved into 4 sets of 6 bits each. Each 6-bit group has a value from 0 to 63, and is represented by a single ASCII character as presented in [Table 250](#).

**Table 250: MIME Base64 Encoding Groups**

6-bit Value	Encoding	6-bit Value	Encoding	6-bit Value	Encoding	6-bit Value	Encoding
0	A	16	Q	32	g	48	w
1	B	17	R	33	h	49	x
2	C	18	S	34	i	50	y
3	D	19	T	35	j	51	z
4	E	20	U	36	k	52	0
5	F	21	V	37	l	53	1
6	G	22	W	38	m	54	2
7	H	23	X	39	n	55	3
8	I	24	Y	40	o	56	4
9	J	25	Z	41	p	57	5
10	K	26	a	42	q	58	6
11	L	27	b	43	r	59	7
12	M	28	c	44	s	60	8
13	N	29	d	45	t	61	9
14	O	30	e	46	u	62	+
15	P	31	f	47	v	63	/

For example, suppose the first three bytes of the data to be sent were the decimal values 212, 39 and 247. These cannot all be expressed in 7-bit ASCII. In binary form they are:

11010100 00100111 11110111

---

We can divide these into four 6-bit groups:

110101 - 00 0010 - 0111 11 - 110111

Which yields the four values 53, 2, 31 and 55. Thus, the values 214, 39 and 247 would be encoded as the three ASCII characters “1Cf3”. The conceptual steps of this process are shown in [Figure 303](#).

Data Bytes in Decimal Form	212		39		247	
Data Bytes In Binary Form	11010100		00100111		11110111	
Data Rearranged Into 6-Bit Groups	110101	000010		011111	110111	
6-Bit Groups In Decimal Form	53	2		31	55	
Groups Converted To ASCII Characters	1	C		f	3	

**Figure 303: MIME Base64 Encoding**

In this simplified example, three binary data bytes are encoded as four ASCII characters using MIME base64 encoding. Instead of transmitting those three bytes, two of which would not be valid in RFC 822, the four ASCII characters “1Cf3” are sent.

**Note:** The sequence of steps for the encoding that I mentioned above and showed in the figure are intended to help you understand the process. Computers inherently deal directly with bits, and so would not bother with converting to decimal before encoding the 6-bit groups into ASCII characters.

This 3-to-4 encoding is done for all the data. The converted ASCII characters are then placed into the body of the entity instead of the raw binary data, 76 characters to a line. I showed how this is done in the second body part in the example of [Table 249](#) (except I didn't put 76 characters per line, to keep the line lengths short). One final character is involved in this scheme, the equal sign (“=”), which is used as a padding character when needed.

Since base64 characters are regular ASCII, they appear to SMTP like a “regular text message”. Of course the data looks like gibberish to us, but that's not a problem since it will be converted back to its regular form and displayed to the recipient as an image, movie, audio or whatever.

**Key Concept:** MIME uses *base64* encoding to transform arbitrary 8-bit files into a form that is acceptable for communication in e-mail. Each set of three 8-bit bytes is divided into four 6-bit groups, and each 6-bit group represented by an ASCII character. Since the data is ASCII, it conforms to the RFC 822 message format standard, even if it is not human-readable. The receiving device reverses the encoding, changing each four-character block back into three 8-bit bytes.

---

The main drawback of the base64 method? It is about 33% less efficient than sending binary data directly, using something like FTP. The reason is that three 8-bit bytes of binary data are sent as four ASCII characters, but of course, each ASCII character is represented using 8 bits itself. So there is 1/3 extra overhead when using base64. In most cases this is not a big deal, but it can be significant if downloading very large e-mail files over a slow Internet connection.

Note that RFC 2046 also defines two other encodings: *ietf-token* and *x-token*. These are included to allow new encoding types to be defined in the future.

### **MIME Extension for Non-ASCII Mail Message Headers**

All of the MIME mechanisms discussed in this section up to this point deal with ways of encoding different kinds of ASCII and non-ASCII data into the **body** of an RFC 822 message. In addition to these capabilities, MIME also includes a way in which non-ASCII data can be encoded into **headers** of an RFC 822 message.

#### ***The Need for MIME-Encoded Headers***

At this point you might be wondering why anyone would want to do this. Sure, it makes sense to be able to use MIME to encode binary data such as an image into an e-mail, but why do it in a header? Well, if you can't see the need for this, chances are that you are a native English speaker. ☺ ASCII does a great job of representing English, but isn't so hot with many other languages. With RFC 822, the speakers of languages that use non-ASCII characters were unable to fully use descriptive headers such as the *Subject* and *Comments* headers. Some could not even properly express their own names!

The solution to this problem is the subject of RFC 2047, the third of the five main MIME standards. It describes how to encode non-ASCII text into ASCII RFC 822 message headers. The idea is straight-forward: just as with message bodies, the non-ASCII text is replaced with ASCII, and information is provided to describe how this was done.

#### ***MIME Encoded-Word Syntax***

In the MIME non-ASCII header technique, the value of a regular header is replaced by a MIME *encoded-word* that has the following syntax:

=?<charset>?<encoding>?<encoded-text>?<encoding>?<charset>=

---

The strings “=?” and “?” are used to *bracket* the non-ASCII header, which flags it as a MIME encoded header to the recipient's e-mail client. The other elements, separated by “?”, indicate how the non-ASCII text is encoded:

- ☉ **<charset>**: The character set used, such as “iso-8859-1”.
- ☉ **<encoding>**: Two different encoding types are defined, each represented by a single letter for brevity:
  - ☉ **“B”**: This indicates *base64* encoding, as described in [the previous topic](#).
  - ☉ **“Q”**: This indicates *quoted-printable* encoding, again as in [the prior discussion](#).
- ☉ **<encoded-text>**: The non-ASCII text that has been encoded as ASCII using the encoding type indicated.

As you can see, this method is analogous to how a non-ASCII message body or body part would be encoded, but the information about the encoding has been condensed so everything can fit in a single header line. The “<charset>” parameter is somewhat analogous to the *Content-Type* header for a message body, but since headers can only contain text, it specifies what kind of text it is. The “<encoding>” parameter is clearly equivalent to the *Content-Transfer-Encoding* header.

### **Example Non-ASCII MIME Header**

Here's an example of a non-ASCII header, using the GB2312 character set (for Chinese characters) and base64 encoding:

Subject: =?GB2312?B?u7bTrbLOvNPDwLn61bm74Q==?=

I hope that doesn't say anything inappropriate; I took it from a piece of spam e-mail I received once! ☺

**Key Concept:** In addition to its many functions for encoding a variety of data in e-mail message bodies, MIME provides a feature that allows non-ASCII information to be placed into e-mail headers. This is done by encoding the data using either *quoted-printable* or *base64* encoding, and then using a special format for the header value that specifies its encoding and character set. This technique is especially useful for e-mail sent in languages that cannot be represented easily in standard ASCII, such as many Asian languages.

---

---

## **TCP/IP Electronic Mail Delivery Protocol: The Simple Mail Transfer Protocol (SMTP)**

I have emphasized in my [overall description of TCP/IP electronic mail](#) that communication using e-mail requires the interaction of various protocols and elements. One mistake that some people make is to equate the method used for delivering e-mail with the entire system. This is, however, an understandable mistake: just as the postal service is only a part of the whole system of mailing a letter; it is nonetheless a very **big** part. Likewise, the delivery of e-mail from sender to recipient is arguably the most important part of e-mail as a whole. In modern TCP/IP, this task is the responsibility of the *Simple Mail Transfer Protocol (SMTP)*.

In this section, I describe in detail the operation of the Simple Mail Transfer Protocol (SMTP). I begin with an overview and history of SMTP and a discussion of the standards that define it. I then examine the way that SMTP client/server communication and message transport works. I explain the way that SMTP servers establish connections and transaction sessions, and then the process by which mail is transferred from one to another. I describe some of the special features implemented in SMTP, and discuss SMTP security issues as well. I conclude with a reference summary of SMTP commands and replies.

**Background Information:** My discussion of SMTP assumes that you already have a basic understanding of the [general concepts of TCP/IP e-mail](#), as well as familiarity with TCP/IP [e-mail addressing](#) and [message formatting](#).

---

### **SMTP Overview, History and Standards**

The [overview and history of the TCP/IP electronic mail system](#) describes how TCP/IP evolved from its early beginnings to its current form. Since the mechanism used to deliver e-mail is such a big part of the system as a whole, any overview of the system must of necessity discuss how delivery mechanisms have changed as well. In the case of TCP/IP, I explained how the delivery of mail evolved through many forms during the 1970s as developers sought to find effective ways of communicating e-mail messages between systems. Most of these efforts involved attempts to transmit mail using existing protocols; this makes sense, since it is easier to adapt a technology than design one from scratch.

#### ***Early SMTP History***

One important achievement was the publishing of the *Mail Transfer Protocol (MTP)*, which was first defined in RFC 772 in September 1980, then updated in RFC 780 in May 1981. MTP describes a set of commands and procedures by which two devices can connect using TCP to exchange e-mail messages. Its operation is described largely using elements borrowed from two early TCP/IP application protocols that were already in use at that time: [Telnet](#) and [FTP](#). The commands of MTP are in fact based directly on those of FTP.

---

There wasn't anything inherently wrong with basing e-mail delivery on something like FTP, but defining it this way made MTP somewhat of a “hack”. It was also restricted to the capabilities defined by FTP, a general file transfer protocol, so it was not possible to include features in the protocol that were specific to sending and receiving mail. Due to the importance of e-mail, a specific protocol designed for the purpose of delivering e-mail was warranted. This protocol was first defined in RFC 788, published in November 1981: the *Simple Mail Transfer Protocol (SMTP)*.

The name suggests that SMTP is “simpler” than the “non-simple” MTP that it replaced. Whether this is true or not is somewhat a matter of opinion; I do note that RFC 788 is 61 pages long, while the earlier RFC 780 was only 43 pages. What SMTP definitely has over MTP is **elegance**; the protocol is designed specifically for the transport of electronic mail. While it retains certain similarities to FTP, it is an “independent” protocol running over TCP. So, from a conceptual standpoint, it can be considered simpler than MTP. In terms of mechanics, the process SMTP uses to transfer an e-mail message is indeed rather simple, especially compared to some other protocols.

RFC 788 described the operation of SMTP carrying e-mail messages corresponding to the ARPAnet text message standard as described in RFC 733. Development of both e-mail messages and the SMTP protocol continued, of course. In August 1982, a milestone in TCP/IP e-mail was achieved when RFCs 821 and 822 were published. RFC 821 revised SMTP, and became the defining standard for the protocol for the next two decades. RFC 822, its companion standard, became [the standard for TCP/IP electronic mail messages](#) carried by SMTP.

**Key Concept:** The most important component of the TCP/IP electronic mail system is the *Simple Mail Transfer Protocol (SMTP)*. SMTP was derived from the earlier Mail Transfer Protocol (MTP), and is the mechanism used for the delivery of mail between TCP/IP systems and users. The only part of the e-mail system for which SMTP is not used is the final retrieval step by an e-mail recipient.

---

## ***SMTP Extensions and Revisions***

As the 1980s progressed and TCP/IP and the Internet both grew in popularity, SMTP gradually overtook other methods to become the dominant method of e-mail message delivery. For a number of years, the protocol was used mostly “as is”, with no new RFCs published to define new versions or formally change its behavior.

This changed in February 1993, when RFC 1425, *SMTP Service Extensions*, was published. As the name suggests, this standard describes a process for adding new capabilities to extend how SMTP works, while maintaining backward-compatibility with existing systems. SMTP with these extensions is sometimes called *Extended SMTP* or *ESMTP* (though use of this term seems to be not entirely universal). As development of

---

SMTP continued, RFC 1425 was revised in RFC 1651 in July 1994 and then RFC 1869 in November 1995. Along with these, a number of other RFCs defining particular SMTP extensions such as pipelining and message size declaration were defined.

In April 2001, another major milestone in TCP/IP e-mail was reached when revisions of RFC 821 and RFC 822 were published, as RFCs 2821 and 2822 respectively. Both documents are “consolidations” of updates and changes that had been made to RFCs 821 and 822 between 1982 and 2001. And no, I don't think it is a coincidence that the old and new RFC numbers are exactly “2000” apart. RFCs 2820 and 2823 were both published in May 2000, so it looks like 2821 and 2822 were reserved for the e-mail standards. I think this was a great idea, as it makes more clear that the new RFCs are revisions of the old ones.

RFC 2821 is the current base standard for SMTP. It incorporates the base protocol description from RFC 821, and the latest SMTP extensions as defined in RFC 1869. Perhaps more importantly, it updates the description of the e-mail communication model to reflect the realities of modern TCP/IP networks, especially the e-mail features built into the Domain Name System (DNS). We'll examine this in more detail in the next topic.

## **SMTP Communication and Message Transport Methods, Client/Server Roles and Terminology**

The TCP/IP [electronic mail communication model](#) describes the way e-mail messages are conveyed from the sender to the recipient. In most cases, this involves the sender's client machine sending the e-mail to its local SMTP server, which in turn sends it to the recipient's local SMTP server, and finally to the recipient's local host. All of these steps except for the last one are performed by SMTP. In fact, the overall e-mail communication model is largely described by the RFC 821 and 2821 SMTP standards.

The initial communication takes place between the sender's client machine and a local SMTP server that the sender is allowed to access. After submission of the e-mail message, that SMTP server becomes responsible for delivering the message to the SMTP server responsible for the recipient's mailbox. There are two different ways that this can happen.

### ***Early E-Mail Communication Using Relaying***

In the first years of electronic mail, when RFC 821 and its predecessors were initially defined, the Internet was very different than it is today. There was no [Domain Name System](#), and this made electronic mail delivery complex, because there was no way to map a mailbox address to the IP address of the SMTP server that managed that mailbox. Also, there were many proprietary networks connected to the Internet, which meant that it was not always possible for any given system to communicate with any other.

Given this, how could e-mail be delivered? The most common way in the early days of SMTP was through a process called *relaying*. SMTP routing information was included along with the e-mail address, to specify a sequence of SMTP servers that the mail should be relayed through to get to its destination. For example, if a sender using SMTP server A wanted to send e-mail to someone whose mailbox was on SMTP server Z, they might have needed to specify that the mail be sent through intermediate SMTP servers at sites D, P

---

and U to get there. An SMTP connection would be established from A to D to send the message on one leg of its journey; then it would go from D to P, P to U and then U to Z. The process is analogous to [how IP routing](#) works, but at the application layer (actually using IP routing at a lower level, of course.)

You can probably see the problems with this quite easily: it's cumbersome, requires many devices to “handle” the mail, results in delays in communication, and also requires the communication of source routes between SMTP servers. It was certainly functional, but far from ideal.

### ***Modern E-Mail Communication Using DNS and Direct Delivery***

The creation of DNS radically changed how e-mail delivery worked. DNS includes support for a special *mail exchanger (MX)* record that allows easy mapping from the domain name in an e-mail address to the IP address of the SMTP server that handles mail for that domain. I explain this in [the topic on the regular e-mail address format](#), as well as [the dedicated topic on DNS e-mail support](#).

In the new system, SMTP communication is much simpler and more direct. The sending SMTP server uses DNS to find the [MX record](#) of the domain to which the e-mail is addressed. This gives the sender the DNS name of the recipient's SMTP server. This is resolved to an IP address, and a connection can be made directly from the sender's SMTP server to the recipient's to deliver the e-mail. While SMTP still supports relaying, direct e-mail delivery using MX records is faster and more efficient, and RFC 2821 makes clear that this is now the preferred method.

In this new system, SMTP is generally only used for two transfers: first, from the sender's client machine to the sender's local SMTP server, and then from that server to the recipient's local SMTP server, as shown in [Figure 301](#). (A distinct [mail access protocol or method](#) is used by the recipient for the last leg of the journey.) Each transfer of an e-mail message between SMTP servers involves the establishment of a TCP connection and then the transfer of the e-mail headers and body using the SMTP mail transfer process. The next two topics describe in detail how this occurs.

**Key Concept:** In the early days of SMTP, mail was delivered using the relatively inefficient process of relaying from server to server across the internetwork. Today, when an SMTP server has mail to deliver to a user, it determines the server that handles the user's mail using the Domain Name System (DNS) and sends the mail to that server directly.

---

### ***SMTP Terminology: Client/Server and Sender/Receiver***

The original RFC 821 standard referred to the device that initiates an SMTP e-mail transfer as the *sender* and the one that responds to it as the *receiver*. These terms were changed to *client* and *server* in RFC 2821 to “reflect current industry terminology”. Strictly speaking, this is correct, but in some ways the more current terminology is significantly **less** clear.

---

As I explained in the [general discussion of TCP/IP client/server operation](#), the terms “client” and “server” are used in many different sense in networking, and this often leads to confusion. In common parlance, the computers that handle e-mail on the Internet are usually all called *SMTP servers*. This is for two reasons. First, they run SMTP server software to provide SMTP services to client machines, such as end-user PCs. Second, these devices are usually dedicated hardware servers running in network centers, typically managed by Internet Service Providers.

However, the terms “client” and “server” are now used to refer to the roles in a particular SMTP communication as well. Since all SMTP servers both send and receive e-mail, they all act as both clients and servers transactionally at different times. An SMTP server that is relaying an e-mail will act as both for that message, receiving it as a server and then sending it to the next server as a client.

Adding to this potential confusion is the fact that the initial stage in sending an e-mail is from the sender's client machine to the sender's local SMTP server. Thus, the client role in an SMTP transaction may not be an actual SMTP server, but the server role will always be a server.

Confused yet? ☺ Me too. For all of these reasons, the old terms “sender” and “receiver” are still used in places in RFC 2821, where needed for clarity. I consider them much more straight-forward and use them in the topics that follow.

**Key Concept:** SMTP servers both send and receive e-mail; the device sending mail acts as a client for that transaction; the one receiving it acts as a server. To avoid confusion, it is easier to refer to the device sending e-mail as the *SMTP sender* and the one receiving as the *SMTP receiver*; these were the terms used when SMTP was originally created.

---

## **SMTP Connection and Session Establishment and Termination**

The delivery of electronic mail using the Simple Mail Transfer Protocol (SMTP) involves the regular exchange of e-mail messages between SMTP servers. SMTP servers are responsible for sending e-mail that users of the server submit for delivery. They also receive e-mail either intended for local recipients, or in some cases for forwarding or relaying to other servers.

### ***Overview of Connection Establishment and Termination***

All SMTP communication is done using the [TCP](#). This allows SMTP servers to make use of TCP's many features that ensure efficient and reliable communication. SMTP servers generally must be kept running and connected to the Internet 24 hours a day, seven days a week, to ensure that mail can be delivered at any time. (This is a big reason why most end-

---

users employ access protocols such as [POP3](#) to access their received e-mail rather than running their own SMTP servers.) The server listens continuously on the SMTP server port, [well-known port](#) number 25, for any TCP connection requests from other SMTP servers.

As explained in [the previous topic](#), an SMTP server that wishes to send e-mail normally begins with a [DNS lookup](#) of the [MX record](#) corresponding to the domain name of the intended recipient's e-mail address, to get the name of the appropriate SMTP server. This name is then resolved to an IP address; for efficiency, this IP address is often included as an *Additional* record in the response to the MX request, to save the sending server from needing to perform two explicit DNS resolutions.

The SMTP sender then *establishes* a SMTP session with the SMTP receiver. Once the session is established, *mail transactions* can be performed, to allow mail to be sent between the devices. When the SMTP sender is done, it *terminates* the connection. All of these processes involve specific exchanges of commands and replies, which are illustrated in [Figure 304](#).

### ***Connection Establishment and Greeting Exchange***

Let's take a look at these processes in more detail, starting of course with SMTP session establishment. The SMTP sender begins by initiating a TCP connection to the SMTP receiver. The sending SMTP server uses an [ephemeral port number](#), since it is playing the role of the client in the transaction. Assuming that the server is willing to accept a connection, it will indicate that it is ready to receive instructions from the client by sending [reply code 220](#). This is called the "greeting" or "service ready" response. It commonly includes the full domain name of the server machine, the version of the SMTP server software it is running, and possibly other information.

Now, it would be rude for the server acting as a client to just start sending commands to the responding server without saying hello first, wouldn't it? So that's exactly what comes next: the client says "hello". In the original SMTP protocol, this is done by issuing a *HELO* command, which includes the domain name of the sending (client) SMTP server as a courtesy. The receiving device then responds back with a return "hello" message using an SMTP reply code 250.

For example, if the SMTP server "smtp.sendersite.org" was making a connection to the SMTP server "mail.receiversplace.com", it would say:

HELO smtp.sendersite.org

After receiving this, "mail.receiversplace.com" would respond back with a "hello" message of its own, something like this:

250 mail.receiversplace.com Hello smtp.sendersite.org, nice to meet you.

**Figure 304: SMTP Transaction Session Establishment and Termination**

An SMTP session begins with the SMTP sender establishing a TCP connection to the SMTP receiver. The receiver sends a ready message; the sender sends a *HELO* or *EHLO* command, to which the receiver responds. Assuming no difficulties, the session is established and mail transactions take place. When the sender is done, it sends a *QUIT* command; the receiver responds with a 221 reply and closes the session.

The “chatty” text is of course purely optional; most of the time SMTP communication is between software programs, so all the pleasantries are mostly just programmers having a sense of humor. Still, isn't such politeness a pleasant thing to see in this sometimes difficult world of ours? ☺

### **Connection Establishment Using SMTP Extensions**

The [SMTP extensions](#) defined at first in RFC 1425 and then in subsequent standards up to RFC 2821 define an alternative “hello” message for the client to use: *EHLO* (*extended hello*). An SMTP sender supporting SMTP extensions (and most do) uses *EHLO* instead of *HELO* in response to the 220 greeting. This serves both to say “hello” to the SMTP receiver, and to tell it that the sender supports SMTP extensions.

---

If the SMTP receiver supports the extensions, it replies back with the usual 250 reply, as well as a series of extra 250 responses. Each of these lists an *EHLO keyword* that indicates a particular SMTP extension the receiver supports. If the receiving server doesn't support the extensions, it will reject the *EHLO* command with a 500 reply code ("syntax error, command not recognized"). This tells the SMTP sender that it cannot use extensions; it will then either issue a conventional *HELO* command, or *QUIT* the connection if it requires the SMTP extensions to be present. (In practice, it is rare for a server to **require** the use of SMTP extensions.)

Here's the same example as above, but using EHLO. The sender says:

EHLO smtp.sendersite.org

Assuming "mail.receiversplace.com" supports the SMTP extensions, a typical reply might be:

250-mail.receiversplace.com Hello smtp.sendersite.org, nice to meet you.  
250-SIZE  
250-DSN  
250 PIPELINING

Each of these additional replies identifies a particular SMTP extension supported by "mail.receiversplace.com"; in this case, message size declaration ("SIZE"), delivery status notification ("DSN") and command pipelining. (The dashes after the "250" indicate a [multiple-line response](#) to a command.)

Once the *HELO* or *EHLO* command has been sent and the receiving device has responded, the session is initiated. Further commands can be sent by the sending SMTP server to the responding server. These usually take the form of e-mail message transfer transactions using the process described in [the following topic](#), and other command/reply exchanges as needed.

### **Connection Termination**

When the sending device is finished sending all the e-mail it has to transfer to the receiving device, and done with all other activities, it terminates the session by issuing the *QUIT* command. This normally results in a 221 "goodbye" message from the SMTP receiver, saying something like "closing transmission channel". The TCP connection is then terminated.

A server may also terminate prematurely in special cases. If it is given a local command to shut down (for example, due to imminent rebooting of the hardware server upon which it is running), it may respond to any routine command with a 421 response ("Service not available, closing transmission channel"). A server is not supposed to terminate a session simply due to receipt of an invalid command, however, only in special cases where session termination cannot be avoided.

**Key Concept:** An SMTP session consists of three basic phases. The session is first *established* through the creation of a TCP connection and the exchange of identity information between the SMTP sender and receiver using the *HELO* command.

Once established, *mail transactions* can be performed. When the SMTP sender is done with the session, it *terminates* it using the *QUIT* command. If *SMTP extensions* are supported, the SMTP sender uses the *EHLO* (*extended hello*) command instead of *HELO*, and the SMTP receiver replies with a list of extensions it will allow the SMTP sender to use.

---

## **SMTP Mail Transaction Process**

The delivery of e-mail message begins with the [establishment of an SMTP session](#) between the devices sending and receiving the message. The SMTP sender initiates a TCP connection to the SMTP receiver, and then sends a *HELO* or *EHLO* command, to which the receiver responds. Assuming there are no problems, the session is then established and ready for actual e-mail message transactions.

### ***SMTP Mail Transaction Overview***

The SMTP mail transaction process itself consists of three steps:

1. **Transaction Initiation and Sender Identification:** The SMTP sender tells the SMTP receiver that it wants to start sending a message, and gives the receiver the e-mail address of the message's originator.
2. **Recipient Identification:** The sender tells the receiver the e-mail address(es) of the intended recipients of the message.
3. **Mail Transfer:** The sender transfers the e-mail message to the receiver. This is a complete e-mail message meeting the [RFC 822 specification](#) (which may be in [MIME](#) format as well).

That's it! So you can see that the word "Simple" in "Simple Mail Transfer Protocol" definitely has at least **some** merit. Especially when compared with other protocols that claim to be simple, such as [SNMP](#). ☺

### ***The Rationale for A Separate E-Mail Message and Envelope***

In fact, one question that sometimes comes up when examining SMTP is why couldn't this process be even **simpler**? The first two steps identify the sender of the e-mail and the intended recipient(s). But all of this information is already contained in headers in the message itself. Why doesn't SMTP just read that information from the message, which would in fact make the mail transaction a *one-step* process?

The explanation for this isn't specifically addressed in the SMTP standards, but I believe there are several reasons:

- 
- ☉ Specifying the sender and recipients separately is more efficient, as it gives the SMTP receiver the information it needs “up front” before the message itself is transmitted. In fact, the SMTP receiver can decide whether or not to accept the message based on the source and destination e-mail addresses.
  - ☉ Having this information specified separately gives greater control on how e-mail is distributed. For example, an e-mail message may be addressed to two recipients, but they may be on totally different systems; the SMTP sender might wish to deliver the mail using two separate SMTP sessions to two different SMTP receivers.
  - ☉ In a similar vein, there is the matter of delivering blind carbon copies. Someone who is “BCC'ed” on a message must receive it without being mentioned in the message itself.
  - ☉ Having this information separate makes implementing security on SMTP much easier.

For these reasons, SMTP draws a distinction between the message itself, which it calls the *content*, and the sender and recipient identification, which it calls the *envelope*. This is of course consistent with our running analogy between regular mail and e-mail. Just as the postal service delivers a piece of mail using only the information written on the envelope, SMTP delivers e-mail using the envelope information and not the content of the message. It's not quite the case that the SMTP server doesn't look at the message itself, just that this is not the information it uses to manage delivery.

**Note:** It is possible for the sender of a message to generate envelope information based on the contents of the message, but this is somewhat “external” to SMTP itself. It is described in the standard but caution is urged in exactly how this is implemented.

---

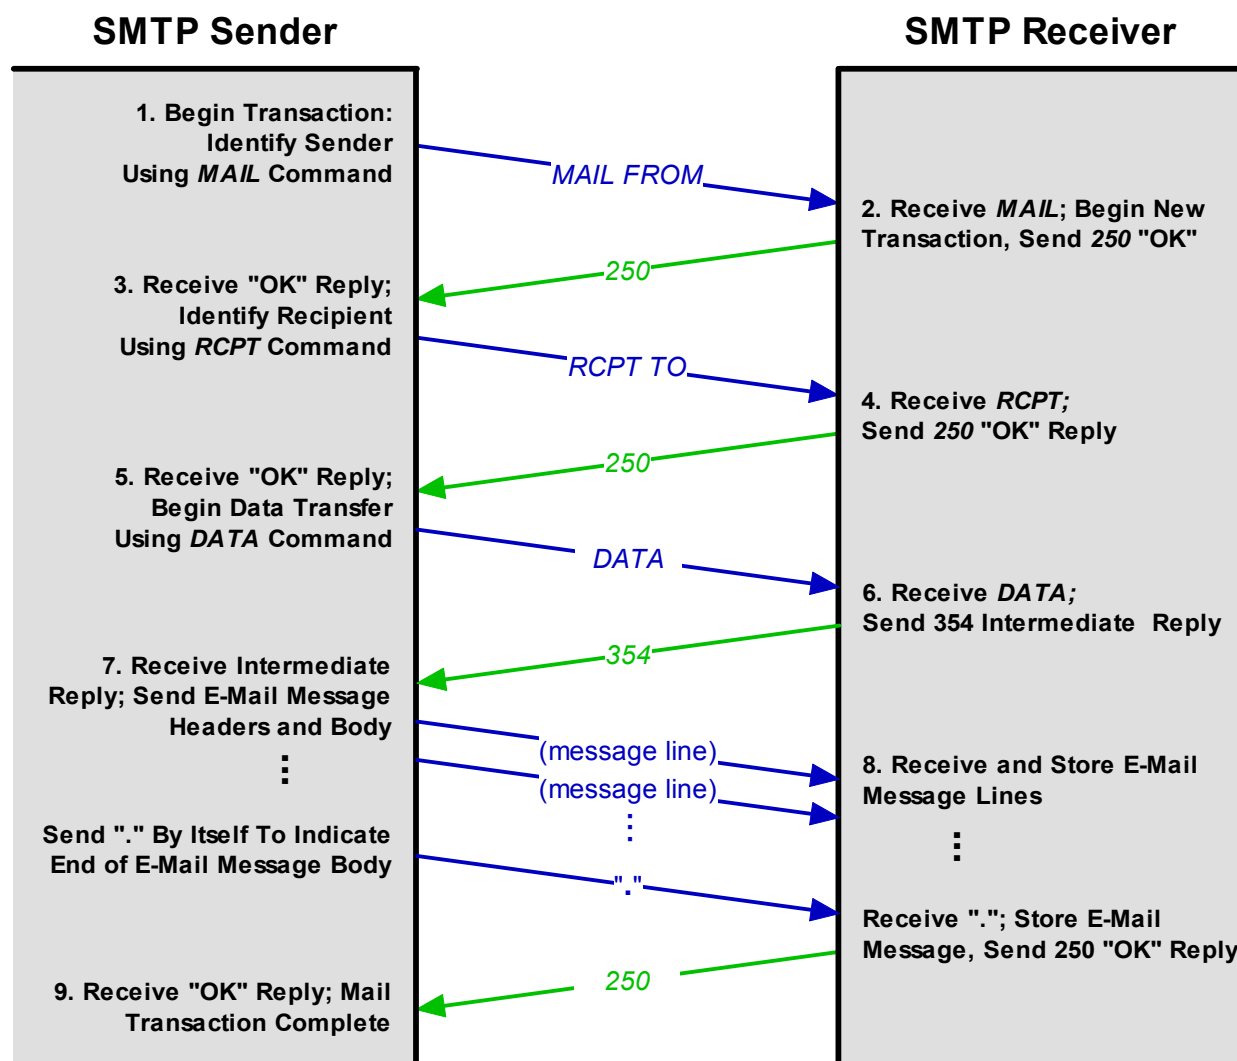

### **SMTP Mail Transaction Details**

Let's take a more detailed look at the SMTP mail transaction process, using as aids the process diagram in [Figure 305](#) and the example transaction of [Table 251](#) (which has commands highlighted in bold and replies in italics). The first two steps in the mail transaction are responsible for providing the receiving SMTP server with the envelope information just discussed. The transaction begins by the SMTP sender issuing a *MAIL* command. This serves to inform the receiver that a new transaction is commencing, and also to tell it the “from” information on the “envelope”. An example:

MAIL FROM:<joe@someplace.org>

The e-mail address of the originator is always enclosed in angle brackets (“<” and “>”). The SMTP receiver acknowledges the command with a *250* (“OK”) reply message, sometimes sending back the address as a confirmation. For example:

250 <joe@someplace.org>... Sender ok

**Figure 305: SMTP Mail Transaction Process**

Once an SMTP session is established between a sender and receiver, each mail transaction consists of a set of three command/reply sequences. The sender is first identified using the *MAIL* command and the recipients are specified using one or more *RCPT* commands. The actual mail message is then transferred using the *DATA* command, which involves a preliminary reply before the actual message is sent, and a completion reply when it has been fully received.

Next, the SMTP sender uses *RCPT* commands to specify the intended recipients of the e-mail that is being sent. Each *RCPT* line can contain only one recipient, so if multiple recipients are indicated, two or more *RCPT* commands must be issued. Each one normally specifies an e-mail address, but if relaying is being used, the command may contain routing information as well. (As described in [the SMTP communication topic](#), this is not as commonly done as it was in the past.) For example:

```
RCPT TO:<jane@somewhereelse.com>
```

---

Assuming the server accepts the e-mail, it will give a 250 “OK” reply again, such as this:

250 <jane@somewhereelse.com>... Recipient ok

The SMTP sender then issues the *DATA* command, which tells the SMTP receiver that the message is coming:

DATA

The SMTP receiver responds with a 354 “intermediate” reply message, such as this:

354 Enter mail, end with “.” on a line by itself

The SMTP sender then sends the e-mail message, one line at a time, with a single “.” on a line to terminate it. The server confirms the receipt of the message with another 250 “OK” reply, and the transaction is done.

**Table 251: Example SMTP Mail Transaction**

```
MAIL FROM:<joe@someplace.org>
250 <joe@someplace.org>... Sender ok
RCPT TO:<jane@somewhereelse.com>
250 <jane@somewhereelse.com>... Recipient ok
DATA
354 Enter mail, end with "." on a line by itself
From: Joe Sender <joe@someplace.org>
To: Jane Receiver <jane@somewhereelse.com>
Date: Sun, 1 Jun 2003 14:17:31 -0800
Subject: Lunch tomorrow

Hey Jane,

It's my turn for lunch tomorrow. I was thinking we could
[rest of message]
Hope you are free. Send me a reply back when you get a chance.
Joe.
.
250 OK
```

**Key Concept:** After an SMTP session is established, e-mail messages are sent using the SMTP *mail transaction process*. The SMTP sender starts the transaction by identifying the sender of the e-mail, and then specifying one or more recipients. The e-mail message itself is then transmitted to the SMTP receiver. Each e-mail to be sent is a separate transaction.

---

---

## **Potential Mail Transaction Complications**

While this indeed is quite simple, I should point out that I have only shown an e-mail from a sender to one recipient, and the case where there are no problems or complications in the transaction. Due to either command syntax or server issues, it is possible for various types of errors to occur at different stages of the process, which may result in the transaction failing. There are also [security concerns](#) that may come into play, that may lead to restrictions in what transactions a server may allow.

## **SMTP Special Features, Capabilities and Extensions**

The primary job of the Simple Mail Transfer Protocol is of course to implement the TCP/IP electronic mail delivery system. Whenever the user of an SMTP server gives it an e-mail message addressed to a non-local mailbox, the server will attempt to transfer it to the appropriate destination server, using the [SMTP mail transaction process](#). Many billions of such transfers are performed every day on the Internet, allowing e-mail to quickly reach its destination anywhere around the world.

### **SMTP Special Features**

In addition to the basic mail transfer mechanism, SMTP includes a number of other features and capabilities. These allow SMTP to support special requirements and auxiliary needs of the mail system, and are described in detail in RFC 2821. It would take many topics to describe them all in detail, so I will just provide a quick summary of the more important ones here so you know a bit about them:

- ☛ **Mail Relaying:** As discussed in the [SMTP communication overview](#), the protocol was once widely used in a “relaying mode” where e-mail was routed from one SMTP server to another to reach its destination. Today, the normal method of e-mail transfer on the Internet today is directly from the sender's SMTP server to the recipient's, using [DNS MX records](#) to determine the recipient SMTP server address. SMTP still includes the ability to relay mail from one server to another, provided certain conditions are met. Note that in addition to the inefficiency of relaying, many servers won't relay mail because this feature has been [abused for spamming and hacking](#).
- ☛ **Mail Forwarding:** Under certain conditions, an SMTP server may agree to accept e-mail for a non-local mailbox and forward it to the appropriate destination. This sounds similar to relaying but is used in a different way. A common example is when a user changes his or her e-mail address. If I have worked at XYZ Industries for years and then retire, the company may no longer wish to let me receive e-mail at the company's SMTP server. As a courtesy, however, they may forward e-mail sent to me there so I still receive it at my new company.
- ☛ **Mail Gatewaying:** Certain SMTP servers may be configured as e-mail gateways. These devices “translate” TCP/IP e-mail into a form suitable for another e-mail system, and vice-versa. Gatewaying is a complex topic because e-mail systems can be so different; one of the more important problems is the [inconsistency of addressing methods of different e-mail systems](#).
- ☛ **Address Debugging:** SMTP includes a *VERFY* (*verify*) command, which can be used to check the validity of an e-mail address without actually sending mail to it.

- ☉ **Mailing List Expansion:** The SMTP command *EXPN* (*expand*) can be used to determine the individual e-mail addresses associated with a [mailing list](#). (Note however that this has nothing directly to do with mailing list software like *Majordomo*.)
- ☉ **“Turning”:** The original SMTP protocol included a command that allows the SMTP sender and SMTP receiver to change roles. This could be used to allow SMTP server A to send e-mail to server B, and then have B send e-mail it has queued for A in the same session. In practice, this capability was not widely used for a variety of reasons, including security considerations. It is now officially “not recommended”, but may still be implemented in some SMTP software.

### ***Other Capabilities and Functions of SMTP Servers***

The list above represents just a few of the features that are mentioned in the SMTP standards. In addition to these, a given type of SMTP server software may be given other features as well by its developers. The *HELP* command is one way to determine what some of the commands that a given SMTP server supports.

SMTP servers also must perform a great deal of “background processing” that doesn't get a great deal of attention. This includes managing connections, checking for errors in commands and e-mail messages, and reacting accordingly. They must also be on the lookout for problem conditions, such as “looping” that may result in an e-mail message being passed back and forth between two SMTP servers, each thinking the other is the intended recipient. In the event of an initial failure to deliver mail, SMTP servers are also required to periodically retry communication with the destination device, and return a failure message to the sender if it cannot deliver the message after a certain period of time. Again, RFC 2821 contains more details.

### ***SMTP Extensions***

As discussed earlier in this section, during the 1990s many extensions to the basic operation of SMTP were defined. These are enabled when two SMTP servers supporting the extension [set up a session](#) using the *EHLO* command and appropriate extension response codes. [Table 252](#) summarizes some of the more interesting SMTP extensions that have been defined, and gives the RFC number where each is described.

**Table 252: SMTP Extensions (Page 1 of 2)**

Extension Keyword	Extension	Defining Document	Description
<b>8BITMIME</b>	8-bit MIME support.	RFC 1652	Theoretically defines support for the 8-bit content transfer encoding type in MIME, but there are complications associated with this. <a href="#">See the discussion of content encoding in the MIME section.</a>
<b>AUTH</b>	Authorization	RFC 2554	Used to implement an authorization mechanism for servers requiring enhanced security.

---

**Table 252: SMTP Extensions (Page 2 of 2)**

Extension Keyword	Extension	Defining Document	Description
<b>DSN</b>	Delivery status notification	RFC 1891	Allows an SMTP sender to request that the SMTP receiver notify it a problem occurs in delivering a message the sender gives to it.
<b>ENHANCED-STATUSCODES</b>	Enhanced status codes. (They should have abbreviated the keyword. ☺)	RFC 2034, RFC 1893	Extends the traditional 3-digit SMTP reply code format with extra codes that provide more information. <a href="#">See the end of the topic on SMTP replies for more.</a>
<b>PIPELINING</b>	Command pipelining	RFC 2920	Allows multiple commands to be transmitted in batches from the SMTP sender to the receiver, rather than sending one command at a time and waiting for a response code.
<b>SIZE</b>	Message size declaration	RFC 1870	Allows information about the size of a message to be declared by an SMTP sender prior to transmitting it, so the SMTP receiver can decide if it wants the message or not.

**On The Web:** The full current set of SMTP extensions can be found here: <http://www.iana.org/assignments/mail-parameters>

---

**Note:** Certain commands in the basic SMTP protocol description that are considered optional are also sometimes considered extensions, such as the *EXPN* and *HELP* commands; I have not listed these here since they are not true SMTP extensions.

---

## **SMTP Security Issues**

If you've already read the sections describing other TCP/IP protocols such as [DHCP](#), [FTP](#) and so forth, you probably already know how I am going to start this section. The theme is a common one in TCP/IP: a lack of security in how a protocol is implemented. And this all goes back to a common root cause: most of these protocols were developed when the "Internet" was just a small group of machines controlled by individuals who mostly knew and trusted each other, or who were able to use physical security means. Developers never imagined TCP/IP being used by millions of anonymous "average Joe" users around the world, which necessitates far more attention to security than a small research internetwork like the ARPAnet.

---

When it comes to SMTP, security matters are if anything **worse** than they are with the other protocols I mentioned above. Not only does SMTP not have any real security mechanism, the original [relaying model of SMTP communication](#) is entirely designed around the idea of “cooperation” and “trust” between servers. Since most SMTP servers would be asked to handle a certain number of intermediate transfers, each server was required to accept mail from any originator to be delivered to any destination.

The basic assumption in this model is that SMTP servers would all be “well-behaved”, and not abuse the system by flooding intermediate servers with lots of mail to be delivered, or sending bogus messages to cause problems. This all changed as the Internet exploded in popularity in the 1990s. Con artists, hackers, and disreputable salespeople all discovered that e-mail could be used for “free” delivery of messages simply by submitting them to an SMTP server for delivery. The result was overloaded servers, primarily due to the sending of large quantities of unwanted e-mail, which Internet users commonly call *spam*.

**Note:** The term “spam”, in this context, does not have anything directly to do with the Hormel processed meat product. Its use in reference to massive amounts of e-mail comes from a Monty Python comedy sketch where that word is repeated over and over again.

---

It is actually very easy to “impersonate” an SMTP server. You can use the [Telnet Protocol](#) to connect directly to an SMTP server on port 25. [SMTP commands](#) are all sent as text, and so are [SMTP replies](#), so you can have a “conversation” with a server and even manually perform a mail transaction. This is useful for debugging, but also makes abuse of a wide open SMTP server trivially easy. Since spammers often don't want to be identified, they employ spoofing techniques to make it more difficult to identify them, which makes matters even more difficult.

### ***Common SMTP Server Security Techniques***

Despite this obvious problem, efforts to implement a general security mechanism in SMTP have been resisted for two main reasons. First, there is no foolproof way to retrofit a new security mechanism onto something as widely used as SMTP without creating incompatibilities between newer and older systems. Second, many administrators were reluctant to completely do away with the general notion of cooperation between sites that has helped make the Internet so successful, simply due to a few “bad apples”.

Still, something had to be done. The compromise was for system administrators to “tighten up” their SMTP servers through the imposition of both technical and policy changes. Naturally, these vary from one organization to another. Some of the more common SMTP security provisions include:

- ☉ Checking the IP address of a device attempting connection and refusing to even start an SMTP session unless it is in a list of authorized client devices.

- 
- ☉ Restriction of certain commands or features, such as e-mail relaying, to authorized users or client servers. This is sometimes done by requiring authentication via the [SMTP extension AUTH](#) before the command will be accepted.
  - ☉ Limiting the use of commands such as *EXPN* to prevent unauthorized users from determining the e-mail addresses of users on mailing lists.
  - ☉ Checking the validity of envelope information before accepting a message for delivery. Some servers will first verify that the originator's e-mail address is valid before agreeing to accept the *MAIL* command. Many will check the recipient's address and refuse the message if delivery is not to a local mailbox. Others use even more advanced techniques.
  - ☉ Limiting the size of e-mail messages that may be sent or the number that may be sent in a given period of time.
  - ☉ Logging all access to the server to keep records of server use and check for abuse.

Because of all the abuse in recent years, you will find that most SMTP servers implement these or other features, even though most of those features are not formally defined by the SMTP standards. They are instead enhancements built into individual SMTP server software packages.

Some of these measures can actually get quite sophisticated. For example, the SMTP server run by pair Networks, the great Web hosting company I have used for years, uses “POP-before-SMTP authentication”. This means that before the server will accept outgoing mail from the user via SMTP, the user must first log in to check incoming mail using the [Post Office Protocol](#). Since POP includes authentication, successful POP login tells the server the user is authorized. This “flips a switch” in the server that allows the user to access the SMTP service after that login for a limited period of time. If this seems convoluted, well, you start to get an idea of the hassle that spammers and hackers have created for Internet service providers today.

It's also worth noting that SMTP does not include any mechanism for encryption to ensure the privacy of e-mail transmissions. Users requiring security in who sees their messages must use a separate encryption scheme to encode the body of the message prior to submission.

**Key Concept:** SMTP was designed in an era where internet security was not much of an issue; as a result, the base protocol includes no security mechanism at all. Since e-mail is so often abused today, most modern SMTP servers incorporate one or more security features to avoid problems.

---

---

## SMTP Commands

I mentioned in [the overview and history of SMTP](#) that early TCP/IP e-mail mechanisms were developed by borrowing techniques and elements from existing application protocols, especially [Telnet](#) and [FTP](#). SMTP is an independent protocol, but its heritage can still be seen clearly in a few areas. One of the more obvious of these is in the method by which commands are issued by an SMTP sender and replies returned by an SMTP receiver.

Like FTP, all SMTP commands are sent as plain ASCII text over the TCP connection established between the client and server in an SMTP connection. These commands must end with the two-character “CRLF” sequence that normally terminates ASCII text as required for the Telnet [Network Virtual Terminal \(NVT\)](#). In fact, you can check the function of an SMTP server and even issue commands to it yourself, simply by using Telnet to connect to it on port 25.

### SMTP Command Syntax

All SMTP commands are specified using a four-letter *command code*. Some commands also either allow or require *parameters* to be specified. The basic syntax of a command is:

<command-code> <parameters>

When parameters are used, they follow the command code and are separated from it by one or more space characters. For example, the *HELO* and *EHLO* commands are specified with the command code, a space character, and then the domain name of the SMTP sender, as we saw in our look at [SMTP connection establishment](#).

### Current SMTP Commands

[Table 253](#) lists the commands currently used in modern SMTP, in the order they are described in RFC 2821, with a brief description of each.

**Table 253: SMTP Commands (Page 1 of 2)**

Command Code	Command	Parameters	Description
<i>HELO</i>	Hello	The domain name of the sender.	The conventional instruction sent by an SMTP sender to an SMTP receiver to initiate the SMTP session.
<i>EHLO</i>	Extended Hello	The domain name of the sender.	Sent by an SMTP sender that supports <a href="#">SMTP extensions</a> to greet an SMTP receiver and ask it to return a list of SMTP extensions the receiver supports. The domain name of the sender is supplied as a parameter.

**Table 253: SMTP Commands (Page 2 of 2)**

Command Code	Command	Parameters	Description
<b>MAIL</b>	Initiate Mail Transaction	Must include a "FROM:" parameter specifying the originator of the message, and may contain other parameters as well.	Begins a <a href="#">mail transaction</a> from the sender to the receiver.
<b>RCPT</b>	Recipient	Must include a "TO:" parameter specifying the recipient mailbox, and may also incorporate other optional parameters.	Specifies one recipient of the e-mail message being conveyed in the current transaction.
<b>DATA</b>	Mail Message Data	None	Tells the SMTP receiver that the SMTP sender is ready to transmit the e-mail message. The receiver normally replies with an intermediate "go ahead" message, and the sender then transmits the message one line at a time, indicating the end of the message by a single period on a line by itself.
<b>RSET</b>	Reset	None	Aborts a mail transaction in progress. This may be used if an error is received upon issuing a <i>MAIL</i> or <i>RCPT</i> command, if the SMTP sender cannot continue the transfer as a result.
<b>VRFY</b>	Verify	E-mail address of mailbox to be verified.	Asks the SMTP receiver to verify the validity of a mailbox.
<b>EXPN</b>	Expand	E-mail address of mailing list.	Requests that the SMTP server confirm that the address specifies a mailing list, and return a list of the addresses on the list.
<b>HELP</b>	Help	Optional command name.	Requests help information: general help if no parameter is supplied, otherwise information specific to the command code supplied.
<b>NOOP</b>	No Operation	None	Does nothing except for verifying communication with the SMTP receiver.
<b>QUIT</b>	Quit	None	Terminates the SMTP session.

Like [FTP commands](#), SMTP commands are not case sensitive.

Certain SMTP extensions make changes to the basic SMTP command set. For example, the *AUTH* extension specifies a new command (also called *AUTH*) that specifies an authentication method the SMTP client wants to use. Other extensions define new parameters for existing commands. For example, the *SIZE* extension defines a *SIZE* parameter that can be added to a *MAIL* command to tell the SMTP receiver the size of the message to be transferred.

**Key Concept:** The SMTP sender performs operations using a set of *SMTP commands*. Each command is identified using a four-letter code. Since SMTP only supports a limited number of functions, it has a small command set.

---

### ***Obsolete SMTP Commands***

The commands in the preceding table are the ones that are most commonly used in SMTP today. In addition to those, there are also certain commands that were originally defined in RFC 821 but have since become obsolete. These include the following:

- ☛ **SEND, SAML (“send and mail”) and SOML (“send or mail”):** RFC 821 defined a distinct mechanism for delivering mail directly to a user's terminal as opposed to a mailbox, optionally in combination with conventional e-mail delivery. These were rarely implemented and obsoleted in RFC 2821.
- ☛ **TURN:** Reverses the role of the SMTP sender and receiver as described in the [SMTP special features topic](#). This had a number of implementation and security issues and was removed from the standard in RFC 2821.

### **SMTP Replies and Reply Codes**

SMTP communication begins with the establishment of an [SMTP session](#) between an SMTP sender (the device acting as a client) and an SMTP receiver (the device acting as a server). All protocol operations then consist of plain ASCII text [SMTP commands](#) issued by the sender to the receiver. The receiver analyzes each command, carries out the instruction requested by the sender if possible, and then responds back with a reply to the sender. The reply serves several functions: confirming command receipt; indicating if the command was accepted or not; and communicating the result of processing the command.

Just as SMTP commands are sent in a manner reminiscent of how [FTP internal commands](#) work, SMTP replies are formatted and interpreted in a way almost identical to that of [FTP replies](#). As with FTP, the reply consists not just of a string of reply text, but a combination of reply text and a numerical *reply code*. And as with FTP, these reply codes use three digits to encode various information about the reply, with each digit having a particular significance. The reply code is really the key part of the reply, with the reply text being merely descriptive.

**Note:** The [topic on FTP reply codes](#) contains a thorough explanation of the benefits of using these structure numeric reply codes. Since the SMTP system is so similar, I won't duplicate that discussion in this topic. I will, however, fully describe the syntax and semantics of SMTP reply codes here, in order both to keep this section on SMTP self-contained, and to indicate where the differences are between FTP and SMTP reply codes.

---

---

## Reply Code Structure and Digit Interpretation

SMTP reply codes can be considered to be of the form “xyz”, where “x” is the first digit, “y” the second and “z” the third. Here is how these digits are used.

### First Reply Code Digit (“x”)

The leading reply code digit indicates the success or failure of the command in general terms, whether a successful command is complete or incomplete, and whether an unsuccessful one should be tried again or not. This particular digit is interpreted in exactly the same way as it is in FTP, as shown in [Table 254](#).

**Table 254: SMTP Reply Code Format: First Digit Interpretation**

Reply Code Format	Meaning	Description
1yz	<b>Positive Preliminary Reply</b>	An initial response indicating that the command has been accepted and processing of it is still in progress. The SMTP sender should expect another reply before a new command may be sent.  Note that while this first digit type is formally defined in the SMTP specification for completeness, it is not currently actually used by any of the SMTP commands. That is to say, there are no reply codes between 100 and 199 in SMTP.
2yz	<b>Positive Completion Reply</b>	The command has been successfully processed and completed.
3yz	<b>Positive Intermediate Reply</b>	The command was accepted, but processing of it has been delayed, pending receipt of additional information. One example of where this type of reply is often made is after receipt of a <i>DATA</i> command, to prompt the SMTP sender to then send the actual e-mail message to be transferred.
4yz	<b>Transient Negative Completion Reply</b>	The command was not accepted and no action was taken, but the error is temporary and the command may be tried again. This is used for errors that may be a result of temporary glitches or conditions that may change, such as a resource on the SMTP server being temporarily busy.
5yz	<b>Permanent Negative Completion Reply</b>	The command was not accepted and no action was taken. Trying the same command again is likely to result in another error. An example would be sending an invalid command.

---

## Second Reply Code Digit (“y”)

The middle digit categorizes messages into functional groups. This digit is used in the same general way as in FTP, but some of the functional groups are different in SMTP, as you can see in [Table 255](#).

**Table 255: SMTP Reply Code Format: Second Digit Interpretation**

Reply Code Format	Meaning	Description
x0z	Syntax	Syntax errors or miscellaneous messages.
x1z	Information	Replies to requests for information, such as status requests.
x2z	Connections	Replies related to the connection between the SMTP sender and SMTP receiver.
x3z	Unspecified	Not defined.
x4z	Unspecified	Not defined.
x5z	Mail System	Replies related to the SMTP mail service itself.

## Third Reply Code Digit (“z”)

The last digit indicates a specific type of message within each of the functional groups described by the second digit. The third digit allows each functional group to have 10 different reply codes for each reply type given by the first code digit (preliminary success, transient failure and so on.)

### *Combining Digit Values to Make Specific Reply Codes*

Again, as in FTP, these “x”, “y” and “z” digit meanings are combined to make specific reply codes. For example, the reply code “250” is a positive reply indicating command completion, related to the mail system. It usually is used to indicate that a requested mail command was completed successfully.

### *Common SMTP Reply Codes*

[Table 256](#) contains a list of some of the more common FTP reply codes taken from RFC 2821, in numerical order. For each, I have shown the “typical” reply text specified in the standard, and provided additional descriptive information where I felt it was needed.

**Table 256: SMTP Reply Codes (Page 1 of 3)**

Reply Code	Reply Text	Description
211	System status or system help reply.	
214	<Help message...>	Used for text sent in reply to the <i>HELP</i> command.

**Table 256: SMTP Reply Codes (Page 2 of 3)**

Reply Code	Reply Text	Description
220	<servername> Service ready.	Greeting message sent when TCP connection is first established to an SMTP server.
221	<servername> closing transmission channel.	Goodbye message sent in response to a <i>QUIT</i> message.
250	Requested mail action okay, completed	Indicates successful execution of a variety of commands.
251	User not local; will forward to <forward-path>	Used when the SMTP receiver agrees to forward a message to a non-local user.
252	Cannot VRFY user, but will accept message and attempt delivery	Indicates that a server tried to verify an e-mail address, but was not able to do so completely. Usually means the address appears to be valid but it was not possible to positively ascertain this to be true.
354	Start mail input; end with <CRLF>.<CRLF>	Intermediate reply to a <i>DATA</i> command.
421	<servername> Service not available, closing transmission channel	Sent in response to any command when the SMTP receiver prematurely terminates the connection. A common reason for this is receipt of a local shutdown command, due for example to a hardware reboot.
450	Requested mail action not taken: mailbox unavailable	Sent when a mailbox is busy due to another process accessing it.
451	Requested action aborted: local error in processing	Local processing problem on the server.
452	Requested action not taken: insufficient system storage.	Time to clean out the server's hard disk! ☺
500	Syntax error, command unrecognized	Response to a bad command or one that was too long.
501	Syntax error in parameters or arguments	
502	Command not implemented	Command is valid for SMTP in general but not supported by this particular server.
503	Bad sequence of commands	Commands were not sent in the correct order, such as sending the <i>DATA</i> command before the <i>MAIL</i> command.
504	Command parameter not implemented.	
550	Requested action not taken: mailbox unavailable	Generic response given due to a problem with a specified mailbox. This includes trying to send mail to an invalid address, refusal to relay to a non-local mailbox and so forth.
551	User not local; please try <forward-path>	Tells the SMTP sender to try a different path; may be used to support mailbox forwarding.

---

**Table 256: SMTP Reply Codes (Page 3 of 3)**

Reply Code	Reply Text	Description
552	Requested mail action aborted: exceeded storage allocation	User's mailbox is full.
553	Requested action not taken: mailbox name not allowed	Specification of an invalid mailbox address.
554	Transaction failed.	General failure of a transaction.

As mentioned before, the actual text string for each reply code is implementation-specific. While the standard specifies “dry” response text such as “Requested action completed” for a 250 message, some servers customize this code, or even give different replies to different 250 messages depending on context. Again, there are examples of this in other topics.

### ***SMTP Multiple-Line Text Replies***

Again, as in FTP, it is possible for a reply to contain more than one line of text. In this case, each line starts with the reply code, and all lines but the last have a hyphen between the reply code and the reply text, to indicate that the reply continues. The last line has a space between the reply code and text, just like a single-line reply. An example of this was given in [the topic on SMTP connections](#) where I showed a multi-line response to a *EHLO* command.

### ***Enhanced Status Code Replies***

When the *ENHANCEDSTATUSCODES* SMTP extension is enabled, this causes supplemental reply codes to be issued by the SMTP receiver in response to each command. These codes are similar in some respects to the standard reply codes; they also use three digits, but the digits are separated by periods. These enhanced codes provide more information about the results of operations, especially errors.

For example, if you try to issue a *RCPT* command specifying a non-local mailbox on a server not supporting this feature, it will send back a “550” reply, which is a generic error (“requested action not taken: mailbox unavailable”). When enhanced status codes are active, the response will be “550 5.7.1”, the more specific message “delivery not authorized, request refused”. A full description of these enhanced codes can be found in RFC 1893.

**Key Concept:** Each time the SMTP sender issues a command, it receives a *reply* from the SMTP receiver. SMTP replies are similar to FTP replies, using both a three-digit reply code and a descriptive text line. A special *enhanced status codes* SMTP extension is also defined; when enabled, this causes the SMTP receiver to return more detailed result information after processing a command.

---

---

## **TCP/IP Electronic Mail Access and Retrieval Protocols and Methods**

The [Simple Mail Transfer Protocol \(SMTP\)](#) is responsible for most of the process of sending an e-mail message from the originator to the recipient. SMTP's job ends when the message has been successfully deposited into the recipient's mailbox on his or her local SMTP server.

In some cases this mailbox is the end of the message's travels through cyberspace. More often, however, it is only a “rest stop”—the last step of the journey is for the message to be actually accessed and read by the user to whom it was sent. This may require that it be retrieved from the mailbox and transferred to another client machine. For a [variety of reasons](#), SMTP is not used for the process of accessing a mailbox, but rather a special set of protocols and methods designed specifically for *electronic mail access and retrieval*.

In this section, I describe some of the more common techniques used for TCP/IP e-mail access and retrieval. I begin with an overview of the subject that describes in general the different paradigms used for e-mail access and gives an overview of the protocols. I then have subsections that cover the two mail TCP/IP e-mail access and retrieval protocols: the Post Office Protocol (POP) and the Internet Message Access Protocol (IMAP). I also have a third, smaller subsection that discusses other methods of e-mail access.

Note that this section assumes that you already have familiarity with SMTP and the operation of the TCP/IP e-mail system as a whole.

---

## **TCP/IP Electronic Mail Mailbox Access Model, Method and Protocol Overview**

In an ideal world... we would all be born knowing everything there is to know about computers and networking, and I'd have become a famous novelist instead of writing thousands of pages of this stuff. ☺ Well, that may be asking a bit **too** much, but wouldn't it have been nice if every device on the Internet simply ran SMTP server software? If so, then that one protocol would be sufficient to implement the entire TCP/IP e-mail system. You would just compose e-mail on your machine, and your SMTP software would send it to your recipient's, and he or she would read it. Nice and simple.

Back here in the real world, however, this is really not possible in general terms. As I explained in [the overview section on e-mail](#) and [the discussion of SMTP](#), an SMTP server must be connected to the Internet and available around the clock to receive e-mail sent at any time by any of the millions of other computers in the world. Most of us either cannot or do not want to run machines continuously connected to the Internet, nor do we want to configure and maintain potentially-complex SMTP software. This is the reason why a complete e-mail exchange normally involves [not two devices but four](#): a message is composed on the sender's client machine, transferred to the sender's SMTP server, then to the recipient's SMTP server, and finally, to the recipient's machine.

### ***The Advantages of Specialized Mail Access and Retrieval Protocols***

The communication between SMTP servers is of course done with SMTP. So is the initial step of sending the e-mail from the sender's machine to the sender's SMTP server. However, SMTP is **not** used for the last part of the process, accessing the recipient's mailbox. Instead, a set of *mailbox access and retrieval* protocols and methods were devised.

A fair question is... why was this done? Why not simply have mail sit “pending” on the recipient's SMTP server and then have it send the mail to the recipient client device when it comes online, using SMTP? There are two main reasons for this. The first is that SMTP was designed for the specific purpose of transporting e-mail only. Having it responsible for client mailbox access would require adding more functionality, making it difficult to keep SMTP “simple”. Also, SMTP works on a “push” model, with transactions being initiated by the sender. It would need changes to allow it to respond to requests from a client device that is only online intermittently.

But the second reason is probably more important: *flexibility* in how electronic mail is accessed. If we used SMTP, all we would be able to do is transfer e-mail to the recipient's client machine. This would be functional, but would greatly limit the capabilities of how e-mail is used. For example, some users might wish to access mail directly on the server and manipulate it there. Also consider the problem of people with special requirements, such as those who travel and may need to access e-mail from a number of different client devices.

---

## ***E-Mail Access and Retrieval Models***

For the reasons just examined, there is an advantage to providing more than one way to access a mailbox. RFC 1733, *Distributed Electronic Mail Models In IMAP4*, describes three different paradigms or models for mail access and retrieval:

- ☹ **Online Access Model:** This is the mode of access that we would all be using in my “ideal world” scenario, where every machine was always connected to the Internet running an SMTP server. You would have constant, direct online access to your mailbox. In the real world, this model is still used by some Internet users, especially those who have UNIX accounts or run their own SMTP servers. I call this *direct server access*.
- ☹ **Offline Access Model:** In this paradigm, a user establishes a connection to a server where his or her mailbox is located. The user downloads received messages to the client device, and then deletes them from the server mailbox. All reading and other activity performed on the mail can be done “offline” once the mail has been retrieved.
- ☹ **Disconnected Access Model:** This is a hybrid of online and offline access. The user downloads messages from the server, so he or she can read or otherwise manipulate them without requiring a continuous connection to the server. However, the mail is **not** deleted from the server, like in the offline model. At some time in the future, the user connects back with the server and synchronizes any changes made on the local device with the mailbox on the server.

What sort of changes? Examples include marking whether or not a message has been read, to keep track of unread mail, and marking messages to which the user has already replied. These are important tools to help those with busy mailboxes keep track of what they need to do.

## ***Comparing E-Mail Access and Retrieval Models***

Of the three, which is best? You should know better than to ask me that question. ☺ Each has advantages and disadvantages, which is why it is good that we have these options rather than the single SMTP protocol for mail access.

[Direct server access](#) has the main benefits of instant speed and universal access from any location. It has the disadvantage that you must be online to read mail, and that it usually requires you to use UNIX e-mail clients that most people are not familiar with. However, the [Internet Message Access Protocol \(IMAP\)](#) can also be used for online access.

Offline access has the main advantages of simplicity and short connection time requirements; you can easily connect to the mailbox, download messages and then read them locally. But that makes this method somewhat inflexible, and poorly-suited to access from different machines. Still, it is right now the most popular access method, because simplicity is important; it is best typified by the popular [Post Office Protocol \(POP\)](#).

Disconnected access attempts to combine the advantages of offline and online access without combining their disadvantages, and does a pretty good job. The advantages are significant: the ability to quickly access mail and use it offline, while retaining and updating the mailbox on the server to allow access from different client machines. [IMAP](#) is the

---

protocol popularly used for disconnected access. In the [IMAP overview](#) I explore its advantages over offline access, as well as its main disadvantages: complexity and far less universal support than POP (though acceptance of IMAP is slowly increasing).

Finally, in recent years, a somewhat new mailbox access method has become popular: [e-mail access using the World Wide Web](#). This technique allows a user to access his or her mailbox from any computer with an Internet connection and a Web browser. It is a good example of “line blurring”, not only between the access models discussed here, but between TCP/IP applications, in this case [the Web](#) and e-mail.

**Key Concept:** For flexibility, TCP/IP uses a variety of *mailbox access and retrieval protocols and methods* to allow users to read e-mail. Three different models describe how these different methods work: the *online* model, in which e-mail is accessed and read on the server; the *offline* model, in which mail is transferred to the client device and used there; and the *disconnected* model, where mail is retrieved and read offline but remains on the server with changes synchronized for consistency.

---

---

## **TCP/IP Post Office Protocol (POP/POP3)**

The [overall communication model](#) used for TCP/IP e-mail gives many options to an e-mail user for accessing his or her electronic mailbox. The most popular access method today is the simple *offline* access model, where a client device accesses a server, retrieves mail and deletes it from the server. The *Post Office Protocol (POP)* was designed for quick, simple and efficient mail access; it is used by millions of people to access billions of e-mail messages every day.

In this section I describe the operation of the Post Office Protocol, focusing on version 3 (POP3). I begin by looking at the protocol in general terms, discussing its history, the various versions of the protocol and the standards that define them. I describe POP3's general operation and the communication between a client and server, concentrating on the three main states through which the session transitions. I then describe each of these states in sequence: the *Authorization* state, *Transaction* state and *Update* state. For each, I explain the communication processes that take place and the commands and replies that implement them.

### **POP Overview, History, Versions and Standards**

Of the three [mailbox access paradigms](#), *online*, *offline* and *disconnected*, the offline model is probably the least capable in terms of features. And it is also the most popular! This may **seem** counter-intuitive, but it is in fact a pattern that repeats itself over and over in the worlds of computing and networking: a good example would be Ethernet beating Token Ring in the LAN market. The reason is that *simplicity* and *ease of implementation* are keys to the success of any technology, and the offline mail access model beats the other two in these areas.

The history of offline e-mail access goes back farther than one might expect—to the early 1980s. Two decades ago, we didn't have nearly everyone and his brother accessing the Internet to check e-mail the way we do today. In fact, there were only a relatively small number of machines connected using TCP/IP, and most users of these machines had the ability to access their e-mail on-server, using the online access model.

However, even back then, developers recognized the advantages of being able to retrieve e-mail from a server directly to a client computer, rather than accessing the mailbox on the server using [Telnet](#) or [NFS](#). In 1984, RFC 918 was published, defining the *Post Office Protocol (POP)*. The idea behind POP was to provide a simple way for a client computer to retrieve e-mail from a mailbox on an SMTP server so it could be used locally.

The emphasis was on **simple**; the RFC for this first version of POP is only 5 pages long, and the standard it defined is extremely rudimentary. It describes only a simple sequence of operations where a user gives a name and password for authentication, and then downloads the entire contents of a mailbox. Simple is good, but there are limits.

---

In February 1985, RFC 937 was published: *Post Office Protocol - Version 2*. POP2 expanded the capabilities of POP by defining a much richer set of commands and replies. This includes the important ability of being able to read only certain messages, rather than dumping a whole mailbox. Of course, this came at the cost of a slight increase in protocol complexity, but POP2 was still quite simple as protocols go.

These two early versions of POP were used in the mid-1980s, but not very widely. Again, this is simply because the need for an offline e-mail access protocol was limited at that time; most people were not on the Internet before the 1990s.

In 1988, RFC 1081 was published, describing version 3 of the Post Office Protocol (*POP3*). By this time, the personal computer (PC) was transitioning from a curiosity to a place of importance in the worlds of computing and networking. POP3 was based closely on POP2, but refined and enhanced with the idea of providing a simple and efficient way for PCs and other clients not normally connected to the Internet to access and retrieve e-mail.

Development on POP3 continued through the 1990s, with several new RFCs published every couple of years. RFC 1081 was obsoleted by, in turn, RFCs 1225, 1460, 1725 and 1939. Despite the large number of revisions, the protocol itself has not changed a great deal since 1988; these RFCs contain only relatively minor tweaks to the original description of the protocol. RFC 1939 was published in 1996 and POP3 has not been revised since that time, though a few subsequent RFCs define optional extensions and additions to the basic protocol, such as alternative authentication mechanisms.

While POP3 has been enhanced and refined, its developers have remained true to the basic idea of a very simple protocol for quick and efficient e-mail transfer. POP3 is a straight-forward state-based protocol, with a client and server proceeding through three stages during a session. A very small number of commands are defined to perform simple tasks, and even after all the changes and revisions described above, the protocol has a minimum of “fluff”.

For reasons that are unclear to me, almost everyone refers to the Post Office Protocol with its version number; that is, they say “POP3” instead of “POP”. This is true despite most people not using version numbers with many other protocols, and almost nobody using any other version of POP anyway. But it is the convention, and I will follow it in the rest of this section.

**Key Concept:** The *Post Office Protocol (POP)* is currently the most popular TCP/IP e-mail access and retrieval protocol. It implements the offline access model, allowing users to retrieve mail from their SMTP server and use it on their local client computers. It is specifically designed to be a very simple protocol and has only small number of commands. The current revision of POP is version 3, and the protocol is usually abbreviated *POP3* for that reason.

---

**Note:** There are some implementations of POP that attempt to implement the *disconnected* access model, with limited success. More often, however, IMAP is used for this purpose, since it is better suited to that access model. [See the overview of IMAP for more details.](#)

---

## **POP3 General Operation, Client/Server Communication and Session States**

As I mentioned in [the previous topic](#), the Post Office Protocol was designed to perform only one main function, and to do it quickly and simply: allow a client computer to access and retrieve e-mail from a server. The operation of the protocol is simple and straight-forward, which is good news for you, the person trying to understand how it works.

### ***Client/Server Communication***

POP3 is a regular [TCP/IP client/server protocol](#). To provide access to mailboxes, POP3 server software must be installed and continuously running on the server where the mailboxes are located. This does not necessarily have to be the same physical hardware device that runs the [SMTP](#) server software that receives mail for those boxes—a mechanism such as [NFS](#) may be used to allow the POP3 and SMTP servers to both “see” mailboxes locally. POP3 clients are regular end-user e-mail programs that make connections to POP3 servers to get mail; examples include Microsoft Outlook, Eudora Email and so forth.

POP3 uses the [Transmission Control Protocol \(TCP\)](#) for communication, to ensure the reliable transfer of commands, responses and message data. POP3 servers “listen” on [well-known port number](#) 110 for incoming connection requests from POP3 clients. After a TCP connection is established, the POP3 session is activated. The client sends commands to the server, which replies with responses and/or e-mail message contents.

### ***Commands and Response Codes***

POP3 commands are three or four letters long and are case-insensitive. They are all sent in plain ASCII text and terminated with a “CRLF” sequence, just as with [FTP](#) and [SMTP](#) commands. POP3 replies are also textual, but the protocol does **not** use the complex [three-digit reply code mechanism of FTP](#) (and SMTP). In fact, it defines only two basic responses:

- ☉ **+OK:** A positive response, sent when a command or action is successful; and
- ☉ **-ERR:** A negative response, sent to indicate that an error has occurred.

These messages may be accompanied by explanatory text, especially in the case of an *-ERR* response, to provide more information about the nature of the error.

### ***Session States***

POP3 is described in terms of a finite state machine (FSM), with a session transitioning through three states during the course of its “lifetime”, as shown in [Figure 306](#).

**Note:** I describe the concepts behind Finite State Machines in [the topic describing the TCP FSM](#).

---

Before you get too intimidated, realize that unlike the FSMs of protocols like TCP, this one really is simple, because it is **linear**. The session goes through each state once and only once, in the following sequence:

1. **Authorization State:** The server provides a greeting to the client to indicate that it is ready for commands. The client then provides authentication information to allow access to the user's mailbox.
2. **Transaction State:** The client is allowed to perform various operations on the mailbox. These include listing and retrieving messages, and marking retrieved messages for deletion.
3. **Update State:** When the client is done with all of its tasks and issues the *QUIT* command, the session enters this state automatically, where the server actually deletes the messages marked for deletion in the *Transaction* state. The session is then concluded and the TCP connection between the two terminated.

POP3 is designed so that only certain commands may be sent in each of these states. The next three topics describe the activities that take place in these three states, including the commands that are issued by the client in each.

**Key Concept:** POP3 is a client/server protocol that is described using a simple linear sequence of states. A POP3 session begins with a POP3 client making a TCP connection to a POP3 server, at which point the session is in the *Authorization* state. After successful authentication, the session moves to the *Transaction* state, where the client can perform mail access transactions. When it is done, the client ends the session and the *Update* state is entered automatically, where cleanup functions are performed and the POP3 session ended.

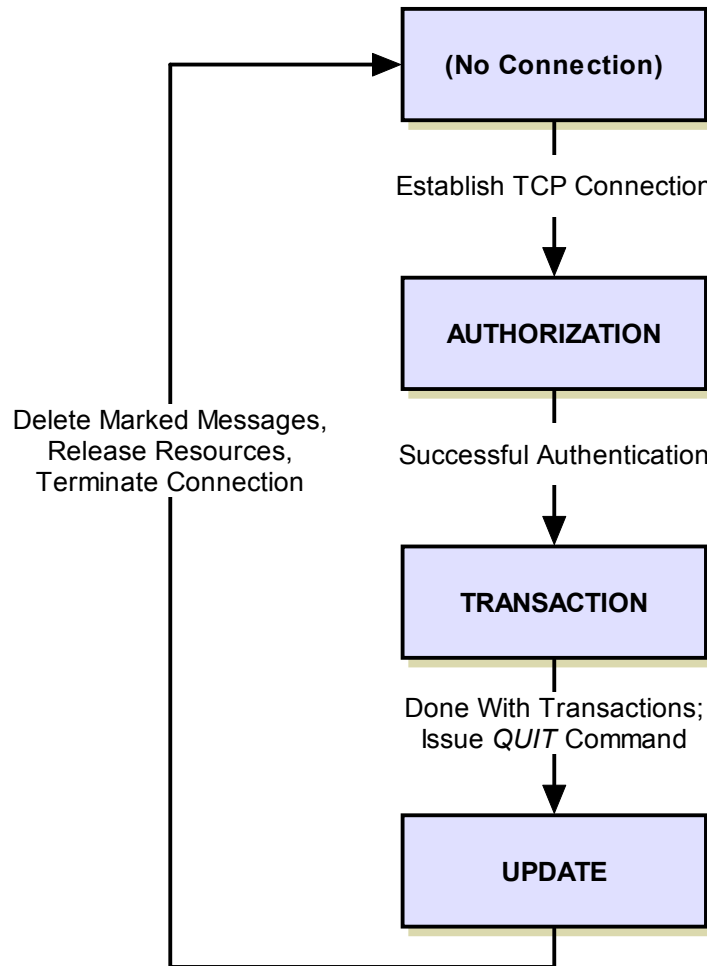

---

### **POP3 Authorization State: User Authentication Process and Commands**

A session between a POP3 client and a POP3 server begins when the client sends a TCP connection request to the server. The connection is established using the standard TCP “[three-way handshake](#)”, and the POP3 session commences. The first of the three states of a POP3 session is the *Authorization* state, which is responsible for authenticating the POP3 client with the server.

When the session first enters this state, the server sends a *greeting* message to the client. This tells the client that the connection is alive and ready for the client to send the first command. An example of such a greeting would be:

+OK POP3 server ready

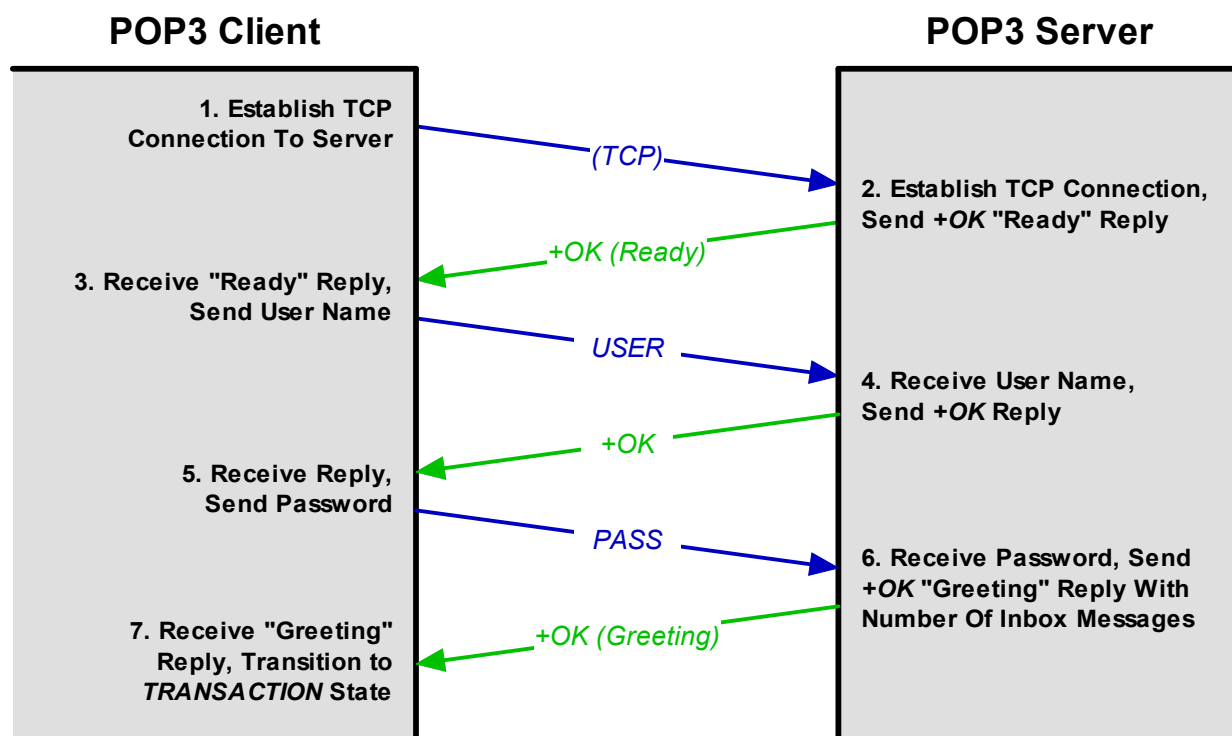

**Figure 306: Post Office Protocol (POP3) Finite State Machine**

POP uses a finite state machine to describe its operation, but it is very simple because it is linear. Once a TCP connection is established between a POP3 client and POP3 server, the session proceeds through three states in sequence, after which the connection is terminated.

The client is now required to *authenticate* the user who is trying to access a mailbox. This both proves that the user has the right to access the server, and identifies the user so the server knows which mailbox is being requested.

### **Standard POP3 Authentication**

The normal method of authorization in POP3 is a standard “username / password” login. This is pretty much identical to [how a login is performed in FTP](#); even the commands are the same. First the client issues a *USER* command along with the user's mailbox name (his or her user name or e-mail address). The server responds with an intermediate acknowledgment. The client then uses the *PASS* command to send the user's password. Assuming the login is valid, the server responds to the client with an acknowledgment that indicates successful authentication. The response will also typically specify the number of messages waiting for the user in the mailbox. This process is illustrated in [Figure 307](#).

**Figure 307: Post Office Protocol (POP3) User Authentication Process**

Once the TCP connection is established from the client to the server, the server responds with a greeting message, and the simple POP3 authentication process begins. The client sends a user name and password to the server using the *USER* and *PASS* commands, and the server evaluates the information to determine whether or not it will allow the client access.

[Table 257](#) shows an example POP3 authorization, with the client's commands highlighted and the server's responses in italics.

**Table 257: Example POP3 Authorization**

```

+OK POP3 server ready
USER jane@somewhereelse.com
+OK
PASS *****
+OK jane@somewhereelse.com has 3 messages
  
```

**Note:** Some servers may require only the name of the user (“jane”) while others require the full e-mail address as shown in the example. Also, I have not shown Jane's password in [Table 257](#); that wouldn't be very nice, would it? ☺

---

If authorization is successful, the POP3 session transitions to the *Transaction* state where [mail access commands can be performed](#). If the user name or password are incorrect, an error response is given and the session cannot proceed. The authorization may also fail due to technical problems, such as an inability by the server to lock the mailbox (perhaps due to new mail arriving via SMTP).

### ***Alternative Authentication Using APOP***

Since user/password authorization is considered by many people to be insufficient for the security needs of modern internetworks, the POP3 standard also defines an alternative authentication method, using the *APOP* command. This is a more sophisticated technique based on the MD5 “message digest” encryption algorithm.

If the server supports this technique, in its opening greeting it provides a string indicating a *timestamp* that is unique for each POP3 session. The client then performs an MD5 calculation using this timestamp value and a “shared secret” known by the server and client. The result of this calculation is included in the client's *APOP* command. If it matches the server's calculation, authentication is successful; otherwise the session remains in the *Authorization* state.

The Post Office Protocol was also designed to allow it to be extended through the addition of other authentication mechanisms. This process is based on the use of the optional *AUTH* command, as described in RFC 1734.

**Key Concept:** A POP3 session begins in the *Authorization* state, where the client device is expected to authenticate with the server. By default, POP3 uses only a simple username/password authentication method. Optional authentication methods are also defined for applications requiring more security.

---

### **POP3 *Transaction* State: Mail and Information Exchange Process and Commands**

Once the POP3 client has successfully authenticated the user who is performing mailbox access, the session transitions from the *Authorization* state to the *Transaction* state. There's no real mystery what this phase of the connection is all about: it is where the POP3 client issues the commands that perform mailbox access and message retrieval transactions.

---

## POP3 Transaction Commands

Most of the commands defined in POP3 are valid only in the *Transaction* state. [Table 258](#) lists each of them, in the order in which they appear in RFC 1939.

**Table 258: POP3 Transaction Commands**

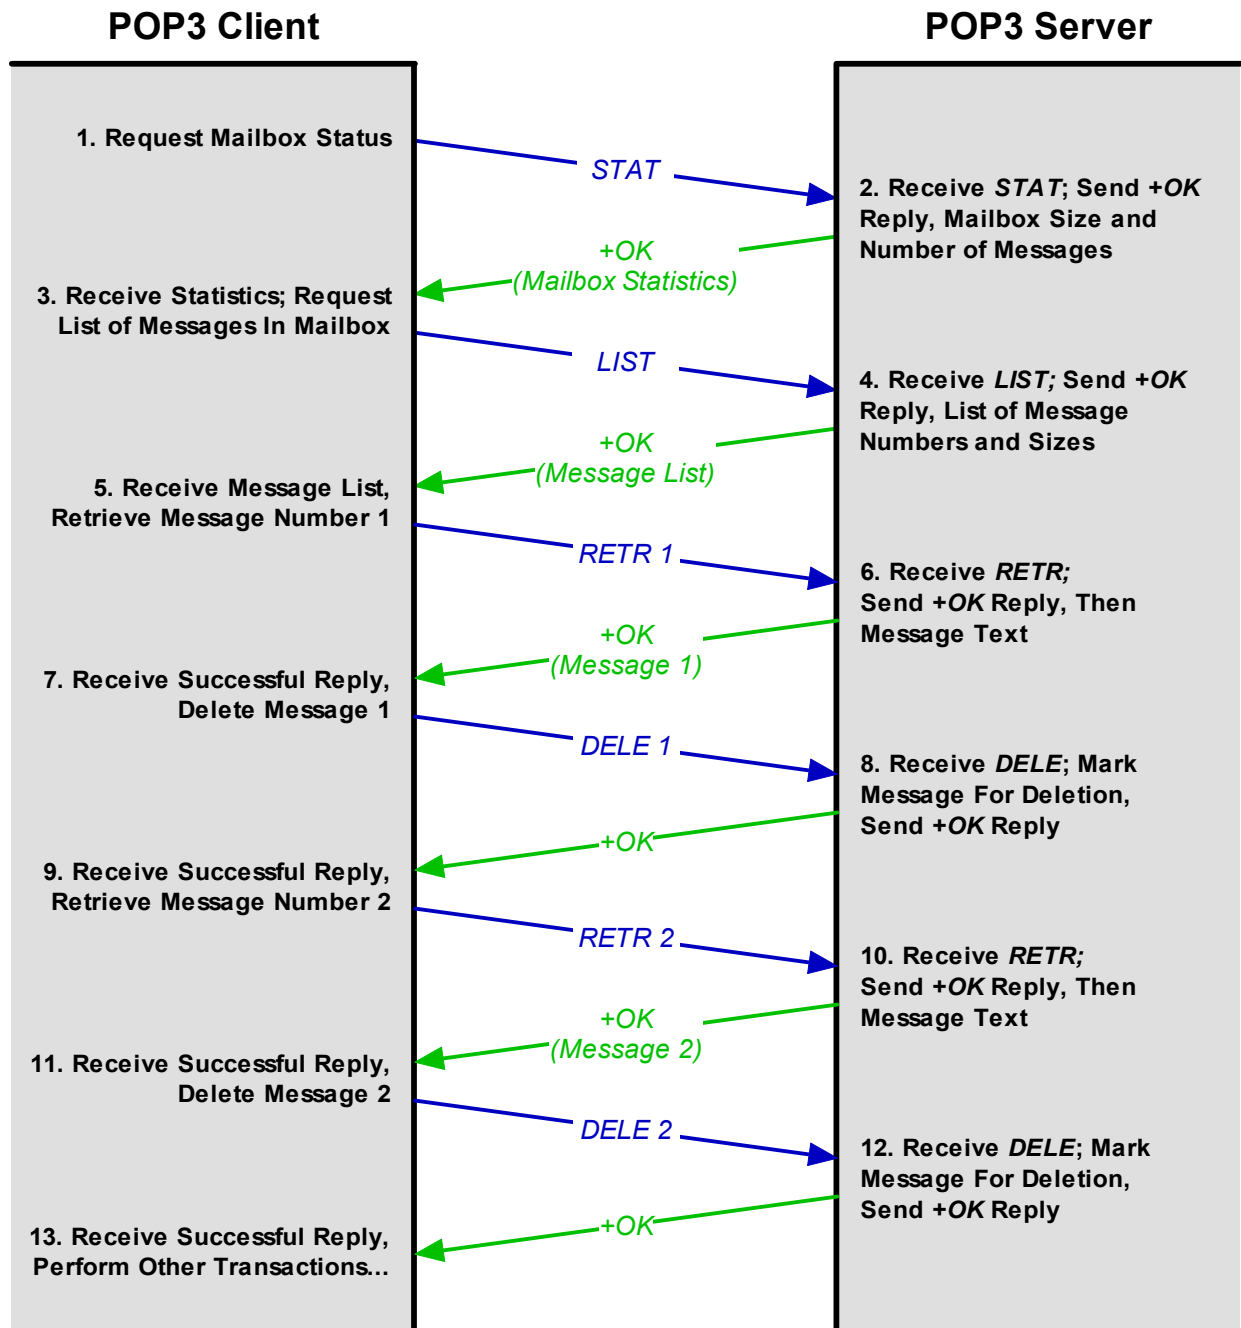

Command Code	Command	Parameters	Description
<b>STAT</b>	<i>Status</i>	None	Requests status information for the mailbox. The server will normally respond telling the client the number of messages in the mailbox, and the number of bytes of data it contains. Optionally, more information may also be returned.
<b>LIST</b>	<i>List Messages</i>	Optional message number	Lists information for the messages in a mailbox; generally this means showing the message number and its size. If a message number is given, only that message's information is provided; otherwise, the full contents of the mailbox are described, one line at a time, with a line containing just a single period at the end.
<b>RETR</b>	<i>Retrieve</i>	Message number	Retrieves a particular message from the mailbox. The server responds with a standard "+OK" message and then immediately sends the message in RFC 822 format, one line at a time. A line with a period by itself is sent after the last line.
<b>DELE</b>	<i>Delete</i>	Message number	Marks a message as deleted. Once deleted, any further attempt to access a message (using <i>LIST</i> or <i>RETR</i> for example) results in an error.
<b>NOOP</b>	<i>No Operation</i>	None	Does nothing; the server just returns a +OK reply.
<b>RSET</b>	<i>Reset</i>	None	Resets the session to the state it was in upon entry to the <i>Transaction</i> state. This includes "undeleting" any messages already marked for deletion.
<b>TOP</b>	<i>Retrieve Message Top</i>	Message number and number of lines	Allows a client to retrieve only the beginning of a message. The server returns the headers of the message and only the first <i>N</i> lines where <i>N</i> is the number of lines specified.  This command is optional and may not be supported by all servers.
<b>UIDL</b>	<i>Unique ID Listing</i>	Optional message number	If a message number was specified, returns a unique identification code for that message; otherwise, returns an identification code for each message in the mailbox.  This command is optional and may not be supported by all servers.

---

### ***Typical POP3 Mail Exchange Sequence***

The *Transaction* state is relatively “unstructured” in that commands do not need to be issued in any particular order to meet the requirements of the standard. However, there is a natural progression to how a mailbox is retrieved, and that means the commands are usually used in the following way:

1. The client issues a *STAT* command to see the number of messages in the mailbox.
2. The client issues a *LIST* command and the server tells it the number of each message to be retrieved.
3. The client issues a *RETR* command to get the first message and if successful, marks it for deletion with *DELE*. The client uses *RETR/DELE* for each successive message.

**Figure 308: Post Office Protocol (POP3) Mail Exchange Process**

This diagram shows the typical exchange of commands and replies employed by a POP3 client to retrieve e-mail from a POP3 server. The *STAT* command is used to get mailbox statistics, followed by the *LIST* command to obtain a list of message numbers. Each message in turn is then retrieved using *RETR* and marked for deletion by *DELE*. (Messages are not actually deleted until the *Update* state is entered.)

---

[Table 259](#) and [Figure 308](#) show a sample access sequence for a mailbox containing two messages that are a total of 574 bytes; the client's commands are highlighted and the server's responses are in italics.

**Table 259: Example POP3 Mail Exchange Process**

```
STAT
+OK 2 574
LIST
+OK
1 414
2 160
.
RETR 1
+OK
(Message 1 is sent)
.
DELE 1
+OK message 1 deleted
RETR 2
+OK
(Message 2 is sent)
.
DELE 2
+OK message 2 deleted
QUIT
```

The exact message sent in reply to each command is server-dependent; some just say “+OK” while others provide more descriptive text as I have done here for the responses to the *DELE* command.

In some cases, a POP3 client may be configured to *not* delete messages after retrieving them. This is useful, for example, when [Web-based access](#) is being combined with a conventional e-mail client program.

**Key Concept:** After successful authorization, the POP3 session transitions to the *Transaction* state, where the client actually accesses e-mail messages on the server. The client normally begins by first retrieving statistics about the mailbox from the server, and obtaining a list of the messages in the mailbox. The client then retrieving each message one at a time, marking each retrieved message for deletion on the server.

---

---

## **POP3 Update State: Mailbox Update and Session Termination Process and Commands**

Once the POP3 client has completed all the e-mail [message access and retrieval transactions](#) that it needed to perform, it is done with the POP3 session—except it isn't really quite done yet. The POP3 standard defines a final session state, the *Update* state, to perform various housekeeping functions, and then terminate both the POP3 session and the underlying TCP connection.

The transition from the *Transaction* state to the *Update* state occurs when the POP3 client issues the *QUIT* command. This command has no parameters, and serves to tell the POP3 server that the client is done and wishes to end the session. The POP3 standard lists this command as part of its description of the *Update* state, though it obviously is really issued from the *Transaction* state.

After the POP3 server receives the *QUIT* command, one thing it does is to delete any messages that were previously marked for deletion by the *DELE* command in the *Transaction* state. It's interesting that the Post Office Protocol chose to implement this two-stage deletion process. The standard doesn't describe specifically why this was done, but it seems likely that it is a precaution to insure against accidental deletion and loss of mail.

By delaying actual deletion until the *Update* state, the server can verify that it has received and processed all commands prior to the move to the *Update* state. It also allows the deletion of messages to be “undone” if necessary, using the *RSET* command, if the user changes his or her mind about the deletion prior to exiting the *Transaction* state. Finally, if any problem occurs with communication between the client and server that causes the TCP connection to be interrupted prematurely before the *QUIT* command is issued, no messages will be removed from the mailbox, giving the client a second chance to retrieve them in case they were not received properly.

Once the deleted messages have been removed, the server returns an acknowledgment to the client; “+OK” if the update was successful, or “-ERR” if there was some sort of a problem removing one or more of the deleted messages. Assuming there were no problems, the “+OK” response will also contain a “goodbye” message of some sort indicating that the session is about to be closed. The TCP connection between the client and server is then torn down and the session is done.

A POP3 mail retrieval session normally lasts a few seconds or minutes, but can take many minutes if the mailbox is large and the connection between the client and server is slow. There is no limit on how long the client and server can be connected, as long as commands continue to be sent by the client. A POP3 server will normally implement an inactivity timer, however, which is customizable but must have a duration of no less than 10 minutes. If the connection is idle for the full duration of the inactivity timer, the server assumes that the client has experienced some sort of a problem and shuts down the connection. If this occurs, the server does *not* delete any messages marked for deletion—again, this is in order to give the client another chance to retrieve those messages if a problem occurred getting them the first time.

**Key Concept:** When the POP3 client is done with its e-mail transactions, it issues the *QUIT* command. This causes the *Update* state to be automatically entered, where the server performs necessary clean-up operations, including deleting any messages marked for deletion in the *Transaction* state.

---

---

## **TCP/IP Internet Message Access Protocol (IMAP/IMAP4)**

The *offline mailbox access model* provides the basic mail access functions that most users need. Using the popular [Post Office Protocol \(POP3\)](#), a user can access his or her mailbox and retrieve messages so they can be read on a local machine. This model has the advantage of simplicity, but does not provide many features that are increasingly in demand today, such as keeping track of the status of messages and allowing access from many client devices simultaneously. To provide better control over how mail is accessed and managed, we must use either the *online* or *disconnected* access models. The *Internet Message Access Protocol (IMAP)* was created to allow these access models to be used, providing rich functionality and flexibility for the TCP/IP e-mail user.

In this section I describe the operation of the Internet Message Access Protocol. I begin as I usually do, with a general look at the protocol, its history, versions and standards. This includes a discussion of its benefits compared to the simpler POP3. I describe the operation of the current version of the standard, IMAP4, focusing on how client and server devices communicate and showing how the IMAP session moves through a series of four states. I describe how IMAP commands, results and responses are used and discuss the commands that can be used at any time during an IMAP session. I then describe the processes that are performed and commands used in each of the three main IMAP states.

**Related Information:** The main price that IMAP pays for having a much richer set of functionality than POP is much more complexity. In this section, I have described IMAP in approximately the same level of detail that I did POP in its section. Please see the appropriate RFC documents for the full description of the protocol and more discussion of some of its nuances, particularly the syntax of the many commands and parameters, which would take dozens of pages to cover fully here.

---

### **IMAP Overview, History, Versions and Standards**

The [Post Office Protocol](#) (POP, or POP3 after its current version) has become the most popular protocol for accessing TCP/IP mailboxes not because of its rich functionality, but in spite of its lack of it. POP implements the *offline* mail access model, where mail is retrieved and then deleted from the server where the mailbox resides, so it can be used on a local machine. Millions of people use POP3 every day to access incoming mail. Unfortunately, due to the way the offline access model works, POP3 cannot really be used for much else.

As I said in my [overview of mailbox access models](#), the online model is the one we would use in an “ideal world”, where all of us were always connected to the Internet all the time. Offline access is a necessity because this is not the case; most user client machines are only connected to the Internet periodically. The transfer of mail from the server to a client machine removes the requirement that we be online to perform mail functions, but costs us the benefits of central mail storage on the server.

---

## ***The Benefits of Centralized E-Mail Storage***

You may find it counterintuitive that it could be **better** to have mail stored on some remote server rather than on our local computer. The main reason is flexibility of access. One of the biggest problems with offline access using POP3 is that mail is transferred permanently from a central server to **one** client machine. This is fine so long as an individual only uses that one machine, but what if the person has separate work and home computers, or travels a great deal? How about if a mailbox is shared by many users? These concerns have become more and more important in recent years.

Another issue is data security and safety. Mail servers run by Internet service providers are usually located in professionally-managed data centers. They are carefully controlled and monitored, and backups are done on a routine basis. Most people do not take this sort of care with their own PCs and Macintoshes, nor do they back up their data routinely. It is thus more likely that mail be lost when it is on a local machine than when it remains on the server.

Of course, we still have the problem of not wanting to force users to be online all the time to access their mail. The solution is the *disconnected* mailbox access model, which marries the benefits of online and offline access. Mail is retrieved for local use as in the offline model, so the user does not have to be connected to the server continuously. However, changes made to the mailbox are synchronized between the client and the server. The mail remains on the server where it can be accessed from a different client in the future, and the server acts as a permanent “home base” for the user's mail.

Recognizing these benefits, some attempts were made to implement POP using the disconnected access model. Typically, this was done by using POP commands to retrieve mail but still leave it on the server, which is an option in many client programs. This works, but only to a limited extent; for example, keeping track of which messages are new or old becomes an issue when they are both retrieved and left on the server. POP simply lacks the features required for proper disconnected access, because it was not designed for it.

## ***IMAP Features***

In the mid-1980s, development began at Stanford University on a new protocol that would provide a more capable way of accessing user mailboxes. The result was the *Interactive Mail Access Protocol*, later renamed the *Internet Message Access Protocol (IMAP)*. IMAP was designed for the specific purpose of providing flexibility in how users access e-mail messages. It in fact can operate in all three of the access modes: online, offline and disconnected access. Of these, it is the online and disconnected access modes that are of interest to most users of the protocol; offline access is similar to how POP works.

IMAP allows a user to do all of the following:

- ☛ Access and retrieve mail from a remote server so it can be used locally while retaining it on the server.
- ☛ Set message flags so that the user can keep track of which messages he or she has already seen, already answered, and so on.

- 
- ☉ Manage multiple mailboxes and transfer messages from one mailbox to another. You can organize mail into categories, which is useful for those working on multiple projects, those who are on various mailing lists and so forth.
  - ☉ Determine information about a message prior to downloading it, to decide whether or not to retrieve it.
  - ☉ Download only portions of a message, such as one body part from a [MIME multipart message](#). This can be quite helpful in cases where large multimedia files are combined with short text elements in a single message.
  - ☉ Manage documents other than e-mail. For example, IMAP can be used to access [Usenet messages](#).

Of course, there are some disadvantages to IMAP, but not many. One is that it is more complex, but it's really not *that* complex, and the protocol has been around for enough years that this is not a big issue. The most important sticking point with IMAP is simply that it is used less commonly than POP, so providers that support it are not as easy to find as those that support POP. This is changing, however, as more people discover IMAP's benefits.

**Key Concept:** The Post Office Protocol is popular because of its simplicity and long history, but POP has few features and normally only supports the rather limited *offline* mail access method. To provide more flexibility for users in how they access, retrieve and work with e-mail messages, the *Internet Message Access Protocol (IMAP)* was developed. IMAP is primarily used in the online and disconnected access models; it allows users to access mail from many different devices, manage multiple mailboxes, select only certain messages for downloading, and much more. Due to its many capabilities, it is growing in popularity.

---

### ***IMAP History and Standards***

IMAP has had a rather interesting history. I mean “interesting” in the sense that the normal orderly development process that is used for most TCP/IP protocols broke down. The result wasn't quite as bad as [what occurred with SNMP](#), but is still unusual.

The first version of IMAP formally documented as an Internet standard was IMAP version 2 (IMAP2) in RFC 1064, published July 1988. This was updated in RFC 1176, August 1990, retaining the same version number. However, it seems that some of the people involved with IMAP were not pleased with RFC 1176, so they created a new document defining version 3 of IMAP (IMAP3): RFC 1203, published in February 1991. This is described by its authors as a “counter proposal”.

For whatever reason, however, IMAP3 was never accepted by the marketplace. Instead, people kept using IMAP2 for a while. An extension to the protocol was later created, called *IMAP2bis*, which added support for [MIME](#) to IMAP. This was an important development due

---

to the usefulness of MIME, and many implementations of IMAP2bis were created. Despite this, for some reason IMAP2bis was never published as an RFC. This may have been due to the problems associated with the publishing of IMAP3.

**Note:** “bis” is a Latin word meaning “again”. It is sometimes used to differentiate changed technical documents from their previous versions when no “official” new version number is allocated.

---

In December 1994, IMAP version 4 (IMAP4) was published in two RFCs: RFC 1730 describing the main protocol, and RFC 1731 describing authentication mechanisms for IMAP4. IMAP4 is the current version of IMAP and the one widely used today. It continues to be refined; the latest specific version is actually called version *4rev1* (*IMAP4rev1*), defined in RFC 2060 and then most recently by RFC 3501. Most people still just call this “IMAP4” and that’s what I will do in the rest of this section.

### **IMAP4 General Operation, Client/Server Communication and Session States**

IMAP does the same basic job as [POP](#): it enables access to a mailbox stored on a remote server. For this reason, it’s not too surprising that IMAP is somewhat similar to POP in operation, and you’ll notice those similarities in this topic if you’ve already read about POP3. However, IMAP has many more features and capabilities than POP. Therefore, it’s also not too surprising that IMAP would be more complex than POP in terms of how it operates, and I think you will notice this as well.

#### ***Client/Server Communication***

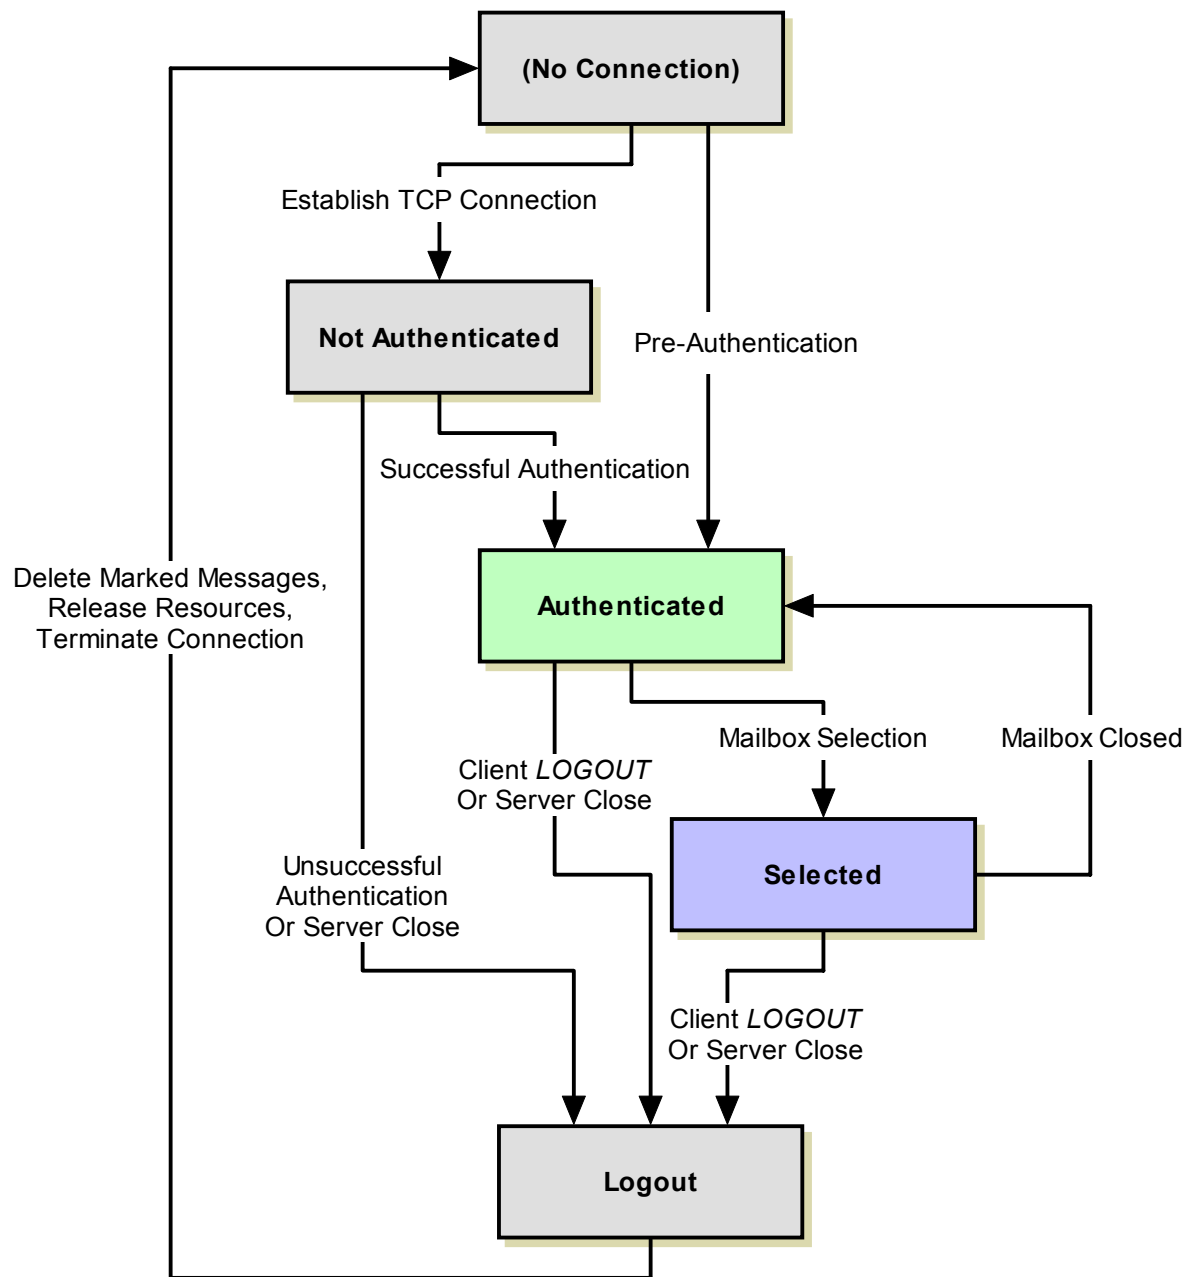

IMAP4 is a standard client/server protocol like POP3 and [most other TCP/IP application protocols](#). For the protocol to function, an IMAP4 server must be operating on the server where user mailboxes are located. Again, as with POP3, this need not necessarily be the same physical server as the one that provides SMTP service. The mailbox must in some way be made accessible to both SMTP for incoming mail and to IMAP4 for message retrieval and modification. A mechanism for ensuring exclusive access to avoid interference between the various protocols is also needed.

IMAP4 uses the [Transmission Control Protocol \(TCP\)](#) for communication. This ensures that all commands and data are sent reliably and received in the correct order. IMAP4 servers listen on [well-known port number](#) 143 for incoming connection requests from IMAP4 clients. After a TCP connection is established, the IMAP4 session begins.

#### ***Session States***

The session between an IMAP4 client and server is described in the IMAP standards using a finite state machine (FSM), a descriptive tool that I explain in [the TCP operational overview](#). Again, this is similar to [how the operation of POP3 is explained](#), except that IMAP4 is a bit more complex. Its FSM defines four states instead of three, and where a

POP3 session is linear (only going through each state once) in IMAP4 the session is not. However, the state flow is still fairly straight-forward, mostly following a logical sequence from one state to the next. The IMAP FSM is illustrated in [Figure 309](#).

**Figure 309: Internet Message Access Protocol (IMAP) Finite State Machine**

The IMAP finite state machine is slightly more complex than that of POP ([Figure 306](#)) but still rather straight-forward. Once the TCP connection is made between client and server, the *Not Authenticated* state is entered; after successful authorization, the session moves to the *Authenticated* state. The session may move between *Authenticated* and *Selected* several times, as different mailboxes are selected for use and then closed when no longer needed. From any state the session may be terminated, entering the *Logout* state.

The following are the IMAP states, in the usual sequence in which they occur for a session:

- 
1. **Not Authenticated State:** The session normally begins in this state after a TCP connection is established, unless the special IMAP *preauthentication* feature has been used (we'll get to this feature shortly). The client at this point cannot really do much aside from providing authentication information so it can move to the next state.
  2. **Authenticated State:** The client has completed authentication, either through an authentication process in the prior state or through preauthentication. The client is now allowed to perform operations on whole mailboxes. The client must select a mailbox before individual message operations are permitted.
  3. **Selected State:** After a mailbox has been chosen, the client is allowed to access and manipulate individual messages within the mailbox. When the client is done with the current mailbox it can close it and return to the *Authenticated* state to select a new one to work with, or can log out to end the session.
  4. **Logout State:** The client may issue a *Logout* command from any of the other states to request that the IMAP session be ended. The session may also enter this state if the session inactivity timer expires. The server sends a response and the connection is terminated.

Of the four IMAP states, only the first three are “interactive”, meaning states where commands are actively issued by the client and responses provided by the server. Some IMAP commands can be used while the session is in any state, while others are state-specific. [The next topic](#) describes IMAP commands and responses in general terms.

**Key Concept:** IMAP is a client/server application, and an IMAP session begins with the client making a TCP connection to the server. The session then normally starts in the *Not Authenticated* state and remains there until successful authentication. In the *Authenticated* state, the client may perform operations on whole mailboxes, but a mailbox must be *selected* to transition to the *Selected* state where individual messages can be manipulated. The client can work with many mailboxes by selecting each one in turn; it then logs out from the server.

---

### ***Normal Session Establishment and Greeting***

The server determines in which state the IMAP session begins, and sends a *greeting* message to tell the client the session is established and indicate which state it is in. Normally, the server will begin the session in the *Not Authenticated* state. This is conveyed to the client with the normal *OK* greeting message, such as this:

\* OK <server-name> server ready

---

## **Preauthentication**

In certain circumstances, a server may already know the identity of the client, perhaps as a result of some external authentication mechanism not part of the IMAP protocol. In this case, a special greeting is used:

\* PREAUTH <server-name> server ready, logged in as <user-name>

This tells the client that it is already in the *Authenticated* state.

If the server decides for whatever reason not to accept a new session from the client, it can respond with a *BYE* response instead of *OK* or *PREAUTH*, and close the TCP connection.

## **IMAP Commands, Results and Responses**

Once an IMAP session is established, all communication between the client and server takes place in the form of *commands* sent by the client and *responses* returned by the server. Like POP3, commands and responses are sent as strings of ASCII text and terminated with a “CRLF” sequence, making them compatible with the way data is sent using the [Telnet Protocol](#). However, IMAP does a few things quite differently than POP and many other TCP/IP application protocols.

The first interesting thing about IMAP commands is that most are not abbreviated into codes of three or four letters—they are spelled out in full. So, where POP3 has a *STAT* command, the one in IMAP is called *STATUS*. Commands are normally shown in upper case, as I do in this Guide, but are in fact case-insensitive.

## ***Command Tagging and the Multiple Command Feature***

IMAP also uses an interesting system of *command tagging* to explicitly match client commands with certain server responses. Each time a client sends a command, it prefixes it with a tag that is unique for the particular session. The tags are usually short strings with a monotonically increasing number in them; the examples in the IMAP standards have the first command tagged “a0001”, then the second “a0002” and so on. That said, as long as each command is uniquely labelled, it doesn't matter what tagging scheme is used. When the server needs to send a response that is specific to a command, it tags the reply with the appropriate command tag. Not all replies are tagged, however.

The standard doesn't state explicitly why this tagging scheme is needed, but I believe it is probably related to IMAP's *multiple command* feature. IMAP clients are allowed to send a sequence of commands to the server to be processed, rather than only sending commands one at a time. This can improve performance when certain commands would take a long time to complete. The only restriction is that the commands must be independent enough that the result of executing them all would be the same regardless of the order in which they were processed. For example, sending a command to read a particular entity in combination with a command to store a value into the same entity is not allowed.

---

**Key Concept:** IMAP tags its commands with a unique identifier. These tags can then be used in replies by the server to match replies with the commands to which they correspond. This enables multiple commands to be sent to an IMAP server in succession.

---

## Command Groups

IMAP commands are organized into groups based on which [session states](#) the IMAP session may be in when they are used. These groups are:

- ☉ **“Any State” Commands:** A small number of commands that can be used at any time during an IMAP session.
- ☉ **Not Authenticated State Commands:** Commands that can be used only in the *Not Authenticated* state. They are usually used for authentication, of course.
- ☉ **Authenticated State Commands:** These commands are used to perform various actions on mailboxes. (Note that despite the name, these commands can also be used in the *Selected* state.)
- ☉ **Selected State:** A set of commands for accessing and manipulating individual messages that can be used only in the *Selected* state.

The reason for having the distinct *Authenticated* and *Selected* states and command groups is that IMAP is designed specifically to enable the manipulation of multiple mailboxes. After the session starts and the client is authenticated, the client is allowed to issue commands that work with entire mailboxes. However, it may not issue commands that manipulate individual messages until it tells the server which mailbox it wants to work with, which puts it in the *Selected* state. The client can also issue mailbox commands from the *Selected* state.

---

**Note:** In addition to these four groups, the standard also defines an *extension mechanism* that allows new commands to be defined. These must begin with the letter “X”.

---

## “Any State” Commands

[Table 260](#) describes the IMAP “any state” commands, which can be used whenever needed.

**Table 260: IMAP “Any State” Commands (Page 1 of 2)**

Command	Parameters	Description
<b>CAPABILITY</b>	None	Asks the server to tell the client what capabilities and features it supports.

---

Table 260: IMAP “Any State” Commands (Page 2 of 2)

Command	Parameters	Description
<b>NOOP</b> (No Operation)	None	Does nothing. This may be used to reset the inactivity timer or to periodically prompt the server to send notification if new messages arrive.
<b>LOGOUT</b>	None	Tells the server that the client is done and ready to end the session, which transitions to the Logout state for termination.

### Results and Responses

Each command sent by the IMAP client elicits some sort of reaction from the IMAP server, of course. The server takes action based on what the client requested, and then returns back one or more text strings to indicate what occurred. There are actually two types of replies that the server can send after a command is received:

- ☉ **Result:** This is a reply usually indicating the status or disposition of a command. It may be tagged with the command tag of the command whose result it is communicating, or may be a general message that is not tagged.
- ☉ **Response:** Any type of information that is being sent by the server to the client. It is usually not tagged with a command tag and is not specifically intended to indicate server status.

**Note:** The IMAP standards sometimes use the terms “result”, “response” and “reply” in a manner that I find to be inconsistent. Watch out for this if you examine the IMAP RFCs.

**Key Concept:** IMAP servers issue two basic types of replies to client commands. *Results* are replies that indicate the success, failure or status of a command; *responses* are general replies containing many different types of information that the server needs to send to the client.

### Result Codes

There are three main result codes sent in reply to a command, and two special ones used in certain circumstances:

- ☉ **OK:** A positive result to a command, usually sent with the tag of the command that was successful. May be sent untagged in the server's initial greeting when a session starts.
- ☉ **NO:** A negative result to a command. When tagged, indicates the command failed; when untagged, serves as a general warning message about some situation on the server.

- 
- ☉ **BAD:** Indicates an error message. It is tagged when the error is directly related to a command that has been sent, and otherwise is untagged.
  - ☉ **PREAUTH:** An untagged message sent at the start of a session to indicate that no authentication is required; the session goes directly to the *Authenticated* state.
  - ☉ **BYE:** Sent when the server is about to close the connection. It is always untagged, and is sent in reply to a *Logout* command or when the connection is to be closed for any other reason.

## Response Codes

In contrast to results, responses are used to communicate a wide variety of information to the client device. Responses normally include descriptive text that provides details about what is being communicated. They may be sent either directly in reply to a command or incidentally to one. An example of the latter case would be if a new message arrives in a mailbox during a session. In this case, the server will convey this information “unilaterally” at its first opportunity, regardless of what command was recently sent.

The following are the response codes defined by the IMAP standard:

- ☉ **ALERT:** An alert message to be sent to the human user of the IMAP client to inform him or her of something important.
- ☉ **BADCHARSET:** Sent when a search fails due to use of an unsupported character set.
- ☉ **CAPABILITY:** A list of server capabilities; may be sent as part of the initial server greeting so the *CAPABILITY* command does not need to be used.
- ☉ **PARSE:** Sent when an error occurs parsing the headers or MIME content of an e-mail message.
- ☉ **PERMANENTFLAGS:** Communicates a list of message status flags that the client is allowed to manipulate.
- ☉ **READ-ONLY:** Tells the client that the mailbox is only accessible in a read-only mode.
- ☉ **READ-WRITE:** Tells the client that the mailbox is accessible in read-write mode.
- ☉ **TRYCREATE:** Sent when an *APPEND* or *COPY* command fails due to the target mailbox not existing, to suggest to the client that it try creating the mailbox first.
- ☉ **UIDNEXT:** Sent with a decimal number that specifies the next unique identifier value to use in an operation. These identifiers allow each message to be uniquely identified.
- ☉ **UIDVALIDITY:** Sent with a decimal number that specifies the unique identifier validity value, used to confirm unique message identification.
- ☉ **UNSEEN:** Sent with a decimal number that tells the client the message that is flagged as not yet seen (a new message).

## IMAP4 Not Authenticated State: User Authentication Process and Commands

An IMAP4 session begins with an IMAP4 client establishing a TCP connection with an IMAP4 server. Under normal circumstances, the IMAP4 server has no idea who the client is, and therefore starts the session in the *Not Authenticated* state. For security reasons, the

---

client is not allowed to do anything until it is authenticated. Thus, the only purpose of this state is to allow the client to present valid credentials so the session can move on to the *Authenticated* state.

### **IMAP Not Authenticated State Commands**

The IMAP4 standard defines three different mechanisms by which a client may authenticate itself. These are implemented using one or more of the three different commands allowed only in the *Not Authenticated* state, which are shown in [Table 261](#).

**Table 261: IMAP Not Authenticated State Commands**

Command	Parameters	Description
<b>LOGIN</b>	User name and password	Specifies a user name and password to use for authentication.
<b>AUTHENTICATE</b>	Authentication mechanism name	Tells the server that the client wants to use a particular authentication mechanism and prompts the client and server to exchange authentication information appropriate for that mechanism.
<b>STARTTLS</b>	None	Tells the IMAP4 server to use the Transport Layer Security (TLS) protocol for authentication, and prompts TLS negotiation to begin.

### **IMAP Authentication Methods**

The authentication methods are:

1. **Plain Login:** This is the typical “username / password” technique, using the *LOGIN* command by itself. This is similar to [the simple scheme used in POP3](#), except that in IMAP4 one command is used to send both the user name and password. Since the command and parameters are sent in plain text, this is by far the least secure method of authentication and is not recommended by the standard unless some other means is used in conjunction.
2. **TLS Login:** This is a secure login where the Transport Layer Security (TLS) protocol is first enabled with the *STARTTLS* command, and then the *LOGIN* command can be used securely. Note that *STARTTLS* only causes the TLS negotiation to begin, and does not itself cause the IMAP client to be authenticated. Either *LOGIN* or *AUTHENTICATE* must still be used.
3. **Negotiated Authentication Method:** The *AUTHENTICATE* command allows the client and server to use any authentication scheme that they both support. The server may indicate which schemes it supports in response to a *CAPABILITY* command. After specifying the authentication mechanism to be used, the server and client exchange authentication information as required by the mechanism specified. This may require one or more additional lines of data to be sent.

In response to a *LOGIN* or *AUTHENTICATE* command, the server will send an “OK” message if the authentication was successful, and then transition to the *Authenticated* state. It will send a “NO” response if authentication failed due to incorrect information. The client can then try another method of authenticating, or terminate the session with the *LOGOUT* command.

**Key Concept:** IMAP supports three basic types of authentication: a plain username/password login; authentication using Transport Layer Security; or the negotiation of some other authentication method between the client and server. In some cases, the IMAP server may choose to *preauthenticate* clients that it is able to reliably identify, in which case the *Not Authenticated* state is skipped entirely.

## **IMAP4 *Authenticated* State: Mailbox Manipulation/Selection Process and Commands**

In the normal progression of an IMAP session, the *Authenticated* state is the first one where the IMAP client is able to perform “useful work” on behalf of its user. This state will normally be reached from the *Not Authenticated* state after successful authentication using the *LOGIN* or *AUTHENTICATE* command. Alternately, a server may *preauthenticate* a client and begin the session in this state directly.

Once in the *Authenticated* state, the client is considered authorized to issue commands to the server. However, it may only give commands that deal with *whole mailboxes*. As mentioned in the [general operation overview](#), IMAP was created to allow access to, and manipulation of, multiple mailboxes. For this reason, the client must specify dynamically which mailbox it wants to use before commands dealing with individual messages may be given. This is done in this state using the *SELECT* or *EXAMINE* commands, which cause a transition to the *Selected* state as we will see.

It is also possible that the *Authenticated* state can be re-entered during the course of a session. If the *CLOSE* command is used from the *Selected* state to close a particular mailbox, the server will consider that mailbox “de-selected” and the session will transition back to the *Authenticated* state until a new selection is made. The same can occur if a new *SELECT* or *EXAMINE* command is given from the *Selected* state but fails.

### ***Authenticated State Commands***

[Table 262](#) provides a brief description of the mailbox-manipulation commands that can be used in the *Authenticated* state:

**Table 262: IMAP *Authenticated* State Commands (Page 1 of 2)**

Command	Parameters	Description
<b><i>SELECT</i></b>	Mailbox name	Selects a particular mailbox so that messages within it can be accessed. If the command is successful, the session transitions to the <i>Selected</i> state. The server will also normally respond with information for the client about the selected mailbox; see below.
<b><i>EXAMINE</i></b>	Mailbox name	Exactly the same as the <i>SELECT</i> command, except that the mailbox is opened “read-only”; no changes are allowed to it.
<b><i>CREATE</i></b>	Mailbox name	Creates a mailbox with the given name.
<b><i>DELETE</i></b>	Mailbox name	Deletes the specified mailbox.

**Table 262: IMAP *Authenticated* State Commands (Page 2 of 2)**

Command	Parameters	Description
<b>RENAME</b>	Current and new mailbox names	Renames a mailbox.
<b>SUBSCRIBE</b>	Mailbox name	Adds the mailbox to the server's set of "active" mailboxes. This is sometimes used when IMAP4 is employed for <a href="#">Usenet</a> message access.
<b>UNSUBSCRIBE</b>	Mailbox name	Removes the mailbox from the "active" list.
<b>LIST</b>	Mailbox name or reference string	Requests a partial list of available mailbox names, based on the parameter provided.
<b>LSUB</b>	Mailbox name or reference string	The same as <i>LIST</i> but only returns names from the "active" list.
<b>STATUS</b>	Mailbox name	Requests the status of the specified mailbox. The server responds providing information such as the number of messages in the box and the number of recently-arrived and unseen messages.
<b>APPEND</b>	Mailbox name, message, optional flags and date/time	Adds a message to a mailbox.

**Note:** All of the commands above may also be used in the *Selected* state; they should really be called "*Authenticated+Selected*" state.commands.

### The *SELECT* and *EXAMINE* Commands

When either the *SELECT* or *EXAMINE* command is successfully issued, the server will return to the client a set of useful information about the mailbox, which can be used to guide commands issued from the *Selected* state. This information includes the following three mandatory responses:

- ☉ **<n> EXISTS:** Tells the client the number of messages in the mailbox.
- ☉ **<n> RECENT:** Tells the client the number of recently-arrived (new) messages.
- ☉ **FLAGS (<flag-list>):** Tells the client which flags are supported in the mailbox. These include the following: "\Seen", "\Answered", "\Flagged" (marked for special attention), "\Deleted", "\Draft" and "\Recent". (The backslashes are part of the flag names.)

The reply from the server may also contain these optional replies:

- ☉ **UNSEEN <n>:** The message number of the first unseen message.
- ☉ **PERMANENTFLAGS (<flag-list>):** A list of flags (as for the *FLAGS* response above) that the client is allowed to change.
- ☉ **UIDNEXT <n>:** The next unique identifier value. This is used to check for changes made to the mailbox since the client last accessed it.

- 
- ☉ **UIDVALIDITY <n>**: The unique identifier validity value, used to confirm valid UID values.

**Key Concept:** In the *Authenticated* state, the IMAP client can perform operations on whole mailboxes, such as creating, renaming or deleting mailboxes, or listing mailbox contents. The *SELECT* and *EXAMINE* commands are used to tell the IMAP server which mailbox the client wants to open for message-specific access. Successful execution of either command causes the server to provide the client with several pieces of important information about the mailbox, after which the session transitions to the *Selected* state.

---

### **IMAP4 *Selected* State: Message Manipulation Process and Commands**

Once the IMAP client has been authorized to access the server, it enters the *Authenticated* state, where it is allowed to execute tasks on whole mailboxes. Since IMAP allows multiple mailboxes to be manipulated, message-specific commands cannot be used until the client tells the server what mailbox it wants to work with. Only one mailbox can be accessed at a time in a given session.

After the *SELECT* or *EXAMINE* command is successfully issued, the session enters the *Selected* state. In this state, the full “palette” of message and mailbox commands is available to the client. This includes the message-specific commands below as well as the mailbox commands defined for the *Authenticated* state. Most of IMAP's message-specific commands do not include a mailbox name as a parameter, since the server knows automatically that the commands apply to whatever mailbox was selected in the *Authenticated* state.

The session remains in the *Selected* state for as long as the client continues to have work to do with the particular selected (or “examined”) mailbox. Three different actions can cause a transition out of the *Selected* state:

- ☉ If the client has nothing more to do when it is done with the current mailbox, it can use the *LOGOUT* command to end the session.
- ☉ The client can use the *CLOSE* command to tell the server it is done with the current mailbox but keep the session active. The server will close the mailbox and the session will go back to the *Authenticated* state.
- ☉ The client can issue a new *SELECT* or *EXAMINE* command. This will implicitly close the current mailbox and then open the new one. The transition in this case is from the *Selected* state back to the *Selected* state, but with a new current mailbox.

---

## Selected State Commands

Table 263 lists the message-specific commands that can only be used in the *Selected* state.

**Table 263: IMAP Selected State Commands**

Command	Parameters	Description
<b>CHECK</b>	None	Sets a “checkpoint” for the current mailbox. This is used to mark when a certain sequence of operations has been completed.
<b>CLOSE</b>	None	Explicitly closes the current mailbox and returns the session to the <i>Authenticated</i> state. When this command is issued, the server will also implicitly perform an <i>EXPUNGE</i> operation on the mailbox.
<b>EXPUNGE</b>	None	Permanently removes any messages that were flagged for deletion by the client. This is done automatically when a mailbox is closed.
<b>SEARCH</b>	Search criteria and an optional character set specification	Searches the current mailbox for messages matching the specified search criteria. The server response lists the message numbers meeting the criteria. See below.
<b>FETCH</b>	Sequence of message numbers and a list of message data items (or a macro)	Retrieves information about a message or set of messages from the current mailbox. See below for more details.
<b>STORE</b>	Sequence of message numbers, message data item name and value	Stores a value for a particular message data item for a set of messages. See below for more details.
<b>COPY</b>	Sequence of message numbers and a mailbox name	Copies the set of messages specified to the end of the specified mailbox.
<b>UID</b>	Command name and arguments	Used to allow one of the other commands above to be performed using unique identifier numbers for specifying the messages to be operated on, rather than the usual message sequence numbers.

### The *FETCH* and *STORE* Commands

This command list might seem surprisingly short; you might wonder, for example, where the specific commands are to read a message header or body, delete a message, mark a message as “seen” and so forth. The answer is that these (and much more) are all implemented as part of the powerful and flexible *FETCH* and *STORE* commands.

The *FETCH* command can be used to read a number of specific elements from either one message or a sequence of messages. The list of “message data items” specifies what information is to be read. The data items that can be read include the headers of the message, the message body, flags that are set for the message, the date of the message and much

---

more. The *FETCH* command can even be used to retrieve **part** of a message, such as one body part of a [MIME multipart message](#), making it very useful indeed. Special “macros” are also defined for convenience. For example, the client can specify the message data item “FULL” to get all the data associated with a message.

The compliment to *FETCH*, *STORE*, is used to make changes to a message. However, this command is not used to modify the basic message information such as the content of headers and the message body. Rather, it exists for changing the message's *status flags*. For example, after replying to a particular message, the client may set the “\Answered” flag for that message using the *STORE* command.

Message deletion in IMAP is done in two stages for safety, as in POP and many other protocols. The client sets the “\Deleted” flag for whichever messages are to be removed, using the *STORE* command. The messages are only really deleted when the mailbox is expunged, typically when it is closed.

The search facility in IMAP4 is also surprisingly quite sophisticated, allowing the client to look for messages based on multiple criteria simultaneously. For example, with the appropriate syntax, you could search for “all posts that are flagged as having been answered, that were sent by Jane Jones before April 1, 2004”. Users of IMAP clients can thus easily locate specific messages even in very large mailboxes, without having to download hundreds of messages to hunt through.

**Key Concept:** After the client opens a specific mailbox, the IMAP session enters the *Selected* state, where operations such as reading and copying individual e-mail messages may be performed. The two most important commands used in this state are *FETCH*, which can be used to retrieve a whole message, part of a message, or only certain message headers or flags; and *STORE*, which sets a message's status information. IMAP also includes a powerful *search* facility, providing users with great flexibility in finding messages in a mailbox. When the client is done working with a particular mailbox, it may choose a different one and re-enter the *Selected* state, close the mailbox and return to the *Authenticated* state, or log out, automatically entering the *Logout* state.

---

---

## **Other TCP/IP Electronic Mail Access and Retrieval Methods**

The [Post Office Protocol \(POP3\)](#) and [Internet Message Access Protocol \(IMAP4\)](#) are the two most common protocols employed for TCP/IP e-mail access and retrieval. The majority of people using e-mail today choose the simplicity and universal acceptance of POP3, while a growing number opt for the power and flexibility of IMAP4. There are, however, some that choose “alternative” ways of accessing e-mail, two of which I feel are worth a closer look.

Both of the methods described in this section are based on the “online” [e-mail access model](#), but they are a study in contrasts in terms of their role in the e-mail system and how they are used. The first is what I call *direct server access*, and describes several ways that mailboxes are accessed without the use of special remote access protocols like POP and IMAP. The second is e-mail access using a World Wide Web browser. This is the newest e-mail access method, and is growing in popularity every year.

### **TCP/IP Direct Server Electronic Mail Access**

In my [overview discussion of e-mail message communication](#), I discussed the different devices involved in a complete mail exchange, and how a message is created and then transported from the originator to the recipient. SMTP is used to carry the message most of the way, to the recipient's mailbox. The last step of the process is to convey the message from the server where the mailbox is located to the machine the client is using.

This final portion of the e-mail journey is usually the job of an e-mail access and retrieval protocol like [POP3](#) or [IMAP4](#). These are *customized* protocols, by which I mean that they were created specifically for the last step of the e-mail communication process. However, there are also several *generic* methods by which an e-mail client can gain access to a mailbox, without the use of a special protocol at all.

### ***E-Mail Direct Access Methods***

These methods are all variations of the *online e-mail access model*. They generally work by establishing *direct access* to the server where the mailbox is located. The mailbox itself is just a file on a server somewhere, so if that file can be made available, it can be viewed and manipulated like any other file using an e-mail client program that reads and writes the mailbox file. The following are some of the ways in which this can be done:

- ☉ **Using The SMTP Server Directly:** Obviously, the simplest method for gaining access to the mailbox is to simply log on to the server itself. This is not an option for most people, and even in years gone by it was not often done, for security reasons as well as others. However, even today there are some people who do run their own SMTP servers, giving them considerable control over access to their e-mail.
- ☉ **File Sharing Access:** Using a protocol such as the [Network File System](#), it is possible to have a mailbox mounted on a user's client machine where it can be accessed as if it were a local file. The mail is still on the server and not the client machine, but the communication between the client and the server occurs “transparently” to both the user and the e-mail client software.

- 
- ☉ **Dial-Up Remote Server Access:** A user on a client machine dials up a server where his or her mailbox is located and logs in to it. The user then can issue commands to access mail on that server as if he or she were logged in to it directly.
  - ☉ **Telnet Remote Server Access:** Instead of dialing in to the server, a user can connect to it for remote access using the [Telnet Protocol](#).

### ***Pros and Cons of Direct Server E-Mail Access***

These techniques are much more commonly associated with timesharing systems, which commonly use the UNIX family of operating systems than others. They are also often combined; for example, remote access is often provided for UNIX users, but most companies don't want users logging in directly to the SMTP server. Instead, an Internet service provider might run an SMTP server on one machine called "mail.companyname.com" and also operate a different server that is designed for client access called "users.companyname.com". A user could access e-mail by dialing into the "users" machine, which would employ NFS to access user mailboxes on the "mail" machine.

Direct server access is a method that has been around for decades. At one time, this was how the majority of people accessed e-mail, for two main reasons. First, if you go back far enough, protocols like POP or IMAP had not yet been developed; the TCP/IP e-mail system as a whole predates them by many years and direct access was the only option back then. Second, the general way that e-mail and networks were used years ago was just different than it is today. Most individuals did not have PCs at home, and there was no Internet as we know it. Remotely accessing a UNIX server using a modem or Telnet for e-mail and other services was just "the way it was done".

I myself got started using direct server access for e-mail over 10 years ago, and still use this today. I Telnet in to a client machine and use a UNIX e-mail program called *elm* to access and manipulate my mailbox. To me, this provides numerous advantages. First and most importantly, I can access my e-mail using Telnet from any machine on the Internet, anywhere around the world. Second, since I am logged in directly, I get immediate notification when new mail arrives, without having to routinely check for new mail. Third, my mailbox is always accessible and all my mail is always on a secure server in a professionally-managed data center. Fourth, I have complete control over my mailbox and can edit it, split it into folders, write custom "spam" filters, or do anything else I need to do.

This probably sounds good, but most people today do not use direct server access because of the disadvantages of this method. One big issue is that you must be logged in to the Internet to access your e-mail. Another one, perhaps even larger, is the need to be familiar with UNIX and a UNIX e-mail program. UNIX is simply not as "user-friendly" as a graphical operating systems such as Windows or the Apple Macintosh. For example, my UNIX e-mail program doesn't support color and cannot show me attached graphic images. I must extract images and other files from [MIME messages](#) and transfer them to my own PC for viewing.

---

Most people today don't know UNIX and don't want to know it. They are much happier using a fancy graphical e-mail program based on POP3 or IMAP4. However, there are still a number of us old UNIX dinosaurs around who feel the benefits of direct access outweigh the drawbacks. Oh, one other benefit that I forgot to mention is that it's very hard to get a virus in e-mail when you use UNIX.

**Key Concept:** Instead of using a dedicated protocol like POP3 or IMAP4 to retrieve mail, on some systems it is possible for a user to have *direct server access* to e-mail. This is most commonly done on UNIX systems, where protocols like Telnet or NFS can give a user shared access to mailboxes on a server. This is the oldest method of e-mail access; it provides the user with the most control over his or her mailbox, and is well-suited to those who must access mail from many locations. The main drawback is that it means the user must be on the Internet to read e-mail, and it also usually requires familiarity with the UNIX operating system, which few people use today.

---

## **TCP/IP World Wide Web Electronic Mail Access**

I don't know about you, but I was pretty darned glad when bell bottoms went out of style... and then, rather mortified when they came **back** in style a few years ago! That's the way the world of fashion is, I suppose. And sometimes, even in networking, "what's old is new again". In this case, I am referring to the use of the online TCP/IP e-mail access model.

Most e-mail users like the advantages of online access, especially the ability to read mail from a variety of different machines. What they don't care for is [direct server access](#) using protocols like [Telnet](#) ("Tel-what?"), UNIX ("my father used to use that I think..." ☺) and non-intuitive, character-based e-mail programs. They want online access but they want it to be simple and easy to use.

In the 1990s, the [World Wide Web](#) was developed and grew in popularity very rapidly, due in large part to its ease of use. Millions of people became accustomed to firing up a Web browser to perform a variety of different tasks, to the point where using the Web became almost "second nature". It didn't take very long before someone figured out that using the Web would be a natural way of providing easy access to e-mail on a server. This is now sometimes called *Webmail*.

### ***How Web-Based E-Mail Works***

This technique is straight-forward: it exploits the flexibility of the [Hypertext Transfer Protocol \(HTTP\)](#) to informally "tunnel" e-mail from a mailbox server to the client. A Web browser (client) is opened and given a URL for a special Web server document that accesses the user's mailbox. The Web server reads information from the mailbox and sends it to the Web browser, where it is displayed to the user.

This method uses the [online access model](#) like direct server access, because requests must be sent to the Web server, and this requires the user to be online. The mail also remains on the server as when [NFS](#) or Telnet are used.

---

## Pros and Cons of Web-Based E-Mail Access

The big difference between Web-based mail and the UNIX methods is that the former is much easier for non-experts to use. Since the idea was first developed, many companies have jumped on the Web-mail bandwagon, and the number of people using this technique has exploded into the millions in just a few years. Many free services even popped up in the late 1990s as part of the “dot com bubble”, allowing any Internet user to send and receive e-mail using the Web at no charge (except perhaps for tolerating advertising). Many Internet Service Providers (ISPs) now offer Web access as an option in addition to conventional POP/IMAP access, which is useful for those who travel. Google’s new Gmail service is the latest entrant into the sweepstakes, offering users 1 GB of e-mail storage in exchange for viewing Google’s text ads on their site.

There are drawbacks to the technique, however, which as you might imagine are directly related to its advantages. Web-based mail is easy to use, but inflexible; the user does not have direct access to his or her mailbox, and can only use whatever features the provider’s Web site implements. For example, suppose the user wants to search for a particular string in his or her mailbox; this requires that the Web interface provide this function. If it doesn’t, the user is out of luck.

Web-based mail also has a disadvantage that is an issue for some people: performance. Using conventional UNIX direct access, it is easy to quickly read through a mailbox; the same is true of access using POP3, once the mail is downloaded. In contrast, Web-based mail services mean each request requires another HTTP request/response cycle. The fact that many Web-based services are free often means server overload that exacerbates the speed issue.

Note that when Web-based mail is combined with other methods such as POP3, care must be taken to avoid strange results. If the Web interface doesn’t provide all the features of the conventional e-mail client, certain changes made by the client may not show up when Web-based access is used. Also, mail retrieval using POP3 by default removes the mail from the server. If you use POP3 to read your mailbox and then later try to use the Web to access those messages from elsewhere, you will find that the mail is “gone”—it’s on the client machine where you used the POP3 client. Many e-mail client programs now allow you to specify that you want the mail left on the server after retrieving it using POP3.

**Key Concept:** In the last few years a new method has been developed to allow e-mail access using the *World Wide Web (WWW)*. This technique is growing in popularity rapidly, because it provides many of the benefits of direct server access, such as the ability to receive e-mail anywhere around the world, while being much simpler and easier than the older methods of direct access such as making a Telnet connection to a server. WWW-based e-mail can in some cases be used in combination with other methods or protocols, such as POP3, giving users great flexibility in how they read their mail.

---

---

## Usenet (Network News) and the TCP/IP Network News Transfer Protocol (NNTP)

**Electronic mail** is one of the “stalwarts” of message transfer on the modern Internet, but is really designed only for communication within a relatively small group of specific users. There are many situations in which e-mail is not ideally suited, such as when information needs to be shared amongst a large number of participants, not all of whom may necessarily even know each other. One classic example of this is sharing *news*; the person providing news often wants to make it generally available to **anyone** who is interested, rather than specifying a particular set of recipients.

For distributing news and other types of general information over internetworks, a messaging system called both *Usenet* (for *user's network*) and *Network News* was created. This application is like e-mail in allowing messages to be written and read by large numbers of users. However, it is designed using a very different model than e-mail, focused on public sharing and feedback. In Usenet, anyone can write a message that can be read by any number of recipients, and can likewise respond to messages written by others. Usenet was one of the first widely-deployed internetwork-based group communication applications, and has grown into one of the largest online communities in the world, used by millions of people for sharing information, asking questions and discussing thousands of different topics.

In this section I describe Usenet in detail, discussing in two subsections how it is used and how it works. The first subsection covers Usenet in general terms, discussing its history and the model it uses for communication and message storage and formatting. The second describes the Network News Transfer Protocol (NNTP), the protocol currently used widely to implement Usenet communication in TCP/IP.

Many people often equate the Usenet system as a whole with the NNTP protocol that is used to carry Usenet messages on the Internet. They are not the same however; Usenet predates NNTP, which is simply a protocol for conveying Usenet messages. Usenet old-timers will be quick to point this out, if you try to say Usenet and NNTP are the same on Usenet itself. ☺ This is one of the reasons why I have separated my discussion into two subsections. In the overview of Usenet I do briefly discuss the methods other than NNTP that have been used in the past to move Usenet messages, but since they are not widely used today I do not place a great deal of emphasis on them.

**Background Information:** There are several aspects of how Usenet works that are closely related to the standards and techniques used for e-mail. I assume in this section that you have basic familiarity with how e-mail works. If you have not read the section on e-mail, please at least review [the overview of the e-mail system](#), and also read the section on the [e-mail message format](#), since Usenet messages are based directly on the RFC 822 e-mail message standard.

---

---

## **Usenet Overview, Concepts and General Operation**

Where [electronic mail](#) is the modern equivalent of the hand-written letter or the inter-office memo, *Usenet* is the updated version of the company newsletter, the cafeteria bulletin board, the coffee break chat, and the water cooler gossip session, all rolled into one. Spread worldwide over the Internet, Usenet newsgroup messages provide a means for people with common interests to form online communities, to discuss happenings, solve problems, and provide support to each other—as well as facilitating plain old socializing and entertainment.

In this section I discuss Usenet as a whole and how it operates. I begin with an overview and history of Usenet. I then provide a high-level look at the model of communication employed by Usenet, discussing how messages are created, propagated, stored and read. I discuss the Usenet addressing mechanism, which takes the form of a hierarchical set of *newsgroups*. I also explain how Usenet messages are formatted and discuss the special headers that provide information about a message and control how it is displayed and communicated.

### **Usenet Overview, History and Standards**

We are by nature both highly social and creative animals, and as a result, are always finding new ways to communicate. It did not take long after computers were first connected together for it to be recognized that those interconnections provided the means to link together *people* as well. The desire to use computers to create an *online community* led to the creation of Usenet over two decades ago.

#### ***History of Usenet***

Like almost everything associated with networking, Usenet had very humble beginnings. In 1979, Tom Truscott was a student at Duke University in North Carolina, and spent the summer as an intern at Bell Laboratories, the place where the UNIX operating system was born. He enjoyed the experience so much that when he returned to school that autumn, he missed the intensive UNIX environment at Bell Labs. He used the *Unix-to-Unix Copy Protocol (UUCP)* to send information from his local machine to other machines and vice-versa, including establishing electronic connectivity back to Bell Labs.

Building on this idea, Truscott and a fellow Duke student, Jim Ellis, teamed up with other UNIX enthusiasts at Duke and the nearby University of North Carolina at Chapel Hill, to develop the idea of an online community. The goal was to create a system where students could use UNIX to write and read messages, to allow them to obtain both technical help and maintain social contacts. The system was designed based on an analogy to an online newsletter that was open to all users of a connected system. To share information, messages were posted to *newsgroups*, where any user could access the messages to read them and respond to them as well.

The early work at Duke and UNC Chapel Hill resulted in the development of both the initial message format and the software for the earliest versions of this system, which became known both as *Network News (Net News)* and *Usenet* (a contraction of *User's network*). At

---

first, the system had just two computers, sharing messages posted in a pair of different newsgroups. The value of the system was immediately recognized, however, and soon many new sites were added to the system. These sites were arranged in a structure to allow messages to be efficiently passed using direct UUCP connections. The software used for passing news articles also continued to evolve and become more capable, as did the software for reading and writing articles.

The newsgroups themselves also changed over time. Many new newsgroups were created, and a hierarchical structure defined to help keep the newsgroups organized in a meaningful way. As more sites and users joined Usenet, more areas of interest were identified. Today there are a staggering number of Usenet newsgroups: over 100,000. While many of these groups are not used, there are many thousands of active ones that discuss nearly every topic imaginable, from space exploration, to cooking, to biochemistry, to PC trouble-shooting, to raising horses. There are also regional newsgroups devoted to particular areas; for example, there is a set of newsgroups for discussing events in Canada; another for discussing happenings in the New York area, and so on.

### ***Overview of Usenet Operation and Characteristics***

Usenet begins with a user writing a message to be distributed. After the message is *posted* to say, the group on TCP/IP networking, it is stored on that user's local news server, and special software sends copies of it to other connected news servers. The message eventually propagates around the world, where anyone who chooses to read the TCP/IP networking newsgroup can see the message.

The real power of Usenet is that after reading a message, any user can respond to it on the same newsgroup. Like the original message, the reply will propagate to each connected system, including the one used by the author of the original message. This makes Usenet very useful for sharing information about recent happenings, for social discussions, and especially for receiving assistance about problems, such as resolving technical glitches or getting help with a diet program.

What is particularly interesting about Usenet is that it is not a formalized system in any way, and is not based on any formally defined standards. It is a classic example of the development of a system in an entirely “ad hoc” manner; the software was created, people started using it, the software was refined, and things just took off from there. Certain standards have been written to codify how Usenet works—such as RFC 1036, which describes the Usenet message format—but these serve more as historical documents than as prescriptive standards.

There is likewise no “central authority” that is responsible for Usenet's operation, even though new users often think there is one. Unlike a dial-up bulletin board system or Web-based forum, Usenet works simply by virtue of cooperation between sites; there is no “manager in charge”. Usenet is for this reason sometimes called an “anarchy”, but this is not accurate. It isn't the case that there are no rules, only that it is the managers of participating systems that make policy decisions such as what newsgroups to support. There are also certain “dictatorial” aspects of the system, in that only certain people (usually system

---

administrators) can decide whether to create some kinds of new newsgroups. The system also has “socialistic” elements in that machine owners are expected to share messages with each other. So the simplified political labels really don't apply to Usenet at all.

Every community has a *culture*, and the same is true of online communities, including Usenet. There is an overall culture that prescribes acceptable behavior on Usenet, and also thousands of newsgroup-specific “cultures” in Usenet, each of which has evolved through the writings of thousands of participants over the years. There are even newsgroups devoted to explaining how Usenet itself operates, where you can learn about *newbies* (new users), *netiquette* (rules of etiquette for posting messages) and related subjects.

### ***Usenet Transport Methods***

As I said earlier, Usenet messages were originally transported using UUCP, which was created to let UNIX systems communicate directly, usually using telephone lines. For many years, all Usenet messages were simply sent from machine to machine using computerized telephone calls (just as e-mail once was). Each computer joining the network would connect to one already on Usenet and receive a *feed* of messages from it periodically; the owner of that computer had in turn to agree to provide messages to other computers.

Once TCP/IP was developed in the 1980s and the Internet grew to a substantial size and scope, it made sense to start using it to carry Usenet messages rather than UUCP. The *Network News Transfer Protocol (NNTP)* was developed specifically to describe the mechanism for communicating Usenet messages over TCP. It was formally defined in RFC 977, published in 1986, with NNTP extensions described in RFC 2980, October 2000.

For many years Usenet was carried using both NNTP and UUCP, but NNTP is now the mechanism used for the vast majority of Usenet traffic, and for this reason is the primary focus of my Usenet discussion in this Guide. NNTP is employed not only to distribute Usenet articles to various servers, but also for other client actions such as posting and reading messages. It is thus used for most of the steps in Usenet message communication.

It is because of the critical role of NNTP and the Internet in carrying messages in today's Usenet that the concepts are often confused. It's essential to remember, however, that Usenet does not refer to any type of physical network or internetworking technology; rather, it is a **logical** network of users. That logical network has evolved from UUCP data transfers to NNTP and TCP/IP, but Usenet itself is the same.

Today, Usenet faces “competition” from many other group messaging applications and protocols, including Web-based bulletin board systems and chat rooms. After a quarter of a century, however, Usenet has established itself and is used by millions of people every day. While to some, the primarily text-based medium seems archaic, it is a mainstay of global group communication and likely to continue to be so for many years to come.

**Key Concept:** One of the very first online electronic communities was set up in 1979 by university students who wanted to keep in touch and share news and other information. Today, this *User's Network (Usenet)*, also called *Network News*, has grown into a logical network that spans the globe. By posting messages to a Usenet newsgroup, people can share information on a variety of subjects of interest. Usenet was originally implemented in the form of direct connections established between participating hosts; today the Internet is the vehicle for message transport

---

### **Usenet Communication Model: Message Composition, Posting, Storage, Propagation and Access**

When the students at Duke University decided to create their online community, electronic mail was already in wide use, and there were many [mailing lists](#) in operation as well. E-mail was usually transported using UUCP during these pre-Internet days, the same method that Usenet was designed to employ. The obvious question then was, why not simply use e-mail to communicate between sites?

The main reason is that e-mail is not really designed to facilitate the creation of an online community where information can be easily shared in a group. The main issue with e-mail in this respect is that only the individuals who are specified as recipients of a message can read it. There is no facility whereby someone can write a message and put it in an open place where anybody who wants can read it, analogous to posting a newsletter in a public place.

Another problem with e-mail in large groups is related to efficiency: if you put 1,000 people on a mailing list, each message sent to that list must be duplicated and delivered 1,000 times. Early networks were limited in bandwidth and resources; using e-mail for wide-scale group communication was possible, but far from ideal.

**Key Concept:** While electronic mail can be used for group communications, it has two important limitations. First, a message must be specifically addressed to each recipient, making public messaging impossible. Second, each recipient requires delivery of a separate copy of the message, so sending a message to many recipients means the use of a large amount of resources.

---

### ***Usenet's Public Distribution Orientation***

To avoid the problems of using e-mail for group messaging, Usenet was designed using a rather different communication and message-handling model than e-mail. The defining difference between the Usenet communication model and that used for e-mail is that Usenet message handling is oriented around the concept of *public distribution*, rather than private delivery to an individual user. This affects every aspect of how Usenet communication works:

- 
- ☉ **Addressing:** Messages are not addressed from a sender to any particular recipient or set of recipients, but rather to a *group*, which is identified with a newsgroup name.
  - ☉ **Storage:** Messages are not stored in individual mailboxes but in a central location on a server, where any user of the server can access them.
  - ☉ **Delivery:** Messages are not conveyed from the sender's system to the recipient's system, but are rather spread over the Internet to *all* connected systems so anyone can read them.

### ***The Usenet Communication Process***

To help illustrate in more detail how Usenet communication works, let's take a look at the steps involved in the writing, transmission and reading of a typical Usenet message (also called an *article*—the terms are used interchangeably). Let's suppose the process begins with a user, Ellen, posting a request for help with a sick horse to the [newsgroup misc.rural](#). Since she is posting the message, she would be known as the message *poster*. Simplified, the steps in the process (illustrated in [Figure 310](#)) are as follows:

1. **Article Composition:** Ellen begins by creating a Usenet article, which is structured according to the [special message format required by Usenet](#). This message is similar to an electronic mail message in that it has a *header* and a *body*. The body contains the actual message to be sent, while the header contains header lines that describe the message and control how it is delivered. For example, one important header line specifies which newsgroup(s) for which the article is intended.
2. **Article Posting and Local Storage:** After completing her article, Ellen submits the article to Usenet, a process called *posting*. A client software program on Ellen's computer transmits Ellen's message to her local Usenet server. The message is stored in an appropriate file storage area on that server. It is now immediately available to all other users of that server who decide to read *misc.rural*.
3. **Article Propagation:** At this point, Ellen's local server is the only one that has a copy of her message. The article must be sent to other sites, a process called *distribution*, or more commonly, *propagation*. Ellen's message would travel from her local Usenet server to other servers to which her server directly connects. It would then in turn propagate from those servers to others *they* connect to, and so on, until all Usenet servers that want it have a copy of the message.
4. **Article Access and Retrieval:** Since Usenet articles are stored on central servers, in order to read them they must be accessed on the server. This is done using a Usenet *newsreader* program. For example, some other reader of *misc.rural* named Jane might access that group and find Ellen's message. If Jane was able to help Ellen she could reply to Ellen by posting an article of her own. This would then propagate back to Ellen's server, where she could read it and reply in turn. Of course, all other readers of *misc.rural* could jump in to the conversation at any time as well, which is what makes Usenet so useful for group communication.

### ***Message Propagation and Server Organization***

Propagation is definitely the most complex part of the Usenet communication process. In the “olden days”, UUCP was used for propagation; each Usenet server would be programmed to regularly dial up another server and give it all new articles it had received

**Figure 310: Usenet (Network News) Communication Model**

This figure illustrates the method by which messages are created, propagated and read using NNTP on modern Usenet; it is similar in some respects to the e-mail model diagram of [Figure 301](#). In this example a message is created by the *poster*, Ellen, and read by a *reader*, Jane. The process begins with Ellen creating a message in an editor and posting it. Her NNTP client sends it to her local NNTP server. It is then propagated from that local server to adjacent servers, usually including its *upstream* server, which is used to send the message around the Internet. Other NNTP servers receive the message, including the one upstream from Jane's local server. It passes the message to Jane's local server, and Jane accesses and reads the message using an NNTP client.

Jane could respond to the message, in which case the same process would repeat, but going in the opposite direction, back to Ellen (and of course, also back to thousands of other readers, not shown here.)

since the last connection. Articles would *flood* across Usenet from one server to another. This was time-consuming and inefficient, however, and only worked because the volume of articles was relatively small.

In modern Usenet, the [Network News Transfer Protocol \(NNTP\)](#) is used for all stages of transporting messages between devices. Articles are posted using an NNTP connection between a client machine and a local server, which then uses the same protocol to propagate the articles to other adjacent NNTP servers. NNTP is also used by client newsreader software to retrieve messages from a server.

NNTP servers are usually arranged in a hierarchy of sorts, with the largest and fastest servers providing service to smaller servers "downstream" from them. Depending on how the connections are arranged, an NNTP server may either establish a connection to

---

immediately send a newly-posted article to an “upstream” server for distribution to the rest of Usenet, or the server may passively wait for a connection from the upstream server to ask if there are any new articles to be sent. With the speed of the modern Internet, it typically takes only a few minutes or even seconds for articles to propagate from one server to another, even across continents.

It is also possible to restrict the propagation of a Usenet message, a technique often used for discussions that are only of relevance in certain regions or on certain systems. Discussing rural issues such as horses is of general interest, and Ellen might well find her help anywhere around the world, so global propagation of her message makes sense. However, if Ellen lived in the Boston area and was interested in knowing the location of a good local steak-house, posting a query to *ne.food* (New England food discussions) with only local distribution would make more sense. There are also companies that use Usenet to provide “in-house” newsgroups that are not propagated off the local server at all. Note, however, that because so many news providers are now national or international, limiting the distribution of messages has largely fallen out of practice.

This is, of course, only a simplified look at Usenet communication. [The section on NNTP](#) provides more details, especially on how articles are handled and propagated.

**Key Concept:** Usenet communication consists of four basic steps. A message is first *composed* and then *posted* to the originator’s local server. The third step is *propagation*, where the message is transmitted from its original server to others on the Usenet system. The last step in the process is *article retrieval*, where other members of the newsgroup access and read the article. The *Network News Transfer Protocol (NNTP)* is the technology used for moving Usenet articles from one host to the next.

---

## **Usenet Addressing: Newsgroups, Newsgroup Hierarchies and Types**

As [the previous topic](#) mentioned, a key concept in Usenet communication is the *newsgroup*. Newsgroups are in fact the addressing mechanism for Usenet, and sending a Usenet article to a newsgroup is equivalent to sending e-mail to an [electronic mail address](#). Newsgroups are analogous to other group communication venues such as mailing lists, chat rooms, [Internet Relay Chat](#) channels or BBS forums—though calling a newsgroup a “list”, “room”, “channel” or “BBS” is likely to elicit a negative reaction from Usenet old-timers.

Like any addressing mechanism, newsgroups must be uniquely identifiable. Each newsgroup has a *newsgroup name* that describes what the topic of the newsgroup is about, and differentiates it from other newsgroups. Since there are many thousands of different newsgroups, they are arranged into sets called *hierarchies*. Each hierarchy contains a tree structure of related newsgroups.

---

## Usenet Newsgroup Hierarchies

The total collection of newsgroup hierarchies is in many ways similar to the [domain name tree structure used in DNS](#). Each Usenet hierarchy is like a collection of all the domain names within a DNS [top-level domain](#). Just as a domain name like `www.pcguides.com` is formed by appending the label of the top level domain “com” to the second-level domain name “pcguides” and the subdomain “www”, newsgroup names are created in the same way. They are created from a top-level newsgroup hierarchy name, to which are attached a set of descriptive label that describe the newsgroup's place in the hierarchy.

One difference between DNS and Usenet hierarchies is that while [DNS names are created from right to left](#) as you go “down the tree”, Usenet newsgroup names are formed in the more “natural” (for English speakers) left to right order. For example, one of the main Usenet hierarchies is the “comp” hierarchy, devoted to computer topics. Within “comp” is a sub-hierarchy on data communications called “dcom”, and within that a group that discusses data cabling. This group is called *comp.dcom.cabling*. Almost all newsgroups are structured in this manner.

### The “Big Eight” Newsgroup Hierarchies

One problem with the “decentralized, anarchistic” nature of Usenet is ensuring coordination in certain areas where we want everyone to be on the same page; one of these is newsgroup naming. If we let just anyone create a newsgroup, we might well end up with many, even dozens of groups that all discuss the same topic. Imagine that someone had a question on data cabling and didn't realize that *comp.dcom.cabling* existed, so they created a new group called *comp.datacomm.cabling*. The two groups could coexist, but this would lead to both confusion and fragmenting of the pool of people interested in this topic.

To avoid this problem, many of the administrators of large Usenet systems collaborated on a system for organizing many of the more commonly-used Usenet groups into eight hierarchies, and devised a specific procedure for creating new newsgroups within them. There is actually a long history behind how this came about; these are today called the *Big Eight* Usenet hierarchies, and are summarized in [Table 264](#).

**Table 264: Usenet “Big Eight” Newsgroup Hierarchies**

Hierarchy	Description
<b>comp.*</b>	Newsgroups discussing computer-related topics, including hardware, software, operating systems and techniques.
<b>humanities.*</b>	Groups discussing the humanities, such as literature and art.
<b>misc.*</b>	Miscellaneous topics that don't fit into other Big Eight hierarchies.
<b>news.*</b>	Groups discussing Usenet itself and its administration.
<b>rec.*</b>	Recreation topics, such as games, sports and activities.
<b>sci.*</b>	Science newsgroups, covering specific areas such as physics and chemistry, research topics and so forth.

---

**Table 264: Usenet “Big Eight” Newsgroup Hierarchies**

Hierarchy	Description
<b>soc.*</b>	Society and social discussions, including groups on specific cultures.
<b>talk.*</b>	Groups primarily oriented around discussion and debate of current events and happenings.

These eight hierarchies contain many of the most widely-used groups on Usenet today. For example, professional baseball is discussed in *rec.sport.baseball*, Intel computers in *comp.sys.intel* and Middle East politics in *talk.politics.mideast*.

The Big Eight hierarchies are rather tightly controlled in terms of their structure and the newsgroups they contain. The process to create a new Big Eight newsgroup is democratic and open; anyone can propose a new group and if there is enough support, it will be created by the cooperating system administrators who agree to follow the Big Eight system. However, this creation process is rather complex and time-consuming. Some people find this unacceptable and even object to the entire concept of this restricted process; others consider it advantageous, as it keeps the Big Eight hierarchies relatively “orderly” by slowing the rate of change to existing newsgroups and the number of new groups added.

### **Other Newsgroup Hierarchies**

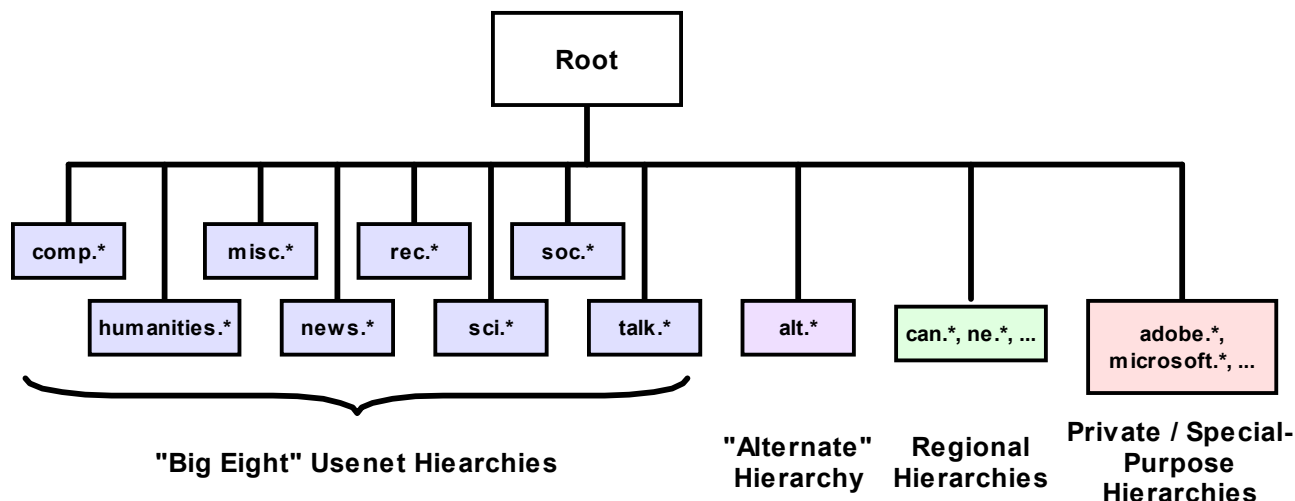

For those who prefer a more free-wheeling environment and do not want to submit to the Big Eight procedures, there is the “alternative” Usenet hierarchy, which begins with the hierarchy name *alt*. This hierarchy includes many thousands of groups. Some are quite popular, but many are not used at all; this is a side-effect of the relative ease with which an alt group can be created.

In addition to these nine hierarchies there are dozens of additional, smaller hierarchies. Many of these are regional or even company-specific. For example, the “ne.” hierarchy contains a set of newsgroups discussing issues of relevance to New England; “fr.\*” covers France, and “de.\*” Germany. Microsoft has its own set of public newsgroups in the “microsoft.\*” hierarchy. [Figure 311](#) shows the Big Eight hierarchies and some of the other hierarchies that exist.

**Key Concept:** Usenet messages are not addressed to individual users; rather, they are posted to *newsgroups*. Each newsgroup represents a topic; those with an interest in the subject of a group can read messages in it, and reply to them as well. Usenet newsgroups are arranged into tree-like *hierarchies* that are similar in structure to DNS domains. Many of the most widely-used newsgroups are found in a collection of general-interest hierarchies called the *Big Eight*. There are also many regional and special-purpose hierarchies.

---

**Figure 311: Usenet Newsgroup Hierarchies**

Usenet newsgroups are arranged into tree-like structures called *hierarchies*. Eight of these are centralized, widely-used, general-purpose hierarchies, which are today called the “Big Eight”. The “alternate” (“alt”) hierarchy is a very loosely-structured set of thousands of groups covering every topic imaginable. In addition to these, there are many hundreds of regional, private and special-purpose hierarchies.

### ***Unmoderated and Moderated Newsgroups***

Most newsgroups are open to all to use, and are called *unmoderated* because a message sent to them goes directly out to the whole Usenet server internetwork. In contrast, a small percentage of newsgroups is *moderated*, which means that all messages sent to the group are screened and only the ones that are approved by a moderator (or moderator team) are really posted.

The purpose of moderated groups is to ensure that discussions in a particular group remain on-topic. They are often created to handle topics that are controversial, to ensure that debates remain constructive and disruption is avoided. For example, *rec.guns* is moderated to ensure that discussions focus on the use of guns and not on endless political arguments related to gun control and the like (which has a place, in *talk.politics.guns*).

Moderated groups are also sometimes used for specialty groups intended only for announcements, or for groups where the content is restricted. For example, *rec.food.recipes* is moderated so that it only contains recipes and recipe requests; this helps people find recipes easily without having to wade through lots of discussion. Finally, moderated versions of unmoderated groups are sometimes created when a few disruptive elements choose to post large volumes in the unmoderated groups, making normal discussion difficult.

---

## ***Cross-Posting to Multiple Newsgroups***

It is possible for a single article to be posted to multiple newsgroups. This process, called *cross-posting*, is used when a message pertains to two topics, or to allow a sender to reach a wider audience. For example, if I live in the Seattle area and have a problem with my house, I might legitimately cross-post to *seattle.general* and *misc.consumers.house*.

This is more efficient than posting the same message to each group independently for two reasons. First, only one copy of the message will be stored on each Usenet server rather than two. Second, Usenet participants who happen to read both groups won't see the message twice. However, cross-posting to very large numbers of newsgroups is usually considered disruptive and a breach of Usenet etiquette.

## **Usenet Message Format and Special Headers**

Usenet is designed to permit users to exchange information in the form of messages that are sent from one computer to another. Like any [message-based networking application](#), it is necessary that all Usenet client and server software agree to use a common *message format*. This ensures that all devices and programs are able to interpret all Usenet articles in a consistent manner.

### ***General Message Format***

While Usenet was created as an alternative to e-mail, and there are obviously differences in how each treats messages, there are also many similarities. Both are text-oriented messaging systems with similar needs for communicating both content and control information. The creators of Usenet realized that there would be many advantages to basing the Usenet message format on the one used for e-mail, rather than creating a new format from scratch. For one thing, the e-mail message format was already widely used, and adopting it for Usenet would save implementation time and effort. It would also enhance compatibility between e-mail and Usenet messages, allowing software designed to process or display e-mail to also work with Usenet articles.

For this reason, the Usenet message format was defined based on the [RFC 822 standard for e-mail messages](#), discussed thoroughly in its own subsection of [the section on e-mail](#) in this Guide. RFC 822 messages begin with a set of *headers* that contain control and descriptive information about the message, followed by a blank line and then the message *body*, which contains the actual content.

One important attribute of the RFC 822 standard is the ability to define custom headers that add to the regular set of headers defined in the standard itself. Usenet articles require some types of information not needed by e-mail, and these can be included in specially-defined headers while still adhering to the basic RFC 822 format. At the same time, headers specific to e-mail that are not needed for Usenet can be omitted.

---

Thus, there is no structural difference at all between a Usenet article and an e-mail message; they differ only in the kinds of headers they contain, and the values for those headers. For example, a Usenet message will always contain a header specifying the newsgroup(s) to which the article is being posted, but will not carry a “To:” line as an e-mail message would.

**Key Concept:** Usenet articles use the same *RFC 822* message format as electronic mail messages. The only difference between a Usenet article and e-mail message is in the header types and values used in each.

---

### ***Usenet Header Categories and Common Headers***

All Usenet headers are defined according to the standard header format defined in RFC 822:

<header name>: <header value>

As with e-mail messages, headers may extend on to multiple lines, following the [indenting procedure described in the RFC 822 standard](#).

The current standard for Usenet messages, RFC 1036, describes the header types for Usenet messages. The headers are divided into two categories: *mandatory* headers and *optional* headers. Some are the same as headers of the equivalent name used for e-mail, some are similar to e-mail headers but used in a slightly different way, while others are unique to Usenet. [Table 265](#) describes these header fields and how they are used.

**Table 265: Usenet Header Categories and Headers (Page 1 of 2)**

Header Category	Header Name	Description
<b>Mandatory Headers</b>	<i>From:</i>	The e-mail address of the user sending the message, as for e-mail.
	<i>Date:</i>	The date and time that the message was originally posted to Usenet. This is usually the date/time that the user submitted the article to his or her local NNTP server.
	<i>Newsgroups:</i>	Indicates the newsgroup or set of newsgroups to which the message is being posted. Multiple newsgroups are specified by separating them with a comma; for example: "Newsgroups: news.onegroup,rec.secondgroup".
	<i>Subject:</i>	Describes the subject or topic of the message. Note that this header is mandatory on Usenet despite being optional for e-mail; it is important because it is used by readers to decide what messages to open.
	<i>Message-ID:</i>	Provides a unique code for identifying a message; normally generated when a message is sent. The message ID is very important in Usenet, arguably more so than in e-mail. The reason is that delivery of e-mail is performed based on recipient e-mail addresses, while the <a href="#">propagation of Usenet messages</a> is controlled using the message ID header.
	<i>Path:</i>	<p>This is an informational field that shows the path of servers that a particular copy of a message followed to get to the server where it is being read. Each time a server forwards a Usenet article, it adds its own name to the list in the <i>Path</i> header. The entries are usually separated by exclamation points.</p> <p>For example, if a user on Usenet server <i>A</i> posts a message, and it is transported from <i>A</i> to <i>G</i>, then <i>X</i>, then <i>F</i> and finally to the server <i>Q</i> where a second user reads it, the person on server <i>Q</i> would see something like this in the <i>Path</i> header: "Q!F!X!G!A".</p>
<b>Optional Headers (part 1 of 2)</b>	<i>Reply-To:</i>	It is possible to reply back to a Usenet article author using e-mail, which by default goes to the address in the <i>From:</i> line. If this header is present, the address it contains is used instead of the default <i>From:</i> address.
	<i>Sender:</i>	This header indicates the e-mail address of the user who is sending the message, if different from the message originator. This is functionally the same as the <i>Sender:</i> header in e-mail messages, but is used in a slightly different way. Normally, when a Usenet message is posted, the sender's e-mail address is automatically filled in to the <i>From:</i> line. If the user manually specifies a different <i>From:</i> line, the address from which the message was actually sent is usually included in the <i>Sender:</i> line. This is used to track the true originating point of articles.
	<i>Followup-To:</i>	<p>A reply to a Usenet message is usually made back to Usenet itself, and is called a <i>follow-up</i>. By default, a follow-up goes to the newsgroup(s) specified in the original message's <i>Newsgroups:</i> header. However, if the <i>Followup-To:</i> header is included, follow-ups to that message go to the newsgroups specified in the <i>Followup-To:</i> header instead.</p> <p>This header is sometimes used to "route" replies to a message to a particular group. Note, however, that when a user replies to a message, this field only controls what appears in the new message's <i>Newsgroups:</i> line by default. The user can override the <i>Newsgroups:</i> header manually.</p>

**Table 265: Usenet Header Categories and Headers (Page 2 of 2)**

Header Category	Header Name	Description
<b>Optional Headers (part 2 of 2)</b>	<i>Expires:</i>	All Usenet messages are maintained on each server for only a certain period of time, due to storage limitations. The expiration interval for each newsgroup is controlled by the administrator of each site. If present, this line requests a different expiration for a particular message; it is usually used only for special articles. For example, if a weekly announcement is posted every Monday morning, each article might be set to expire the following Monday morning, to make sure that people see the most current version.
	<i>References:</i>	This header lists the message IDs of prior messages in a conversation. For example, if someone posts a question to a newsgroup with message ID “AA207”, and a reply to that message is made, the software will automatically insert the line “References: AA207” into the reply. This is used by software to group together articles into conversations (called <i>threads</i> ) to make it easier to follow discussions on busy newsgroups.
	<i>Control:</i>	Indicates that the article is a control message and specifies a control action to be performed, such as creating a new newsgroup.
	<i>Distribution:</i>	By default, most messages are propagated on Usenet worldwide. If specified, this line restricts the distribution of a message to a smaller area, either geographical or organizational.
	Organization:	Describes the organization to which the article sender belongs. Often filled in automatically with the name of the user’s Internet Service Provider.
	Keywords:	Contains a list of comma-separated keywords that may be of use to the readers of the message. Keywords can be useful when searching for messages on a particular subject matter. This header is not often used.
	Summary:	A short summary of the message; again, rarely used in practice.
	Approved:	This header is added by the moderator of a moderated newsgroup to tell the Usenet software that the message has been approved for posting.
	Lines:	A count of the number of lines in the message.
	Xref:	While Usenet articles are identified by message ID, they are also given a number by each Usenet server as they are received. These article numbers, which differ from one system to the next, are usually listed in this cross-reference header.  This information is used when a message is cross-posted to multiple groups. In that case, as soon as a user reads the message in one group, it is marked as having been read in all the others where it was posted. This way, if the user later reads one of those other groups, they will not see the message again.

### **Additional Usenet Headers**

Usenet messages may also contain additional headers, just as is the case with e-mail messages. Some of these headers are entirely “custom” and are included by individual users to provide extra information about an article. Others are used in many or even most

---

current Usenet articles, and have become almost “de facto” standard headers through common use. Many of these custom headers are preceded by “X-”, indicating that they are “experimental” or “extra” headers.

Some of the more frequently encountered “additional” Usenet headers are shown in [Table 266](#).

**Table 266: Common Additional Usenet Headers**

Header Name	Description
<b>NNTP-Posting-Host:</b>	Specifies the IP address or the DNS domain name of the host used to originally post the message. This is usually either the address of the client that the author used for posting the message, or the sender's local NNTP server.
<b>User-Agent: (or) X-Newsreader:</b>	The name and version number of the software used to post the message.
<b>X-Trace:</b>	Provides additional information that can be used to trace the message.
<b>X-Complaints-To:</b>	An e-mail address to use to report abusive messages. This header is now included automatically by many Internet Service Providers.

### ***Usenet MIME Messages***

Since Usenet follows the RFC 822 standard, [Multipurpose Internet Mail Extensions \(MIME\)](#) can be used to format Usenet messages. When this is done, you will see the usual [MIME headers](#) (such as *MIME-Version*, *Content-Type* and so forth) in the message.

Note that the use of MIME in Usenet messages is somewhat controversial. Some newsreaders are not MIME-compliant and make a mess when trying to display some of these messages, and many Usenet veterans object to the use of anything but plain text in Usenet messages. Despite this, MIME messages are becoming more common, for better or worse.

---

## **TCP/IP Network News Transfer Protocol (NNTP)**

[Usenet](#) started out as an informal network of UNIX computers using dial-up UUCP connections to transmit messages between servers. This arrangement arose out of necessity, and it worked fairly well, though it had a number of problems. Once the Internet became widely used in the 1980s, it provided the ideal opportunity for a more efficient means of distributing Usenet articles. A special TCP/IP protocol was developed for sending these messages, called the *Network News Transfer Protocol (NNTP)*. NNTP is used today to carry billions of copies of Usenet messages from computer to computer every day.

In this section I provide a detailed description of the operation of the Network News Transfer Protocol. I begin with an overview of how NNTP works in general terms. I then explain the two fundamental ways that NNTP is used: for the propagation of news articles between servers, and for client article posting and access. I then provide more information about standard NNTP commands, as well as the newer NNTP command extensions, and also illustrate NNTP status responses and the common response codes.

**Background Information:** NNTP is similar to the [Simple Mail Transfer Protocol \(SMTP\)](#) in many ways, including its [basic operation](#) and [command set](#) and [reply format](#). You may therefore find this section easier to understand if you are familiar with SMTP.

---

### **NNTP Overview and General Operation**

Usenet began as a *logical* internetwork of cooperating hosts that contacted each other directly. In the early Usenet, a user would post a message to his or her local server. There it would stay until that server either contacted or was contacted by another server. The message would then be transferred to the new server, where it would stay until the second server contacted a third one, and so on.

This transport mechanism was functional, but seriously flawed in a number of ways. Servers were not continually connected to each other; they could only communicate by making a telephone call using an analog modem. Thus, messages would often sit for hours before they could be propagated. Modems in those days were also very slow by today's standards—2400 bits per second or even less—so it took a long time to copy a message from one server to another. Worst of all, unless two sites were in the same city, these phone calls were long distance, making them quite expensive.

Why was this system used despite all of these problems? Simple: there was no alternative. In the late 1970s and early 1980s, there was no Internet as we know it, and no other physical infrastructure existed to link Usenet sites together. It was either use UUCP over telephone lines, or nothing.

---

## ***The Development of NNTP***

Everything changed as the fledgling [ARPAnet](#) grew into the modern Internet. As the Internet expanded, more and more sites connected to it, including many sites that were participating in Usenet. Once a pair of sites were both on the Internet, it was an easy decision to use the Internet to send Usenet articles rather than slow, expensive telephone calls. Over time, more and more Usenet sites joined the Internet, and it became clear that just as e-mail had moved from UUCP to the TCP/IP Internet, the future of Usenet was on the Internet as well.

The shifting of Usenet from UUCP connections to TCP/IP internetworking meant that some rethinking was required in how Usenet articles were moved from server to server. On the Internet, Usenet was just one of many applications, and the transfer of messages had to be structured using one of [the two TCP/IP transport protocols](#), TCP or UDP.

Thus, like other applications, Usenet required an [application-level protocol](#) to describe how to carry Usenet traffic over TCP/IP. Just as Usenet had borrowed its message format from e-mail's [RFC 822](#), it made sense to model its message delivery protocol on the one used by e-mail: the [Simple Mail Transfer Protocol \(SMTP\)](#). The result was the creation of the *Network News Transfer Protocol (NNTP)*, published as RFC 977 in February, 1986.

### ***Overview of NNTP Operation***

The general operation of NNTP is indeed very similar to that of SMTP. NNTP uses [TCP](#), with servers listening on [well-known TCP port](#) 119 for incoming connections, either from client hosts or other NNTP servers. As in SMTP, when two servers communicate using NNTP, the one that initiates the connection plays the role of client for that exchange.

After a connection is established, communication takes the form of commands sent by the client to the server, and replies returned from the server to the client device. [NNTP commands](#) are sent as plain ASCII text, just like those used by SMTP, [FTP](#), [HTTP](#) and other protocols. [NNTP responses](#) take the form of three-digit reply codes as well as descriptive text, again just like SMTP (which in turn borrowed this concept from FTP).

NNTP was designed to be a comprehensive vehicle for transporting Usenet messages. It is usually most often considered as a delivery protocol for moving Usenet articles from one server to another, but is also used for connections from client hosts to Usenet servers for posting and reading messages. Thus, the NNTP command set is quite extensive, and includes commands to handle both inter-server and client-server communication. For [message propagation](#), a set of commands is provided to allow a server to request new articles from another server, or to provide new articles to another server. For [message posting and access](#), commands allow a client to request lists of new newsgroups and messages, and to retrieve messages for display to a user.

The commands defined in RFC 977 were the only “official” ones for over a decade. However, even as early as the late 1980s, implementors of NNTP server and client software were adding new commands and features to make NNTP both more efficient and useful to users. These *NNTP extensions* were eventually documented in RFC 2980, published in 2000. [I describe them in more detail later in this section.](#)

**Key Concept:** The *Network News Transfer Protocol (NNTP)* is the protocol used to implement message communication in modern Usenet. It is used for two primary purposes: to propagate messages between NNTP servers, and to permit NNTP clients to post and read articles. It is a standalone protocol, but shares many characteristics with e-mail's Simple Mail Transfer Protocol (SMTP).

---

## **NNTP Inter-Server Communication Process: News Article Propagation**

The Network News Transfer Protocol (NNTP) is used for all of the transfer steps in the modern Usenet communication process. However, NNTP is most often associated with the process of Usenet article *propagation*. This is arguably the most important function of NNTP: providing an efficient means of moving large volumes of Usenet articles from one server to another. It is thus a sensible place to start looking at the protocol.

### ***Understanding the Usenet Server Structure***

To see how NNTP propagation works, we must begin with a look at the way that the modern Usenet network itself is organized. Usenet sites are now all on the Internet, and theoretically, any NNTP server can contact any other to send and receive Usenet articles. However, it would be ridiculous to have a new article submitted to a particular server need to be sent via separate NNTP connections to each and every other NNTP server. For this reason, the Usenet logical network continues to be very important, even in the Internet era.

In theory, all that is required of the Usenet structure is that each site be connected to at least one other site in some form. The logical network could be amorphous and without any formal structure at all, as long as every site could form a path through some sequence of intermediate servers to each other one. However, modern Usenet is very large, with thousands of servers and gigabytes of articles being posted every day. This calls for a more organized structure for distributing news.

For this reason, the modern Usenet logical network is structured loosely in a hierarchy. A few large Internet Service Providers and big companies with high-speed Internet connections and large servers are considered to be at the top of the hierarchy, in what is sometimes called the Usenet *backbone*. Smaller organizations connect to the servers run by these large organizations; these organizations are considered to be *downstream* from the backbone groups. In turn, still smaller organizations may connect further downstream from the ones connected to the large organizations.

This hierarchical structure means that most Usenet servers only maintain a direct connection to their upstream neighbor, and to any downstream sites to which they provide service. A server is said to receive a *news feed* from its upstream connection, since that is the place from which it will receive most of its news articles. It then provides a news feed to all the servers downstream from it. I illustrated this in [Figure 310](#) in the topic describing the [Usenet communication model](#).

---

As an example, suppose Company A runs a large Usenet server called *largenews* that is connected to the backbone. Downstream from this server is the NNTP server *mediumnews*. That server in turn provides service to *smallnews*. If a user posts an article to *mediumnews*, it will be placed on that server immediately. That server will send the article downstream, to *smallnews*, so that it can be read by that server's users. *mediumnews* will also, at some point, send the article to *largenews*. From *largenews*, the message will be distributed to other backbone sites, which will in turn pass the message down to their own downstreams. In this way, all sites eventually get a copy of the message, even though *mediumnews* only needs to connect to two other servers directly.

The term used to describe how news is propagated with NNTP is *flooding*. This is because of the way that a message begins in one server and “floods” outward from it, eventually reaching the backbone sites and then going down all the downstream “rivers” to reach every site on Usenet.

Even though I described the logical Usenet network as a hierarchy, it is not a strict hierarchy. For redundancy, many NNTP servers maintain connections to multiple other servers to ensure that news propagates quickly. The transmission of articles can be controlled by looking at message IDs to avoid duplication of messages that may be received simultaneously by one server from more than one neighbor.

### **Basic NNTP Propagation Methods**

Now let's look at how messages are actually propagated between servers using NNTP. There are two techniques by which this can be done:

- ☉ **“Pushing” News:** In the *push model*, as soon as a server receives a new message, it immediately tells its upstream and downstream neighbors about the message and asks them if they want a copy of it.
- ☉ **“Pulling” News:** In the *pull model*, servers do not offer new articles to their neighbors. The neighboring servers must ask for a list of new messages if they want to see what has arrived since the last connection was established, and then request that the new messages be sent to them.

There are advantages and disadvantages to both of these techniques, but pushing is the model most commonly used today.

**Key Concept:** One important role that NNTP plays is its *propagation* of articles between Usenet servers, which is what makes the entire system possible. Two models are used for article propagation: the *push model*, in which a server that receives a new message offers it to connected servers immediately, and the *pull model*, where servers that receive new messages hold them until they are requested by other servers. The push model is usually preferred since it allows for quicker communication of messages around the system.

---

---

## Article Propagation Using the "Push" Model

Here's how the push model works. When the administrators of an NNTP server establish a service relationship with an upstream Usenet service provider, they furnish the provider with a list of newsgroups that the downstream server wants to carry. Whenever a new article arrives at the upstream server within that list of groups, it is automatically sent to the downstream site. This saves the downstream server from constantly having to ask "has anything arrived?"

In the classical NNTP protocol as defined in RFC 977, the exchange of articles is based on the push model, and performed using the *IHAVE* command. Suppose three new messages arrive at the *largenews* server. It would establish an NNTP connection to *mediumnews* and use *IHAVE* to provide the message IDs of each of the three new messages, one at a time. The *mediumnews* server would respond to each one indicating whether it already had that message or not. If not, *largenews* would send it the message. An example article transaction using the push model of propagation is illustrated in [Figure 312](#).

The main advantage of this technique is that it ensures that a server is not sent a duplicate copy of a message that it already has. The problem with it in modern Usenet is that it is slow, because the server must respond to the *IHAVE* command before the message or the next command can be sent by the client.

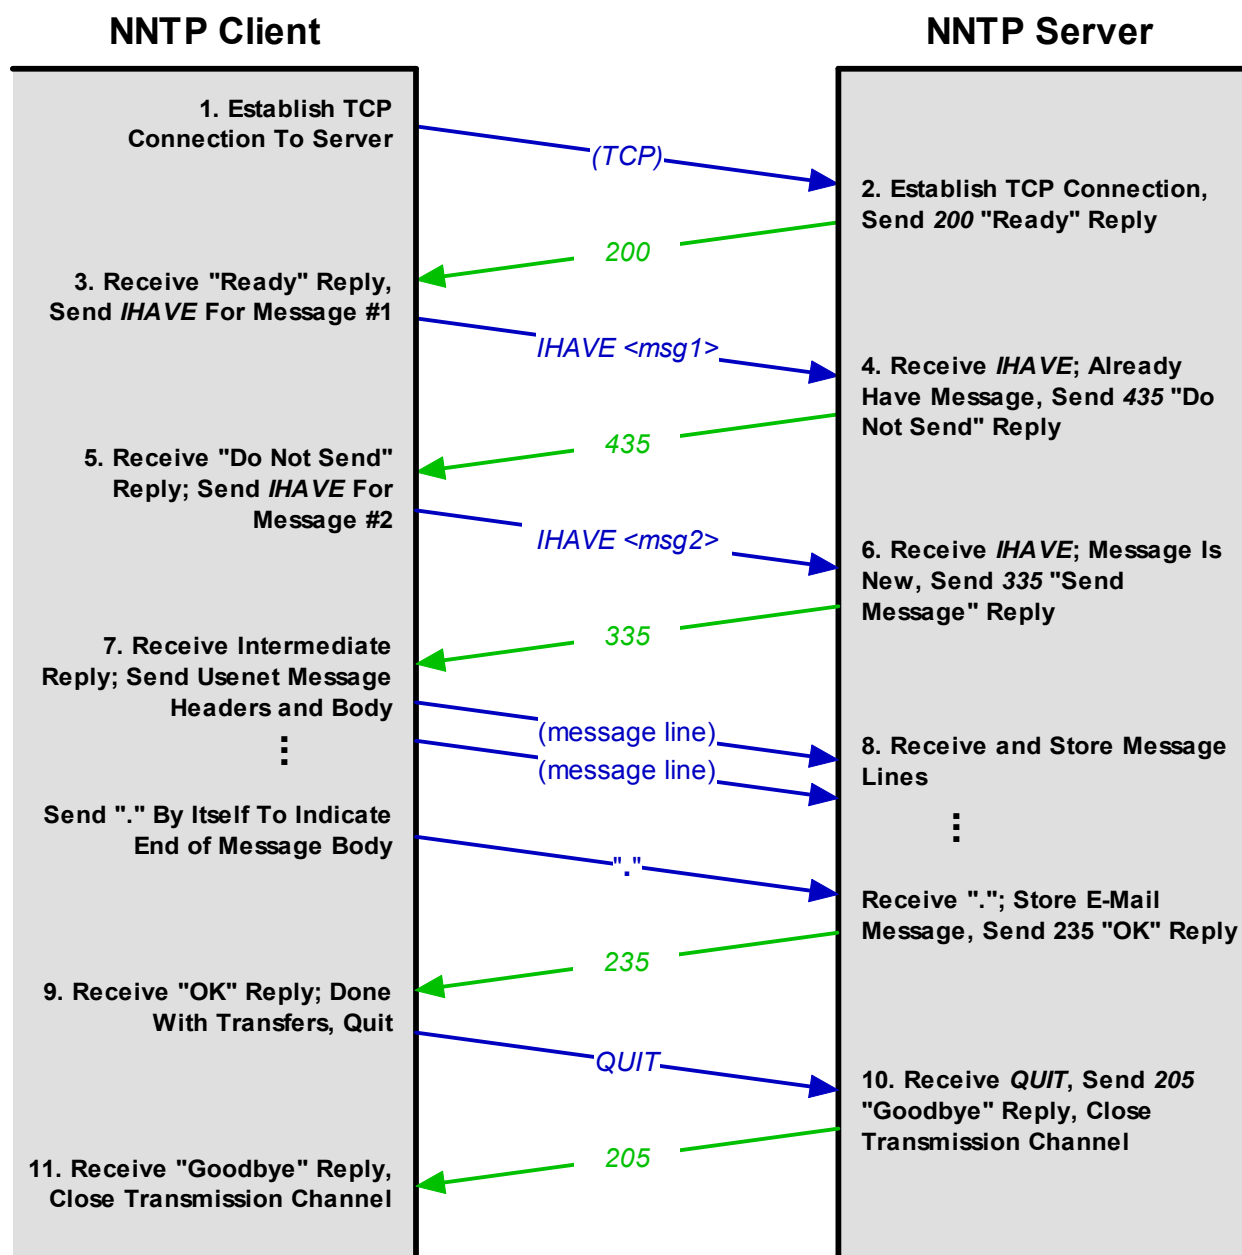

## Improving Push Propagation Efficiency With Streaming Mode

Due to the inefficiency problem just described, one of the more important [NNTP extensions](#) is *streaming mode*, which changes how news pushing is done. When this mode is enabled, the client machine uses the *CHECK* command instead of *IHAVE* to ask the server if it wants a particular message. The server responds back as for *IHAVE* to indicate if it wants the message; if it does, the client sends the message with the *TAKETHIS* command.

The benefit of *CHECK/TAKETHIS* is that the client does not have to wait for a reply to *CHECK* before sending the next command. While the client is waiting for a reply to the first *CHECK* command, it can do something else, like sending the next *CHECK* command, allowing commands to be streamed for greater efficiency. So the client could send a *CHECK* command for the first new message, then a *CHECK* for the second while waiting for a reply from the server to the first one. Many *CHECK* commands could be sent in a stream and then *TAKETHIS* commands sent for each reply received to *CHECK*s sent earlier indicating that the message was wanted by the server.

## Article Propagation Using the "Pull" Model

The pull model is implemented using the *NEWNEWS* and *ARTICLE* commands. The client connects to the server and sends the *NEWNEWS* command with a date specifying the date and time that it last checked for new messages. The server responds with a set of message IDs for new articles that have arrived since that date. The client then requests each new message using the *ARTICLE* command.

**Figure 312: NNTP Article Propagation Using The "Push" Model**

This example shows how Usenet articles are moved between servers using the conventional "push" model of propagation. Here, the device acting as an NNTP client (which recall may in fact be an NNTP server) has two messages available to offer to the server. It sends the *IHAVE* command specifying the message ID of the first message, but the server already has that message so it sends a 435 "do not send" reply. The client then issues an *IHAVE* with the second message ID; the server wants this one, so it sends a 335 reply; the client sends the Usenet message, ending with a single period on a line by itself. The server indicates that it received the message and the client, done with its transactions, quits the session.

---

Note that the push and pull models can be combined in a single session. A client can connect to a server, use *NEWNEWS* to check for new messages on that server, and then *IHAVE* or *CHECK* to inform the server about new messages the client wants to send. In practice, it is more common for only one or the other of the models to be used between a pair of servers on any given exchange.

In addition to propagating new messages, NNTP is also used to allow servers to communicate information about new newsgroups that have been created. This is done using the *NEWGROUPS* command, which is specified with a date and time like *NEWNEWS*. In response, the server sends to the client a list of new newsgroups that have been created since the specified date/time.

## **NNTP Client-Server Communication Process: News Posting and Access**

The propagation of Usenet articles is indeed a defining function of the Network News Transfer Protocol (NNTP)—would I lie to you? ☺ However, one critical area where NNTP differs from its progenitor, *SMTP*, is that NNTP is used not just for inter-server communication. It is also the protocol utilized for the initial posting of Usenet messages, and reading them as well. In fact, the majority of NNTP commands deal with the interaction between user client machines and NNTP servers, not communication between servers.

An NNTP client is any software program that knows the NNTP protocol and is designed to provide user access to Usenet. NNTP clients are usually called *newsreaders*, and provide two main capabilities to a user: *posting* (creating) and *reading* Usenet messages. Usenet newsreaders exist for virtually all hardware and software platforms, and range greatly in terms of capabilities, user interface and other characteristics. Most people today use a Usenet newsreader on a client computer that must make NNTP connections to a separate NNTP server to read and post news. These programs are analogous to e-mail clients, and in fact, many e-mail clients also function as NNTP clients.

### ***News Posting***

Posting a Usenet message is the first step in the overall Usenet communication process (although many Usenet articles are actually replies to other articles, so it's a bit of a “chicken and egg” thing.) Article posting is quite straight-forward with NNTP. The client establishes a connection to the server and issues the *POST* command. If the server is willing to accept new articles it replies with a prompt for the client to send it the article. The article is then transmitted by the client to the server. Some newsreaders may “batch” new articles so they can be sent in a single NNTP session rather than submitting them one at a time.

### ***News Access and Article Reading***

Newsreaders also establish an NNTP connection to a server to read Usenet articles. NNTP provides a large number of commands to support a variety of different article access and retrieval actions that may be taken by a user. The first step in reading is sometimes to examine the list of available newsgroups. Using the *LIST* command, the client requests from the server a list of the newsgroups available for reading and posting. RFC 977 defined

---

the basic *LIST* command, which returns a list of all groups to the client. RFC 2980 defines numerous extensions to the command to allow a client to retrieve only certain types of information about groups on the server. Since the number of Usenet newsgroups is so large today, many times this listing of newsgroups is now skipped unless the user specifically requests it.

The next step in Usenet message access is typically to select a newsgroup to read from the list of groups available. Again, since there are so many groups today, most newsreaders allow a user to search for a group name using a pattern or partial name string. The *GROUP* command is then sent to the server with the name of the selected group. The server returns the first and last current article numbers for the group to the client.

Messages are identified in two ways, one absolute and the other site-specific. The article's *Message ID* is a fixed identifier that can be used to uniquely represent it across Usenet; this is what is used in inter-server communication to determine whether or not each site has a copy of a given message. In contrast, *article numbers* are server-specific; they represent the numbers assigned to those articles as they arrived at that server and are used as a "short hand" to more easily refer to articles in a newsgroup. Thus, the same message will have a different article number on each NNTP server. They are used for convenience, since an article number is much shorter than a message ID. During a session, the NNTP server also maintains a "current article pointer" that can be used for stepping sequentially through a newsgroup.

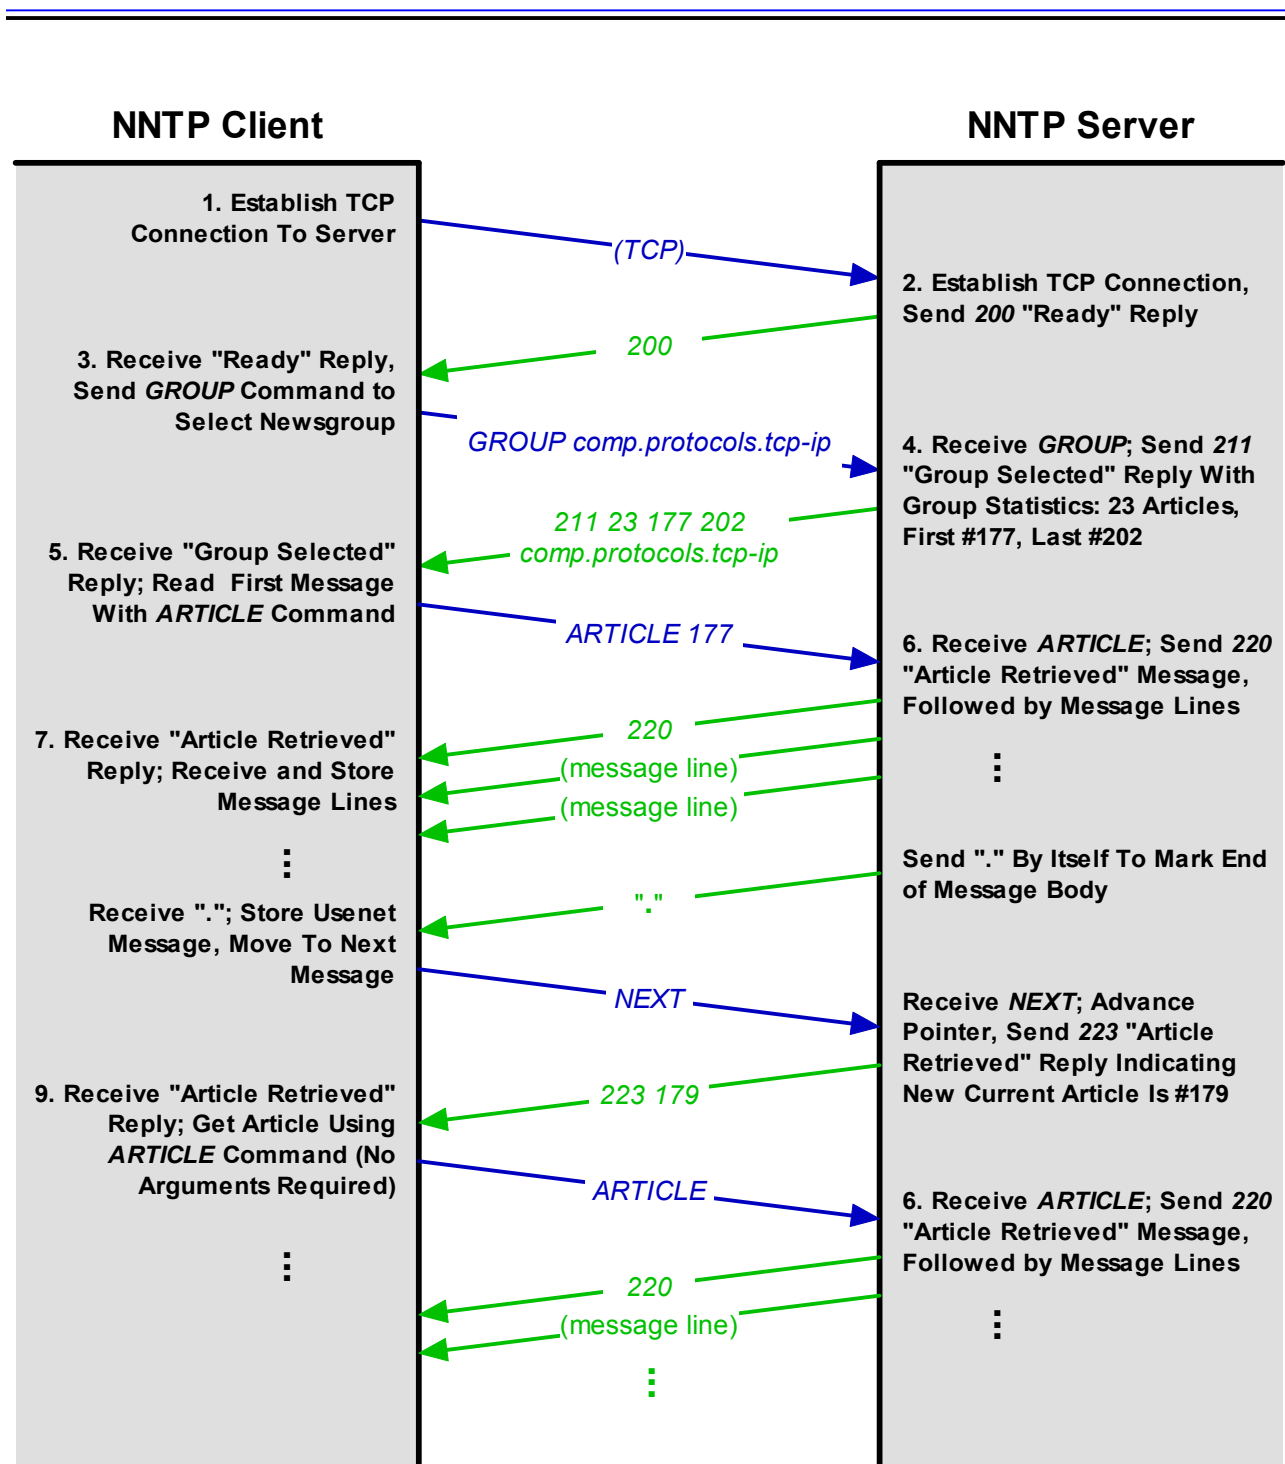

### **News Access Methods**

There are several different ways that the newsreader can access messages in a group, depending on how it is programmed and on what the user of the software wants.

#### **Full Newsgroup Retrieval**

This is the "brute force" technique: the client simply requests that the server send it all the messages in the group. This is done by issuing the *ARTICLE* command to select the first current message in the group, using the first article number returned by the *GROUP* command. This sets the server's internal pointer for the session to point to the first article, so it can be retrieved. The *NEXT* command is then used to advance the pointer to the next message, and the *ARTICLE* command to retrieve it. This continues until the entire group has been read. [Figure 313](#) illustrates the process.

The retrieved messages are stored by the newsreader and available for instant access by the user. This method is most suitable for relatively small newsgroups and/or users with fast Internet connections.

**Figure 313: NNTP Full Newsgroup Retrieval Process**

There are many ways that an NNTP client can access and read Usenet messages on a server. One common method is to retrieve the entire contents of a newsgroup. In this example, the client uses the *GROUP* command to select the newsgroup *comp.protocols.tcp-ip* for reading; the server responds with a 211 "group selected" reply, which includes important statistics about the group. The client uses the *ARTICLE* command with the number of the first article in the group, 177, to read it from the server. The server then sends the message line by line, ending it with a single period on a line. The client uses the *NEXT* command to tell the server to advance its internal article pointer to the next message, which often will *not* be the next consecutive number after the one just read; here it is 179. The client can then read that message by sending the *ARTICLE* command by itself; since no parameters are given the server returns the current message (#179).

---

## Newsgroup Header Retrieval

Since downloading an entire newsgroup is time-consuming, many newsreaders compromise by downloading the headers of all messages instead of the full message. The process is the same as for full newsgroup retrieval, but the *HEAD* command is used to retrieve just an article's headers instead of the *ARTICLE* command. This takes less time than retrieving each message in its entirety.

The *XHDR* command extension can also be used, if the server supports it, to more efficiently retrieve only a subset of the headers for the messages, such as the subject line and author.

## Individual Article Retrieval

It is also possible to retrieve a single message from a group, using the *ARTICLE* command and specifying the article's message identifier.

**Key Concept:** While NNTP is best known for its role in inter-server propagation, it is also used by Usenet clients to write and read articles. A number of different commands provides flexibility in how articles can be read by a client device. A client can retrieve an entire newsgroup, only a set of newsgroup headers, or individual articles. Other commands also support various administrative functions.

---

## Other Client-Server Functions

In addition to reading and posting, NNTP includes commands to support other “miscellaneous” tasks that a Usenet user may wish to perform. The client can ask the server for help information using the *HELP* command, or get a list of new newsgroups using the *NEWGROUPS* command, as described in [the inter-server communication topic](#).

Most modern newsreaders include capabilities that go far beyond the basic posting and reading functions described above. Most maintain their own sets of configuration files that allow a user to maintain a set of favorite “subscribed” newsgroups, rather than having to choose a group to read from the master list each time Usenet is accessed. Newsreaders also keep track of which articles have been read by a user in each subscribed newsgroup, so one need not wade through a whole newsgroup to see new messages that have been posted.

## Article Threading

One particularly useful enhancement to basic Usenet article reading is *threading*. This feature allows a newsreader to display articles not strictly in either alphabetical or chronological order, but rather grouped into conversations using the information in the articles' *References* headers. Threading is especially useful in busy newsgroups, as it allows you to see all the articles in a particular discussion at once, rather than trying to juggle messages from many conversations simultaneously.

---

A problem with threading is that it takes a long time for a newsreader to sift through all those *References* lines and construct the article threads. To speed up this process, many servers now cache extra threading or overview information for newsgroups, which can be retrieved by the client to save time when a newsgroup is opened. This is done using the *XTHREAD* or *XOVER* [NNTP command extensions](#).

## **NNTP Commands**

One of the great strengths of the [open, cooperative process](#) used to develop Internet standards, is that new protocols are usually designed by building upon successes in older ones. This both saves development time and effort, and promotes compatibility between technologies. As I explained in [the overview of NNTP](#), it was based in many ways on principles from [SMTP](#); SMTP in turn borrowed ideas from earlier protocols, [Telnet](#) and [FTP](#). This legacy can be seen in the similarities between NNTP commands and those of these earlier protocols.

### ***Command Syntax***

As in SMTP, all NNTP commands are ASCII text that are sent over the NNTP TCP connection to an NNTP server, from the device acting as the client (which may be a newsreader client or an NNTP server itself). These are standard text strings adhering to the [Telnet Network Virtual Terminal \(NVT\) format](#), terminated by the two-character “CRLF” sequence. As is the case with SMTP and FTP, you can conduct an interactive session with an NNTP server by using Telnet to connect to it on port 119.

The basic syntax of an NNTP command is as follows:

`<command-code> <parameters>`

Unlike SMTP, NNTP commands are not restricted to a length of four characters. The parameters that follow the command are separated by one or more space characters, and are used to provide necessary information to allow the server to execute the command. NNTP commands are not case-sensitive.

---

## Base Command Set

The main NNTP specification, RFC 977, describes the base set of commands supported by NNTP clients and servers. They are not broken into categories but rather listed alphabetically, as I have done in [Table 267](#). Additional details on how most of these commands are used can be found in the topics on [news article propagation](#) and [news posting and access](#).

**Table 267: NNTP Base Commands (Page 1 of 2)**

Command Code	Command	Parameters	Description
<b>ARTICLE</b>	<i>Retrieve Article</i>	Message ID or server article number.	Tells the server to send the client a particular Usenet article. The article to be retrieved may be specified either using its absolute, universal message ID, or its locally-assigned article number.  When the command is issued with an article number, this causes the server's internal message pointer to be set to the specified article. If the message pointer is already set to a particular article, the <i>ARTICLE</i> command can be issued without an article number and the current message will be retrieved.
<b>HEAD</b>	<i>Retrieve Article Headers</i>	Message ID or server article number.	Same as the <i>ARTICLE</i> command, but retrieves only the article's headers.
<b>BODY</b>	<i>Retrieve Article Body</i>	Message ID or server article number.	Same as the <i>ARTICLE</i> command, but returns only the body of the article.
<b>STAT</b>	<i>Retrieve Article Statistics</i>	Server article number	Conceptually the same as the <i>ARTICLE</i> command, but does not return any message text, only the message ID of the article. This command is usually used for the purpose of setting the server's internal message pointer, so <i>STAT</i> is normally invoked only with an article number (and not a message ID).
<b>GROUP</b>	<i>Select Newsgroup</i>	Newsgroup name	Tells the server the name of the newsgroup that the client wants to access. Assuming the group specified exists, the server returns to the client the numbers of the first and last articles currently in the group, along with an estimate of the number of messages in the group. The server's internal article pointer is also set to the first message in the group.
<b>HELP</b>	<i>Get Help Information</i>	None	Prompts the server to send the client help information, which usually takes the form of a list of valid commands that the server supports.
<b>IHAVE</b>	<i>Offer Article To Server</i>	Message ID	Used by the client in an NNTP session to tell the server that it has a new article that the server may want. The server will check the message ID provided and respond to the client indicating whether or not it wants the client to send the article.

**Table 267: NNTP Base Commands (Page 2 of 2)**

Command Code	Command	Parameters	Description
<b>LAST</b>	<i>Go To Last Message</i>	None	Tells the server to set its current article pointer to the last message in the newsgroup.
<b>LIST</b>	<i>List Newsgroups</i>	None	Asks the server to send a list of the newsgroups that it supports, along with the first and last article number in each group. The command as described in RFC 977 is simple, supporting no parameters and causing the full list of newsgroups to be sent to the client. <a href="#">NNTP command extensions</a> significantly expand the syntax of this command.
<b>NEWGROUPS</b>	<i>List New Newsgroups</i>	Date and time, and optional distribution specification	Prompts the server to send a list of new newsgroups created since the date and time specified. The client may also restrict the command to return only new newsgroups within a particular regional distribution.
<b>NEWNEWS</b>	<i>List New News Articles</i>	Date and time, and optional distribution specification	Requests a list from the server of all new articles that have arrived since a particular date and time. Like the <b>NEWGROUPS</b> command, this may be restricted in distribution. The server responds with a list of message IDs of new articles.
<b>NEXT</b>	<i>Go To Next Message</i>	None	Advances the server's current article pointer to the next message in the newsgroup.
<b>POST</b>	<i>Post Article</i>	None	Tells the server that the client would like to post a new article. The server responds with either a positive or negative acknowledgment. Assuming that posting is allowed, the client then sends the full text of the message to the server, which stores it and begins the process of propagating it to other servers.
<b>QUIT</b>	<i>End Session</i>	None	Terminates the NNTP session. To be "polite", the client should issue this command prior to closing the TCP connection.
<b>SLAVE</b>	<i>Set Slave Status</i>	None	This command is intended for use in special configurations where one NNTP server acts as a subsidiary to others. It is not often used in practice.

RFC 2980 defines a number of extensions that both add new commands to this set and make changes to one of these commands (*LIST*). NNTP extensions are described in the next topic.

**Key Concept:** The main NNTP standard defines a number of base *NNTP commands* that are used by the device initiating an NNTP connection to accomplish article propagation, posting or reading functions. NNTP commands consist of a command code and optionally, parameters that specify how the command is to be carried out.

---

## **NNTP Command Extensions**

The [base command set](#) described in RFC 977 was sufficient to enable client-server and inter-server functionality, but was in many ways quite basic and limited in efficiency and usefulness. As Usenet grew larger and more popular in the late 1980s, demand grew for changes to improve the usability of NNTP. In 1991, work began on a formal revision to the NNTP standard, but was never completed. Despite this, many of the concepts from that effort were adopted “informally” in NNTP implementations in subsequent years. In addition, some Usenet software authors created their own non-standard features to improve the protocol. Some of these themselves became [de facto standards](#) through widespread adoption.

As a result, by the late 1990s, most Usenet software actually implemented variations of NNTP with capabilities far exceeding what was documented in the standard. Naturally, not all NNTP software supported the same “extra” features, leading to potential compatibility difficulties between servers and clients. RFC 2980, [Common NNTP Extensions](#), was published in October 2000 to formalize many of these extensions to the base NNTP standard as defined in RFC 977.

The NNTP extensions primarily consist of new NNTP commands that are added to the basic NNTP command set, as well as some minor changes to how other commands and functions of NNTP work. The extensions generally fall into three categories: those that improve the efficiency of NNTP [message transport between servers](#); those that make NNTP more effective for [client message access](#), and “miscellaneous” ones that don’t fall into either of those two groups.

### ***NNTP Transport Extensions***

The first group is called the NNTP *transport extensions* and consists of a small group of related commands that are designed to improve inter-server message propagation. Most of these implement NNTP’s *stream mode*, which provides a more effective way of moving large numbers of articles from one server to another, as described in [the topic on inter-server communication](#). [Table 268](#) describes the new transport commands.

**Table 268: NNTP Transport Extensions (Page 1 of 2)**

Command Code	Command	Parameters	Description
<b>MODE STREAM</b>	<i>Set Stream Mode</i>	None	Used to tell the server that the client wants to operate in stream mode, using the <i>CHECK</i> and <i>TAKETHIS</i> commands.
<b>CHECK</b>	<i>Check If Article Exists</i>	Message ID	Used in stream mode by a server acting as a client to ask another server if it has a copy of a particular article. The server responds back indicating whether or not it wishes to be sent a copy of the article. This command is similar to <i>IHAVE</i> , except that the client does not have to wait for a reply before sending the next command.

**Table 268: NNTP Transport Extensions (Page 2 of 2)**

Command Code	Command	Parameters	Description
<b>TAKETHIS</b>	<i>Send Article To Server</i>	Message ID	When a server responds to a <i>CHECK</i> command indicating that it wants a copy of a particular message, the client sends it using this command.
<b>XREPLIC</b>	<i>Replicate Articles</i>	List of newsgroups and article numbers	This command was created for the special purpose of copying large numbers of articles from one server to another. It is not widely used.

### **NNTP Newsreader Extensions**

The second group of extensions defined by RFC 2980 are the *newsreader extensions*, which focus primarily on commands used by newsreader clients in interactions with NNTP servers. These extensions consist of several new commands as well as significant enhancements to one important command that was very limited in its functionality in RFC 977: *LIST*.

The original *LIST* command has no parameters and only allows a client to retrieve the entire list of newsgroups a server carries. This may have been sufficient when there were only a few hundred Usenet newsgroups, but there are now tens of thousands. RFC 2980 defines a number of new variations of the *LIST* command, to allow the client much more flexibility in the types of information the server returns. [Table 269](#) shows the new *LIST* command variations.

**Table 269: NNTP LIST Command Extensions (Page 1 of 2)**

Command Code	Command	Parameters	Description
<b>LIST ACTIVE</b>	<i>List Active Newsgroups</i>	Newsgroup name or pattern	Provides a list of active newsgroups on the server. This is semantically the same as the original <i>LIST</i> command, but the client may provide a newsgroup name or a pattern to restrict the number of newsgroups returned.  For example, the client can ask for a list of only the newsgroups that contain "football" in them.
<b>LIST ACTIVE.TIMES</b>	<i>List Active Newsgroup Creation Times</i>	None	Prompts the server to send the client its <i>active.times</i> file, which contains information about when the newsgroups carried by the server were created.
<b>LIST DISTRIBUTIONS</b>	<i>List Distributions</i>	None	Causes the server to send the client the contents of the <i>distributions</i> file, which shows what regional distribution strings the server recognizes (for use in the <i>Distribution</i> header of a message).

**Table 269: NNTP *LIST* Command Extensions (Page 2 of 2)**

Command Code	Command	Parameters	Description
<b><i>LIST DISTRIB.PATS</i></b>	<i>List Distribution Patterns</i>	None	Asks the server for its <i>distribution.pats</i> file, which is like the <i>distributions</i> file but uses patterns to summarize distribution information for different newsgroups.
<b><i>LIST NEWSGROUPS</i></b>	<i>List Newsgroups</i>	Newsgroup name or pattern	Provides a list of newsgroup names and descriptions. This differs from <i>LIST ACTIVE</i> in that only the newsgroup name and description are returned, and not the article numbers for each newsgroup. It is functionally the same as <i>XGTITLE</i> (see <a href="#">Table 270</a> ) and is usually employed by a user to locate a newsgroup to be added to his or her subscribed list.
<b><i>LIST OVERVIEW.FMT</i></b>	<i>Display Overview Format</i>	None	Prompts the server to display information about the format of its <i>overview</i> file. See the <i>XOVER</i> command description below for more.
<b><i>LIST SUBSCRIPTIONS</i></b>	<i>Retrieve Default Subscription List</i>	None	Asks the server to send the client a default list of subscribed newsgroups. This is used to set up a new user with a suggested list of newsgroups. For example, if an organization has an internal support newsgroup, they could put this group on the default subscription list so all new users learn about it immediately when they first start up their newsreader.

In addition to these changes to the *LIST* command, many new newsreader-related command extensions are defined, which are described in [Table 270](#).

**Table 270: NNTP Newsreader Extensions (Page 1 of 2)**

Command Code	Command	Parameters	Description
<b><i>LISTGROUP</i></b>	<i>List Article Numbers In Newsgroup</i>	Newsgroup name	Causes the server to return a list of local article numbers for the current messages in the newsgroup. The server's current article pointer is also set to the first message in the group.
<b><i>MODE READER</i></b>	<i>Set Newsreader Mode</i>	None	Tells the server that the device acting as a client is in fact a client newsreader and not another NNTP server. While technically not required—all commands can be sent by any device acting as client—some servers may be optimized to respond to newsreader-oriented commands if given this command.
<b><i>XGTITLE</i></b>	<i>Retrieve Newsgroup Descriptions</i>	Newsgroup name or pattern	Used to list the descriptions for a newsgroup or a set of newsgroups matching a particular text pattern. This command is functionally the same as the <i>LIST NEWSGROUP</i> command extension (see <a href="#">Table 269</a> ). It is therefore recommended that <i>XGTITLE</i> no longer be used.

**Table 270: NNTP Newsreader Extensions (Page 2 of 2)**

Command Code	Command	Parameters	Description
<b>XHDR</b>	<i>Retrieve Article Headers</i>	Header name and optionally, either a message ID or a range of article numbers	<p>Allows a client to ask for only a particular header from a set of messages. If only the header name is provided, the header is returned for all messages in the current group. Otherwise, the header is provided for the selected messages.</p> <p>This extension provides a newsreader client with a more efficient way of retrieving and displaying important headers in a newsgroup to a user.</p>
<b>XINDEX</b>	<i>Retrieve Index Information</i>	Newsgroup name	Retrieves an <i>index</i> file, used by the newsreader <i>TIN</i> to improve the efficiency of newsgroup perusal. <i>TIN</i> now supports the more common “overview” format, so the <i>XOVER</i> command is preferred to this one.
<b>XOVER</b>	<i>Retrieve Overview Information</i>	Article number or range of article numbers in a newsgroup	Retrieves <i>overview</i> for an article or set of articles. Servers supporting this feature maintain a special database for their newsgroups that contains information about current articles in a format that can be used by a variety of newsreaders. Retrieving the overview information allows features like <a href="#">message threading</a> to be performed more quickly than if the client had to retrieve the headers of each message and analyze them manually.
<b>XPAT</b>	<i>Retrieve Article Headers Matching A Pattern</i>	Header name, pattern, and either a message ID or a range of article numbers	This command is similar to <i>XHDR</i> in that it allows a particular header to be retrieved for a set of messages. The difference is that the client can specify a pattern that must be matched for the header to be retrieved. This allows the client to have the server search for and return certain messages, such as those with a subject line indicating a particular type of discussion, rather than requiring the client to download all the headers and search through them.
<b>XPATH</b>	<i>Retrieve Filename Information</i>	Message ID	Allows a client to ask for the name of the actual file in which a particular message is stored on the server.
<b>XROVER</b>	<i>Retrieve Overview Reference Information</i>	Article number or range of article numbers in a newsgroup	Like the <i>XOVER</i> command, but specifically retrieves information in the <i>References</i> header for the indicated articles. This is, of course, the header containing the data needed to create threaded conversations.
<b>XTHREAD</b>	<i>Retrieve Threading Information</i>	Optional “DBINIT” parameter	<p>Similar to <i>XINDEX</i>, but retrieves a special threading information file in the format used by the newsreader <i>TRN</i>. Like <i>TIN</i>, <i>TRN</i> now supports the common “overview” format so <i>XOVER</i> is preferred to this command.</p> <p>The “DBINIT” parameter can be used to check for the existence of a thread database.</p>

---

## Other NNTP Extensions

The last extension group is the “other” extensions, miscellaneous ones not strictly related to either inter-server or client-server NNTP interaction. There are two commands in this group: *AUTHINFO* and *DATE*. The latter is a simple command that causes the server to tell the client its current date and time. *AUTHINFO* is more interesting: it is used by a client to provide authentication data to a server.

You may have noticed that there are no commands related to security described in the RFC 977 protocol. That's because the original NNTP had no security features whatsoever. Like many protocols written before the modern Internet era, security was not considered a big issue back in the early 1980s. Most news servers were used only by people within the organization owning the server, and simple security measures were used, such as restricting access to servers by IP address or through the use of access lists.

One of the more important changes made by many NNTP software implementation as soon as Usenet grew in size was to require authentication. Modern clients will usually issue *AUTHINFO* as one of its first commands upon establishing a connection to a server, because the server will refuse to accept most other commands before this is done. A special reply code is also added to NNTP for a server to use if it rejects a command due to improper authentication.

The *AUTHINFO* command can be invoked in several different ways. The original version of the command required the client to issue an *AUTHINFO USER* command with a user name, followed by *AUTHINFO PASS* with a password. Naturally, this is simple user/password login authentication. A variation of this is the *AUTHINFO SIMPLE* command, where the client needs to send just a password.

A client and server can also agree to use more sophisticated authentication methods by making use of the *AUTHINFO GENERIC* command. The client provides to the server the name of the authentication method it wants to use, along with any arguments required for authentication. The client and server then exchange messages and authentication information as required by the particular authenticator they are using.

**Key Concept:** A number of limitations in its base command set led to a proliferation of non-standard enhancements to NNTP during the 1980s and 1990s. These were eventually documented in a set of NNTP *command extensions* that formally supplement the original RFC 977 commands. The extensions are conceptually divided into three groups: *transport extensions* that refine how NNTP propagates messages; *newsreader extensions* that improve client article access; and miscellaneous extensions, of which the most important is the *AUTHINFO* extension that adds security to NNTP.

---

---

## **NNTP Status Responses and Response Codes**

Each time the device acting as a client in an NNTP connection sends a command, the server sends back a *response*. The response serves to acknowledge receipt of the command, to inform the client of the results of processing the command, and possibly to prompt for additional information. Since NNTP commands are structured and formatted in a way very similar to that of SMTP commands, I'm sure it will come as no great surprise that NNTP responses are likewise very similar to [those of SMTP](#). In turn, SMTP responses are based on [the system designed for replies in FTP](#).

The first line of an NNTP response consists of a three-digit numerical *response code*, as well as a line of descriptive text that summarizes the response. These response codes are structured so that each digit has a particular significance, which allows the client to quickly determine the status of the command to which the reply was sent. After the initial response line, depending on the reply, a number of additional response lines may follow. For example, a successful *LIST* command results in a 215 response code, followed by a list of newsgroups.

**Background Information:** [The topic on FTP reply codes](#) discusses more completely the reasons why numeric reply codes are used in addition to descriptive text.

---

### ***Reply Code Structure and Digit Interpretation***

As with SMTP and FTP, NNTP reply codes can be considered to be of the form “xyz”, where “x” is the first digit, “y” the second and “z” the third.

#### **First Reply Code Digit (“x”)**

The first digit indicates the success, failure or progress of the command in general terms, whether a successful command is complete or incomplete, and the general reason why an unsuccessful command did not work. The values of this digit are defined slightly differently than in SMTP and FTP. In some cases, the terminology is just simplified; for example, the second category is “Command OK” instead of “Positive Completion Reply”. [Table 271](#) shows the specific meaning of the possible values of this digit.

**Table 271: NNTP Reply Code Format: First Digit Interpretation (Page 1 of 2)**

Reply Code Format	Meaning	Description
1yz	<b>Informative Message</b>	General information; used for help information and debugging.
2yz	<b>Command OK</b>	The command was completed successfully.

**Table 271: NNTP Reply Code Format: First Digit Interpretation (Page 2 of 2)**

Reply Code Format	Meaning	Description
3yz	<b>Command OK So Far, Send The Rest</b>	An intermediate reply, sent to prompt the client to send more information. Typically used for replies to commands such as <i>IHAVE</i> or <i>POST</i> , where the server acknowledges the command and then requests that an article be transmitted by the client.
4yz	<b>Command Was Correct, But Couldn't Be Performed</b>	The command was valid but could not be performed. This type of error usually occurs due to bad parameters, a transient problem with the server, bad command sequence or similar situations.
5yz	<b>Command Unimplemented Or Incorrect, Or Serious Program Error</b>	The command was invalid or a significant program error prevented it from being performed.

### Second Reply Code Digit ("y")

The second digit categorizes messages into functional groups. This digit is used in the same general way as in SMTP and FTP, but the functional groups are different; they are described in [Table 272](#).

**Table 272: NNTP Reply Code Format: Second Digit Interpretation**

Reply Code Format	Meaning	Description
x0z	<b>Connection, Setup and Miscellaneous</b>	Generic and miscellaneous replies.
x1z	<b>Newsgroup Selection</b>	Messages related to commands used to select a newsgroup.
x2z	<b>Article Selection</b>	Messages related to commands used to select an article.
x3z	<b>Distribution Functions</b>	Messages related to the transfer of messages.
x4z	<b>Posting</b>	Messages related to posting messages.
x5z	<b>Authentication</b>	Messages related to authentication and the <i>AUTHINFO</i> command extension. (This category is not officially listed in the standard, but these responses have a middle digit of "5").
x8z	<b>Nonstandard Extensions</b>	Reserved for private, non-standard implementation use.
x9z	<b>Debugging</b>	Debugging output messages.

### Third Reply Code Digit ("z")

This last digit indicates a specific type of message within each of the functional groups described by the second digit. The third digit allows each functional group to have 10 different reply codes for each reply type given by the first code digit.

---

## Combining Digit Values to Make Specific Reply Codes

As in FTP and SMTP, these “x”, “y” and “z” digit meanings are combined to make specific reply codes. For example, the reply code “435” is sent by the server if a client issues the *IHAVE* command but the server doesn't want the article being offered. The command was correct but the reply is negative, thus it starts with “4”, and the message is related to message distribution, so the middle digit is “3”.

### Common NNTP Reply Codes

[Table 273](#) contains a list of some of the more common NNTP reply codes in numerical order, along with typical reply text from the standard, and additional descriptive information.

**Table 273: NNTP Reply Codes (Page 1 of 3)**

Reply Code	Reply Text	Description
100	help text follows	Precedes response to <i>HELP</i> command.
111	(date and time)	Response to <i>DATE</i> command extension.
199	(debugging output)	Debugging information.
200	server ready - posting allowed	Sent by the server upon initiation of the session, if the client is allowed to post messages.
201	server ready - no posting allowed	Sent by the server upon initiation of the session, if the client is not allowed to post messages.
202	slave status noted	Response to the <i>SLAVE</i> command.
203	streaming is ok	Successful response to <i>MODE STREAM</i> command.
205	closing connection - goodbye!	Goodbye message sent in response to a <i>QUIT</i> message.
211	n f l s group selected	Successful response to the <i>GROUP</i> command, indicating the estimated number of messages in the group (“n”), first and last article numbers (“f” and “l”) and group name (“s”).
215	list of newsgroups follows (OR) information follows	Successful response to <i>LIST</i> command. The second form is for variations of <i>LIST</i> defined as <a href="#">NNTP command extensions</a> .
218	tin-style index follows	Successful response to <i>XINDEX</i> command extension.
220	n <a> article retrieved - head and body follow	Successful response to the <i>ARTICLE</i> command, indicating the article number and message ID of the article.
221	n <a> article retrieved - head follows	Successful response to the <i>HEAD</i> command, indicating the article number and message ID of the article.
222	n <a> article retrieved - body follows	Successful response to the <i>BODY</i> command, indicating the article number and message ID of the article.
223	n <a> article retrieved - request text separately	Successful response to the <i>STAT</i> command, indicating the article number and message ID of the article.
224	overview information follows	Successful response to the <i>XOVER</i> command extension.

**Table 273: NNTP Reply Codes (Page 2 of 3)**

Reply Code	Reply Text	Description
230	list of new articles by message-id follows	Successful response to the <i>NEWNEWS</i> command.
235	article transferred ok	Successful response to the <i>IHAVE</i> command, after article has been sent.
239	article transferred ok	Successful response to the <i>TAKETHIS</i> command.
240	article posted ok	Successful response to the <i>POST</i> command, after article has been posted.
250 or 281	authentication accepted	Successful authentication using the <i>AUTHINFO</i> command extension.
282	list of groups and descriptions follows	Positive response to the <i>XGITLE</i> command extension.
288	binary data to follow	Successful response to the <i>XTHREAD</i> command extension.
335	send article to be transferred	Preliminary response to the <i>IHAVE</i> command.
340	send article to be posted	Preliminary response to the <i>POST</i> command.
381	more authentication information required	Preliminary response to the <i>AUTHINFO</i> command extension.
400	service discontinued	Session is being terminated, perhaps due to user request.
411	no such newsgroup	Invalid newsgroup name specified.
412	no newsgroup has been selected	Attempt to issue a command that refers to the current newsgroup before one has been selected using <i>GROUP</i> .
420	no current article has been selected	Attempt to issue a command that refers to the current article using the server's current article pointer, before the pointer has been set through article selection.
421	no next article in this group	Response to <i>NEXT</i> command when at last article of a newsgroup.
422	no previous article in this group	Possible response to <i>LAST</i> ; I have no idea why the word "previous" is in there.
423	no such article number in this group	Command with invalid article number.
430	no such article found	Article not found; it may have been deleted.
435	article not wanted - do not send it	Negative response to <i>IHAVE</i> if server doesn't need the article.
436	transfer failed - try again later	Temporary failure of article transfer, retry.
437	article rejected - do not try again	Article refused for whatever reason.
438	already have it, please don't send it to me	Same as reply code 435, but for the <i>CHECK</i> command extension.
440	posting not allowed	<i>POST</i> command issued when posting is not allowed.

---

**Table 273: NNTP Reply Codes (Page 3 of 3)**

Reply Code	Reply Text	Description
441	posting failed	<i>POST</i> command failed.
450	authorization required for this command	Response sent when server requires authentication but client has not yet authenticated.
452	authorization rejected	Failed authentication.
480	transfer permission denied	Response to <i>CHECK</i> if transfer is not allowed.
500	command not recognized	Bad command.
501	command syntax error	Bad syntax in command.
502	access restriction or permission denied	Permission denied; sent if the client has not properly authenticated but the server requires it.
503	program fault - command not performed	General fatal error message.

**Key Concept:** Each command sent by the device acting as the client in an NNTP connection results in the server returning a *reply*. NNTP replies consist of a three-digit reply code and a string of descriptive text; they are modelled after those of SMTP, and in turn, FTP.

---

---

## TCP/IP World Wide Web (WWW, "The Web") and the Hypertext Transfer Protocol (HTTP)

So finally, we come to the Big Kahuna. ☺ In my [overview of file and message transfer protocols](#), I said that the World Wide Web was “almost certainly” the most important TCP/IP application. If anything, I was probably understating the case. The Web is not only quite clearly the most important TCP/IP application today, it is arguably the single most important application in the history of networking, and perhaps even computing as a whole.

Does this sound a little melodramatic? More than a little? Perhaps, but consider what the Web has done in the decade or so that it has been around. It has transformed not only how internetworks are used, but in many ways, has changed society itself. The Web put the Internet “on the map”, so to speak, moving it from the realm of technicians and academics and making it a big part of the mainstream world.

In this section I describe the World Wide Web in two subsections. The first discusses the Web and the concepts behind hypertext and hypertext documents in general terms. The second explains the operation of the all-important *Hypertext Transfer Protocol (HTTP)*, the TCP/IP application layer protocol that makes the Web work.

**Note:** As I've said in many other section headers, I simply cannot do complete justice here to a topic as large as the World Wide Web. There have not only been whole books written about the Web, there are **shelves** full of such books. Due to the already large size of this Guide, and its overall focus on how protocols and technologies work, I must contain my enthusiasm and limit my scope to providing an overview of what the Web is all about, while focusing on the nuts and bolts of HTTP itself.

---

---

## **TCP/IP World Wide Web and Hypertext Overview and Concepts**

The World Wide Web expands the concepts of messaging beyond the limits of simple text file transfer of [e-mail](#), [FTP](#) and [Usenet](#). Its power is in its combination of *hypertext*, a system that allows related documents to be linked together, its rich document format that supports not just text but graphics and multimedia, and the special protocol that allows efficient movement of those media. The result is a powerful system that once introduced, caught on almost immediately amongst everyone from large companies to individuals, and in a few short years came to dominate all other applications on the Internet.

In this section, I take a high-level, summarized look at the concepts behind the World Wide Web. I begin with a short overview and history of the Web and hypertext, and a discussion of the components that comprise the Web system. I briefly describe the documents and media used on the Web and explain the importance of the Hypertext Markup Language (HTML). I conclude with an overview of how documents are addressed on the Web using Uniform Resource Locators (URLs).

### **World Wide Web and Hypertext Overview and History**

At one point, I considered putting my section on the Web in a distinct location, separate from the discussion of other file and message transfer protocols. It didn't "seem" at first like a message transfer protocol to me. But I realized that, boiled down, the Web really *is* just another way of storing information and then transferring it from one computer to another. A question immediately struck me: if this is the case, what was so special about the Web that caused it to become popular in a way that no prior messaging applications ever had?

There is no simple one-word answer to this question. However, if I had to give one anyway, it would be this: *hypertext*. Sure, applications like e-mail and Usenet allow users to send and receive information, and FTP lets a user access a set of files on a server. But what these methods lack is any way of easily representing the *relationship* between documents or providing a way of moving from one to another. Highly simplified, hypertext does exactly that: it allows the creator of a document to include links to related information either elsewhere in that document or in others. With the appropriate software, a user can easily move from one location to another.

Big deal? In fact, this is more important than it may initially seem. Without some way of linking documents together, they remain in unconnected "islands". In some ways, hypertext-linked documents are to unlinked documents what networked computers are to those that are not networked. Consider the difference between this Guide and a hard-copy book; if I mention a topic in passing I can provide a link to it; a printed book cannot. Hopefully you've already discovered the advantages that this offers. ☺

---

## History of Hypertext

The ideas behind hypertext actually go back far beyond the Web and even electronic computers. Vannevar Bush (1890-1974) is generally credited with introducing the idea in his 1945 description of a theoretical device called the *Memex*, which was intended to be used to store and retrieve documents. He described the concept of a **trail** that would link together related information to make it easier to organize and access the information in the device.

Bush's ideas were used as the basis of the work of several researchers who followed. One of these was Ted Nelson, who coined the term “hypertext” and in 1960, first described a system called *Xanadu*, which is considered one of the original hypertext software models.

The history of the World Wide Web itself goes back to 1989 at *CERN*, the European Organization for Nuclear Research, in Geneva. (The acronym stands for *Conseil Européene pour la Recherche Nucléaire*, the French name of the organization.) Many of the projects undertaken at CERN were large, complex, and took many years to complete. They also involved many scientists who had to work with and share related documents.

## Development and Growth of the Web

A researcher at CERN, Tim Berners-Lee, proposed the idea of creating a “web” of electronically-linked documents. The rapidly-growing Internet was the obvious conduit for this project. He designed the first (very crude and simple) version of the [Hypertext Transfer Protocol \(HTTP\)](#) for TCP/IP in 1990. He was also responsible for developing or co-developing several of the other key concepts and components behind the Web, such as [Uniform Resource Identifiers \(URIs\)](#) and the [Hypertext Markup Language \(HTML\)](#).

The ability to link documents and files together had tremendous appeal, and it took little time before creative individuals found many different uses for this new technology. The early 1990s saw a flurry of development activity. Web server and client software was developed and refined, and the first graphical Web browser, *Mosaic*, was created by the National Center for Supercomputer Applications (NCSA) in 1993. (The developer of this program, Marc Andreessen, eventually formed Netscape Communications.)

Once the Web started to form, it grew very quickly indeed. In fact, to call the growth of the Web anything but “explosive” would not do it justice. In early 1993, there were only 50 active HTTP Web servers. By late 1993, there were over 1,000. By late 1995, thousands of new Web sites were coming online every day, and HTTP requests and responses had overtaken all other TCP/IP application traffic. By the end of the decade there were *millions* of Web sites and over a billion documents available on the Web.

## The World Wide Web Today

While the rapid growth in the size of the Web is amazing, what is even more fascinating is its growth in **scope**. Since you are reading a Guide about networking, you are most likely a Web user, and familiar with the incredible array of different types of information you can find on the WWW today. Early hypertext systems were based on the use of only text

---

documents; today the Web is a world of many media including pictures, sounds and movies. The term *hypertext* has in many contexts been replaced with the more generic *hypermedia*—functionally, if not officially.

The Web has also moved beyond simple document retrieval to providing a myriad of services. A Web site can serve much more than just documents, allowing users to run thousands of kinds of programs. This enables everything from online shopping to entertainment. Web sites are also blurring the lines between different types of applications, offering [Web-based e-mail](#), Web-based Usenet access, bulletin boards and other interactive forums for discussion, and much more.

The Web has had an impact on both networking and society as a whole that even its most enthusiastic early fans could never have anticipated. In fact, the Web was the ultimate “killer application” for the Internet as a whole. In the early 1990s, big corporations viewed the Web as an amusing curiosity; by the end of the decade it was for many a business necessity. Millions of individuals and families discovered the wealth of information that was at their fingertips, and Internet access became for many another “utility”, like telephone service. In fact, the huge increase in Web traffic volume spawned the spending of billions of dollars on Internet infrastructure.

The “dot-com collapse” of the early 21st century took some of the wind out of the Web's sails. The incredible growth of the Web could not continue at its original pace, and has slowed somewhat. But the Web as a whole continues to expand and mature, and will likely be the most important information and service resource on the Internet for some time to come.

**Key Concept:** The *World Wide Web (WWW)* began in 1989 as a project designed to facilitate the representation of relationships between documents and the sharing of information between researchers. The main feature of the Web that makes it so powerful is *hypertext*, which allows links to be made from one document to another. The many benefits of the Web caused it to grow in only a few short years from a small application to the largest and arguably most important application in the world of networking; it is largely responsible for bringing the Internet into the mainstream of society.

---

## **World Wide Web System Concepts and Components**

[Hypertext](#) is the main concept that makes the World Wide Web more than just another message transfer system. However, the idea behind hypertext had been around for decades before the Web was born, as had certain software products based on that idea. Obviously, more than just a concept is needed for an idea to be developed into a successful system.

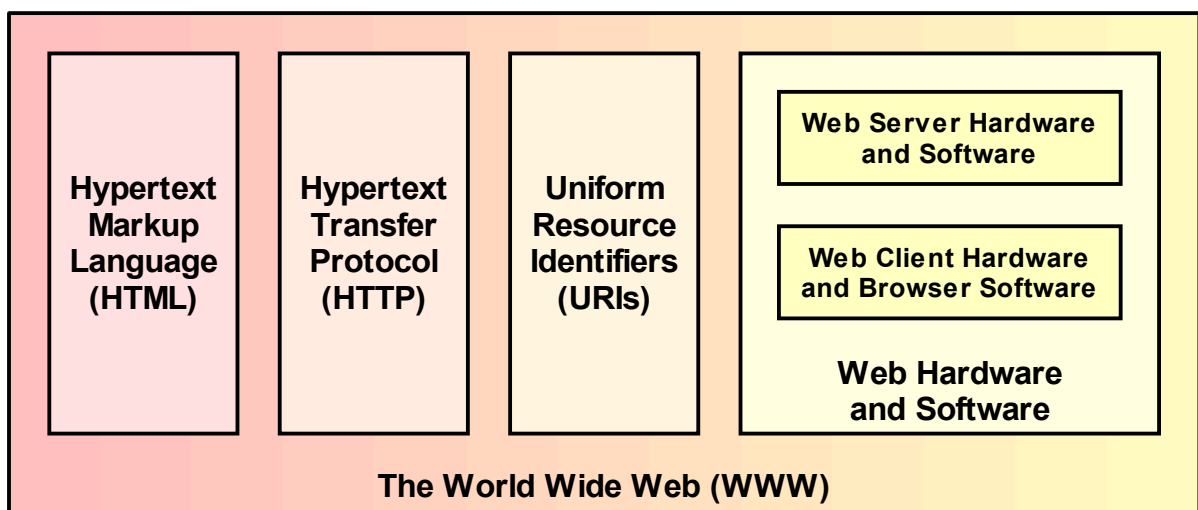

The Web became a phenomenon because it combined the basic idea of hypertext with several other concepts and technologies, to create a rich, comprehensive mechanism for interactive communication. This system today encompasses so many different concepts

---

and software elements, and is so integrated with other technologies, that it's hard to find any two people who agree on what exactly comprises the Web, and which are most critical parts.

For example, one of the keys to the success of the World Wide Web is undeniably the combination of the [TCP/IP internetworking protocol suite](#) and the Internet infrastructure that connects together the computers of the world. Is the Internet then an essential component of the World Wide Web? In many ways it is; and in fact, due to how popular the Web is today, it is common to hear people call the Web “the Internet”.

The functional components of the World Wide Web are illustrated in [Figure 314](#). Let's take a look at them in a bit more detail now.

**Figure 314: Major Functional Components of the World Wide Web**

### ***Major Functional Components of the Web***

We know that equating the Web to the entire Internet is not a precise use of terms, but it shows how important the Web is and how closely it is tied to the Internet. Still, while the Internet and TCP/IP are obviously important parts of the Web's success, they are generic in nature. When it comes to defining the World Wide Web system itself more specifically, three particular components are usually considered most essential:

- ☛ **HyperText Markup Language (HTML):** A text language used to define hypertext documents. The idea behind HTML was to add simple constructs, called *tags*, to regular text documents, to enable the linking of one document to another, as well as to allow special data formatting and the combining of different types of media. HTML has become the standard language for implementing information in hypertext, and has spawned the creation of numerous other related languages.

- 
- ☛ **Hypertext Transfer Protocol (HTTP):** The TCP/IP application-layer protocol that implements the World Wide Web, by enabling the transfer of hypertext documents and other files between a client and server. HTTP began as a very crude protocol for transferring HTML documents between computers, and has evolved to a full-featured and sophisticated messaging protocol. It supports transfers of many different kinds of documents, streaming of multiple files on a connection, and various advanced features including caching, proxying and authentication.
  - ☛ **Uniform Resource Identifiers (URIs):** A method of defining labels that identify resources on an internet so that they can be easily found and referenced. URIs were originally developed to provide a means by which the users of the Web could locate hypertext documents so they could be retrieved. URIs are actually not specific to the Web, though they are most often associated with the Web and HTTP.

**Note:** [Uniform Resource Locators \(URLs\)](#) are a subset of [Uniform Resource Identifiers \(URIs\)](#). The terms are often used interchangeably in World Wide Web discussions.

---

All three of these were created and developed at around the same time, and taken together represent the key technologies that define the World Wide Web. The next two topics in this section describe [HTML](#) and [the use of URIs](#) in the context of the World Wide Web. HTTP is really the heart of the Web and is covered extensively in [its own section](#) later in this Guide.

### ***Web Hardware and Software***

These three main components are supplemented by a number of other elements that play “supporting roles” in rounding out the system as a whole. Chief among these are the hardware and software used to implement client/server communication that makes the Web work: *Web servers* and *Web browsers*.

Web servers are computers that run special server software to allow them to provide hypertext documents and other files to clients who request them. Millions of such machines around the world now serve as a virtual, distributed repository of the enormous wealth of information that the Web represents.

Web browsers are HTTP client software programs that run on TCP/IP client computers to access Web documents on Web servers. These browser programs retrieve hypertext documents and display them, and also implement many of the Web's advanced features, such as caching. Today's browsers support a wide variety of media, allowing the Web to implement many different functions aside from simply hypertext document transfer. Examples include displaying images, playing sounds and implementing interactive programs.

Last but certainly not least, it is the **users** of the Web that are perhaps its most important component. This is sort of “cheating”, as this is in some ways like defining the Internet as being part of the Web. At the same time, I feel that user involvement has had more of a role in shaping the development of Web technology than any other networking application. The

---

Web began as a simple means of exchanging documents; today it has grown to encompass thousands of different applications and services, largely as a result of the creativity of users. Content providers have pushed the boundaries of what the Web can do by creating new ideas for information and services, to satisfy the insatiable demands of the end user community.

**Key Concept:** The World Wide Web is a complete system that is comprised of a number of related components, of which three are most essential. The first is *Hypertext Markup Language (HTML)*, which describes how hypertext documents are constructed; HTML is what allows links between documents to be represented. The second is the *Hypertext Transfer Protocol (HTTP)*, the application layer protocol that moves hypertext and other documents over the Web. The third is the *Uniform Resource Identifier (URI)* mechanism, which provides a consistent means of identifying resources, both on the Web and more generally on the Internet as a whole.

---

## **World Wide Web Media and the Hypertext Markup Language (HTML)**

We've seen in the last two topics that the World Wide Web is based around the central concept of *hypertext*. The prefix “hyper” usually means “above” or “beyond”, and thus hypertext is like text, but goes beyond it in terms of functionality. Documents written in hypertext are similar to regular text files, but include information that implements hypertext functions. These are, of course, usually called *hypertext documents* or *hypertext files*.

The extra information in a hypertext document is used to tell the computer program that displays the file to a user how to format it. This information takes the form of special instructions that are interspersed with the actual text of the document itself, which are written according to the syntax of a defining language. This addition of extra elements to the content of a document is commonly called *marking up* the document.

### ***Overview of HTML***

The standard language used by the World Wide Web is thus called the *Hypertext Markup Language (HTML)*. HTML is one of the three primary [system components of the World Wide Web](#), and was invented in 1990 by the creator of the Web, Tim Berners-Lee. It was not created in a vacuum; rather, it is a specific application of the general concept of a markup language that is described in ISO standard 8879:1986: *Standard Generalized Markup Language (SGML)*.

The idea behind a markup language is to define special items that provide information to the software displaying the document about how it should be presented. For the purposes of hypertext, the most basic type of information in a document is a special instruction that specifies how one document can be linked to another—after all, this linking process is the defining attribute of hypertext.

---

However, HTML goes far beyond just this; it defines a full set of text codes for describing nearly every aspect of how a document is shown to a user. This includes instructions for formatting text (such as defining its color, size and alignment), methods for displaying tabular data, specifications for how to present images and other media along with the document, interactive forms and much more. In theory, the language is only supposed to define the document and leave up to the browser how it should be displayed, but in practice, modern HTML documents also usually contain rather specific instructions for how their information should be presented.

To do justice to HTML, I would have to devote several dozen pages to the subject. I have decided not to do this, because even though HTML is an important part of the Web, it is actually not that important in understanding how the Web works. Knowing HTML is essential if you are writing Web content, and is also critical if you want to understand how to write Web software. Perhaps ironically though, to the actual mechanisms that make the Web work, such as HTTP, “a document is a document”. HTTP is not designed under the assumption that it will transfer HTML, and servers in most cases do not even look at the contents of an HTML file—they just transfer it.

That said, a basic understanding of HTML is important, and it just wouldn't seem right not to provide at least an overview of the language, so I will do that here. I encourage you to seek out one of the many good HTML resources if you want to learn more: there are dozens of them on the World Wide Web (where else? ☺)

## ***HTML Elements and Tags***

In simplest terms, an HTML document is a plain ASCII text file like an e-mail message or other text document. The biggest difference between HTML and regular text, however, is that HTML documents are *structured*. The document is logically organized into a series of *elements* that are arranged according to the rules of the language. Each element defines one part of the document as a whole. For example, the title of a document, a paragraph, a table and a hyperlink to another document are all examples of elements.

Each element is described using special text *tags* that follow a particular syntax. Each tag begins with the “<” symbol, which is then followed by the (case-insensitive) element name, and optionally, additional parameters that describe the element. The tag ends with the “>” symbol. Here's how a tag looks generally:

```
<element parameter1=“value1” parameter2=“value2” ...>
```

Some elements are entirely described by the presence of a tag, and in such cases that tag is the entire element. More often, tags occur in pairs surrounding the actual content of the element; the *start tag* begins with the name of the element and the *end tag* begins with the name of the element preceded by a slash symbol. For example, the title of a document is an element defined as follows:

```
<title>This Is A Great Story</title>
```

---

The content of each element can contain other elements, which causes tags to be nested within each other. For example, if we wanted to highlight the word “Great” in our title by displaying it in bold letters, we can add the “<b>” tag as follows:

```
<title>This Is A <b>Great</b> Story</title>
```

Each whole HTML document is in fact defined as a single “element” called “html”; the whole document is enclosed in “<html>” and “</html>” tags. Within this element, the document is divided into two standard sub-elements that must be present in each document: the *head* and the *body*. The head of the document contains information that describes the document and how it is to be processed; it most commonly contains the title of the document as described above. The body contains the actual content of the document. These three elements define the basic HTML document structure:

```
<html>
<head>
(head elements go here...)
</head>
<body>
(body elements go here...)
</body>
</html>
```

The bulk of the document consists of the body elements that are placed between the “<body>” and “</body>” tags. HTML documents can range from very simple bodies containing only elements such as text paragraphs and perhaps a few links, to very sophisticated documents that are computer-generated and contain hundreds or even thousands of nested tags of various sorts.

### **Common HTML Elements**

[Table 274](#) provides a brief description of some of the more common elements used in the body of an HTML message and the tags that define them, to give you a feel for how the language works:

**Table 274: Common Hypertext Markup Language (HTML) Elements (Page 1 of 3)**

Element	Example Element and Tags	Description
Paragraph	<pre>&lt;p&gt;Jack and Jill went up the hill to fetch a pail of water...&lt;/p&gt;</pre>	Delineates a paragraph of text. Note that everything between the start and end tags will be considered one paragraph, even if split onto multiple lines as I have done here; line breaks are not significant in HTML formatting, only tags.
Line Break	<pre>George W. Bush&lt;br&gt; The White House&lt;br&gt; 1600 Pennsylvania Ave., NW&lt;br&gt; Washington, DC 20500</pre>	Forces a line break. Used instead of the paragraph tag to present lines close together, such as addresses.

**Table 274: Common Hypertext Markup Language (HTML) Elements (Page 2 of 3)**

Element	Example Element and Tags	Description
Heading	<pre>&lt;h1&gt;First Topic&lt;/h1&gt; &lt;h2&gt;Subtopic&lt;/h2&gt;</pre>	Defines section headings, to allow information in a long document to be displayed in hierarchical form. Six sets of tags are defined, from <code>&lt;h1&gt;</code> and <code>&lt;/h1&gt;</code> to <code>&lt;h6&gt;</code> and <code>&lt;/h6&gt;</code> . Browsers will automatically display the “higher-level” headings in more prominent ways, by using larger fonts, underlining the text, or similar.
List	<pre>&lt;p&gt;Shopping list: &lt;ul&gt; &lt;li&gt;Milk &lt;li&gt;Eggs &lt;li&gt;Sushi &lt;/ul&gt; &lt;/p&gt;</pre>	Allows information to be presented as a list. The tag “ <code>&lt;ul&gt;</code> ” means “unnumbered list” and causes the list items to be shown usually as bullet points. Alternately, “ <code>&lt;ol&gt;</code> ” (“ordered list”) can be used to show the items preceded by 1, 2, 3 and so on.
Horizontal Rule	<pre>...end of this part of the story.&lt;/p&gt; &lt;hr size= “3”&gt; &lt;p&gt;Start of next part of story...</pre>	Draws a horizontal line across the page; the “size” parameter controls its thickness. Used to separate logical sections in a document.
Image	<pre>&lt;img src=“companylogo.gif” alt=“XYZ Industries Logo” align=“center”&gt;</pre>	Displays an inline image in the appropriate section of the text. The “src” parameter is a relative or absolute URL for the image, and numerous other parameters can be included to define the image’s alignment, size, “alternate text” to display if the browser is non-graphical (as shown here with the “alt” parameter) and much more.
Link	<pre>&lt;a href=“http:// www.PCGuide.com”&gt;Click here to visit The PC Guide&lt;/a&gt;</pre>	<p>Hyperlinks to another document. The “a” in the tag stands for “anchor”, which is the formal name for a hyperlink. the “href” parameter specifies the URL of the link.</p> <p>Most browsers will underline or otherwise highlight the text between the start and end tags to make it clear that the text represents a hyperlink. It is also possible to give a hyperlink to an image by combining the “<code>&lt;img&gt;</code>” and “<code>&lt;a&gt;</code>” tags.</p>
Bookmark	<pre>&lt;a name=“Step4”&gt;Step 4: Remove paint using scrubbing tool.&lt;/a&gt;</pre>	Creates a bookmark that can be used to hyperlink to a particular section in a document. For example, if the bookmark in this example was in a document at URL “ <a href="http://www.homefixitup.com/repainting.htm">http://www.homefixitup.com/repainting.htm</a> ”, the URL “ <a href="http://www.homefixitup.com/repainting.htm#Step4">http://www.homefixitup.com/repainting.htm#Step4</a> ” refers to this particular place in the document. <a href="#">See the next topic on URLs for more details.</a>

**Table 274: Common Hypertext Markup Language (HTML) Elements (Page 3 of 3)**

Element	Example Element and Tags	Description
Table	<pre>&lt;table&gt; &lt;tr&gt; &lt;td&gt;1st row, 1st column.&lt;/td&gt; &lt;td&gt;1st row, 2nd column.&lt;/td&gt; &lt;/tr&gt; &lt;tr&gt; &lt;td&gt;2nd row, 1st column.&lt;/td&gt; &lt;td&gt;2nd row, 2nd column.&lt;/td&gt; &lt;/tr&gt; &lt;/table&gt;</pre>	Displays information in tabular form. Each “<tr>” and “</tr>” tag set defines one row of the table; within each row, each “<td>” and “</td>” pair defines one table data element. Many different parameters can be provided for each of these tags to control table size and appearance.
Form	<pre>&lt;form method="POST" action="https:// www.myfavesite.com/order.php"&gt; &lt;input type="hidden" name="PRODUCT" value="widget"&gt; &lt;input type="text" name="QUANTITY" size="3"&gt; &lt;input type="submit" value="Click Here to Proceed to the Secure Processing Site"&gt; &lt;/form&gt;</pre>	Defines an HTML form, allowing various sorts of information to be submitted by a client to a program on a Web site designed to process forms. The form consists of the initial “<form>” tag that describes what action to be taken when the submission button is pressed, and other form items such as predefined variables, text entry fields, and buttons; one example of each of these items is shown here.
Script	<pre>&lt;script language=javascript&gt; (<i>Javascript code</i>) &lt;/script&gt;</pre>	Allows instructions in a scripting language to be included in an HTML document. Most often used for Javascript.

### Common Text Formatting Tags

There are also numerous tags that are used to format the appearance of text within a document; some of the more common ones:

- ☛ **<b>text</b>**: Present the enclosed text in bold.
- ☛ **<i>text</i>**: Present the enclosed text in italics.
- ☛ **<u>text</u>**: Present the enclosed text underlined.
- ☛ **<font (parameters)>text</font>**: Present the enclosed text using the indicated font type, size or color.

Again, this is just the tip of the iceberg when it comes to HTML. If you are not familiar with HTML, however, knowing these basic tags should be enough to help you interpret basic HTML documents and learn how HTTP works.

**Key Concept:** The language used by World Wide Web hypertext documents is called the *Hypertext Markup Language (HTML)*. HTML documents are as ASCII text files, but are arranged using a special structure of HTML *elements* that define the different parts of the document and how they should be displayed to the user. Each element is described using special text *tags* that define it and its characteristics.

---

## **World Wide Web Addressing: HTTP Uniform Resource Locators (URLs)**

The main reason that hypertext is so powerful and useful is that it allows related documents to be linked together. In the case of the World Wide Web, this is done using a special set of [Hypertext Markup Language \(HTML\)](#) tags that specifies in one document the name of another document that is related in some important way. A user can move from one document to the next using a simple mouse click. The Web has succeeded largely on the basis of this simple and elegant method of referral.

The notion of hyperlinking has some important implications on how Web documents and other resources are addressed. Even though the Web is at its heart a message transfer protocol similar to the [File Transfer Protocol \(FTP\)](#), the need to be able to define hyperlinks meant that the traditional FTP model of using a set of commands to specify how to retrieve a resource had to be abandoned. Instead, a system was needed whereby a resource could be uniquely specified using a simple, compact string.

The result of this need was the definition of one of the three primarily elements of the World Wide Web: the *Uniform Resource Identifier (URI)*. URIs are divided into two categories: *Uniform Resource Locators (URLs)* and *Uniform Resource Names (URNs)*. While URIs, URLs and URNs grew out of the development of the Web, they have now been generalized to provide an addressing mechanism for a wide assortment of TCP/IP application layer protocols. They are thus [described in detail in a separate section](#); this topic will provide more information on how they are used specifically for the Web.

At the present time, the Web uses [URLs](#) almost exclusively; [URNs](#) are still in development. Web URLs specify the use of the [Hypertext Transfer Protocol \(HTTP\)](#) for resource retrieval, and are thus normally called *HTTP URLs*. These URLs allow a resource such as a document, graphical image or multimedia file to be uniquely addressed by specifying the host name, directory path and file name where it is located.

**Key Concept:** *Uniform Resource Identifiers (URIs)* were developed to allow World Wide Web resources to be easily and consistently identified; they are also now used for other protocols and applications. The type of URI currently used on the Web is the *Uniform Resource Locator (URL)*, which identifies the use of HTTP to retrieve a resource, and provides information on where and how it can be found and retrieved.

---

---

## HTTP URL Syntax

HTTP URLs may be [absolute or relative](#). Absolute URLs are usually used for hyperlinks from one Web site to another, or by users requesting a new document without any prior context. Absolute HTTP URLs are based on the following [common Internet URL syntax](#):

`<scheme>://<user>:<password>@<host>:<port>/<url-path>;<params>?<query>#<fragment>`

For the Web, the scheme is “http:” and the semantics of the different URL elements is defined to have meanings that are relevant to the Web. The general structure of an HTTP URL is thus:

`http://<user>:<password>@<host>:<port>/<url-path>?<query>#<bookmark>`

The following shows how these syntactic elements are specifically defined for HTTP absolute URLs:

- ☉ **<user> and <password>**: Optional authentication information, for resources located on password-protected servers. This construct is rarely used in practice and so most people don't realize it is an option; it has thus become a target of abuse by con artists who use it to [obscure undesirable URLs](#).
- ☉ **<host>**: The host name of the Web server upon which the resource is located. This is usually a [fully-qualified DNS domain name](#), but may also be an IP address.
- ☉ **<port>**: The [TCP port number](#) to use for connecting to the Web server. This defaults to 80 for HTTP and is usually omitted. Rarely, you may see some other port number used, sometimes to allow two copies of Web server software devoted to different uses on the same IP address; port 8080 is especially common as an alternative.
- ☉ **<url-path>**: The path pointing to the specific resource to be retrieved using HTTP. This is usually a full directory path expressing the sequence of directories to be traversed from the root directory to the place where the resource is located, and then the resource's name. It's important to remember that the path is case-sensitive, even though DNS domain names are not.
- ☉ **<query>**: An optional query or other information to be passed to the Web server. This feature is commonly used to implement interactive functions, because the query value can be specified by the user and then be passed from the Web browser to the Web server. The alternative method is by using the [HTTP POST method](#).
- ☉ **<bookmark>**: Identifies a particular location within an [HTML document](#). This is commonly used in very large HTML documents to allow a user to click a hyperlink and scroll to a particular place in the document. See the example in the previous topic (near the end of [Table 274](#)).

Although the URL syntax for the Web is quite “rich” and potentially complex, most Web URLs are actually quite short. The vast majority of these components are omitted, especially the user, password, port and bookmark elements; queries are also used only for special purposes. This leaves the more simplified form you will usually encounter for URLs:

`http://<host>/<url-path>`

---

## Resource Paths and Directory Listings

The <url-path> used to reference a particular document can also be omitted. This provides a convenient way for a user to see what content is offered on a Web site without needing to know what particular document to request. For example, a user who wants to just see what the current headlines are on CNN would just go to “http://www.cnn.com”. In this case, the request is sent to the Web server for the null document “/” (which is implied if it is not specified; technically you are supposed to specify “http://www.cnn.com/”).

How such a “/” request is handled depends on the server. Technically, such a request is actually asking the server “please show me the contents of the root directory of the server”. However, this is both ugly (a listing of file names is not the best way to make a first impression) and a potential security issue (as anyone can see the name of every file on the server). Instead, most HTTP servers are set up to automatically recognize such requests and return a default document, often named something like “index.html” or “default.html”. Many servers will similarly return a default document of some sort if any other directory is specified in a URL; for example, “http://www.pcguide.com/ref” actually returns “http://www.pcguide.com/ref/index.htm”.

The forms above apply to absolute HTTP URLs. URLs may also be relative; this is the norm for links between closely related documents, such as graphics that go with a document, or between documents in a set or project. In this case, usually only a fractional portion of a URL path is specified; this is described fully in [the topic on relative URLs](#).

Note that while it is technically incorrect to leave the “http://” off an HTTP URL, most Web browsers will add it automatically if omitted. As a result, many Web users are in the habit of entering “URLs” that are simply a host name, such as just “www.pcguide.com”.

---

## **TCP/IP Hypertext Transfer Protocol (HTTP)**

The success of the [World Wide Web](#) is a result of the efficiency and usefulness of the complete hypermedia system it implements. We examined in [the last section](#) the basic concepts behind hypertext, and looked at two of the three major components that comprise the World Wide Web system: [HTML](#) and [URLs](#). The third major component of the Web is arguably the most important: the protocol that actually transfers hypertext documents and other files between Web servers and Web clients (browsers). This is one of the most widely-known software protocols in all of networking: the *Hypertext Transfer Protocol (HTTP)*.

In this section I provide a detailed description of the Hypertext Transfer Protocol. I begin with an overview of HTTP and a discussion of its history and versions, and the standards that define them. I then describe the operation of the protocol in five subsections. The first discusses HTTP's operation in general terms, focusing on how connections are established and maintained. The second describes HTTP messages and how they are formatted, and describes HTTP methods (commands) and status codes. The third details the many HTTP headers, which are critically important as they are the primary way that information is communicated between HTTP servers and clients. The fourth subsection provides information about how resources, called entities, are encoded and transferred in HTTP. The final subsection describes special features and capabilities of the modern HTTP protocol.

**Background Information:** Like so many TCP/IP protocols, when HTTP was designed, its creators “borrowed” elements from other application protocols. In this case, HTTP uses certain elements from e-mail, especially the [Multipurpose Internet Mail Extensions \(MIME\)](#). I would recommend familiarity with both the [RFC 822 e-mail message format](#) and MIME, especially MIME [headers](#) and [media types](#), before reading this section. The relationship between HTTP and MIME is covered in [the topic discussing HTTP entities and media types](#).

---

---

## **HTTP Overview, History, Versions and Standards**

The World Wide Web had [humble beginnings](#), as a research project at the Swiss research institute, CERN. The primary goal of the project was to allow hypertext documents to be electronically linked, so selecting a reference in one document to a second one would cause it to be retrieved. To implement this system, some sort of mechanism was needed to allow a client computer to tell a server to send it a document. To fill this function, the early developers of the Web created a new TCP/IP application layer protocol: the *Hypertext Transfer Protocol (HTTP)*.

### ***HTTP/0.9***

The original version of HTTP was intended only for the transfer of hypertext documents, and was designed to be very simple to make implementation of the fledgling Web easier. This early HTTP specifies that an HTTP client establishes a connection to an HTTP server using [TCP](#). The client then issues a single “GET” request specifying a resource to be retrieved. The server responds by sending the file as a stream of text bytes, and the connection is terminated. The entire document defining this version of HTTP is only a couple of pages long!

This first version of HTTP was functional, but extremely limited in its capabilities. It didn't support the transfer of any types of data other than hypertext, and it provided no mechanism for any sort of “intelligent” communication between the client and server. This early HTTP prototype was not up to the task of providing the basis for data transfer for the future of the World Wide Web. It was never made an official RFC standard, and in fact, never even had a formal version number; it is known today as HTTP version 0.9, or “HTTP/0.9” using the version format used by HTTP. I believe this number has no particular significance other than being a bit smaller than the number of the first official version of the protocol.

### ***HTTP/1.0***

The skeleton of functionality that HTTP/0.9 formed the basis for a rapid evolution of HTTP in the early 1990s. As the World Wide Web grew in size and acceptance, many new ideas and features were incorporated into HTTP. The result of a great deal of development effort was the formalization of the first HTTP standard: version 1.0. This much enhanced HTTP was published in May 1996 as RFC 1945, *Hypertext Transfer Protocol — HTTP/1.0*. It had been in use for several years prior to that formal publication date, however.

HTTP/1.0 transformed HTTP from a trivial request/response application to a true messaging protocol. It described a complete message format for HTTP, and explained how it should be used for client requests and server responses. One of the most important changes in HTTP/1.0 was the generalization of the protocol to handle many types of different media, as opposed to strictly hypertext documents. This was done by borrowing concepts and header constructs from the [Multipurpose Internet Mail Extensions \(MIME\)](#) standard defined for e-mail. At the same time that it defined much more capable Web servers and clients, HTTP/1.0 retained backwards compatibility with servers and clients still using HTTP/0.9.

---

HTTP/1.0 was the version of HTTP that was widely implemented in the mid-1990s as the Web exploded in popularity. After only a couple of years, HTTP accounted for the majority of the traffic on the burgeoning Internet. The popularity of HTTP was in fact so great that it single-handedly prompted the installation of a lot of new hardware to handle the load of browser requests and Web server replies.

Unfortunately, much of this huge load of traffic was due to some limitations in HTTP itself. These only became apparent due to the tremendous growth in the use of the protocol which, combined with the normal growing pains of the Internet, led to many frustrated Web users. The inefficiencies of HTTP version 1.0 were a result of design limitations such as the need for each site to be hosted on a different server, the fact that each HTTP session handled only one client request, and a general lack of support for necessary performance-enhancing features such as caching, proxying and partial resource retrieval.

## **HTTP/1.1**

While impatient pundits coined sarcastic terms such as the “World Wide Wait”, the IETF continued to work to improve HTTP. In January 1997, the first draft version of HTTP/1.1 appeared: in RFC 2068. This document was later revised and published as RFC 2616, *Hypertext Transfer Protocol — HTTP/1.1*, in June 1999. HTTP/1.1 retains backwards compatibility with both HTTP/1.0 and HTTP/0.9. It is accompanied by RFC 2617, *HTTP Authentication: Basic and Digest Access Authentication*, which deals with security and authentication issues.

HTTP/1.1 introduces several significant improvements over version 1.0 of the protocol, most of which specifically address the performance problems I just described. Some of the more important improvements in version 1.1 are:

- ☉ **Multiple Host Name Support:** In HTTP/1.0, there was no way to specify the host name of the server to which the client needed to connect. As a result, the Web server at a particular IP address could only support one domain name. This was not only inefficient, it was exacerbating the [depletion of IP addresses](#) in the 1990s, because each new Web server to come online required a new IP address. HTTP/1.1 allows one Web server to handle requests for dozens or even hundreds of different virtual hosts.
- ☉ **Persistent Connections:** HTTP/1.1 allows a client to send multiple requests for related documents to a server in a single TCP session. This greatly improves performance over HTTP/1.0, where each request required a new connection to the server.
- ☉ **Partial Resource Selection:** In HTTP/1.1, a client can ask for only part of a resource rather than the entire document, which reduces the load on the server and saves transfer bandwidth.
- ☉ **Better Caching and Proxying Support:** HTTP/1.1 includes many provisions to make caching and proxying more efficient and effective than they were in HTTP/1.0. These techniques can improve performance by providing clients with faster replies to their requests while reducing the load on servers, as well as enhancing security and implementing other functionality.
- ☉ **Content Negotiation:** A negotiation feature was added that allows the client and server to exchange information to help select the best resource or version of a resource when multiple variants are available.

- 
- ☞ **Better Security:** HTTP/1.1 defines authentication methods and is generally more “security aware” than HTTP/1.0 was.

In addition to these notable improvements, many other minor enhancements were made in HTTP/1.1. Several of these take the form of new headers that can be included in client requests to better control under what circumstances resources are retrieved from the server, and headers in server responses to provide additional information to the client.

### ***Future HTTP Versions***

HTTP/1.1 continues to be the current version of the Hypertext Transfer Protocol, even though it is now several years old. This may seem somewhat surprising, given how widely used HTTP is. Then again, it may be the fact that so many millions of servers and clients implement HTTP/1.1 that no new version has been created. For a while there was speculation that version 1.2 of HTTP would be developed, but this has not happened.

In the late 1990s, work began on a method of expanding HTTP through extensions to the existing version 1.1. Development of the *HTTP Extension Framework* proceeded for a number of years, and in 1998 a proposed draft for a new Internet standard was created. However, as I just said, HTTP/1.1 is so widely deployed and so important that it was very difficult to achieve consensus on any proposal to modify it. As a result, when the HTTP Extension Framework was finally published in February 2000 as RFC 2774, the universal acceptance required for a new standard did not exist. The framework was given “experimental” status, and never became a formal standard.

**Key Concept:** The engine of the World Wide Web is the application protocol that defines how Web servers and clients exchange information: the *Hypertext Transfer Protocol (HTTP)*. The first version of HTTP, HTTP/0.9, was part of the early World Wide Web and was a very simple request/response protocol with limited capabilities that could transfer only text files. The first widely-used version was HTTP/1.0, which is a more complete protocol that allows the transport of many types of files and resources. The current version is HTTP/1.1, which expands HTTP/1.0’s capabilities with several features that improve the efficiency of transfers and address many of the needs of the rapidly growing modern World Wide Web.

---

---

## **HTTP General Operation and Connections**

The Hypertext Transfer Protocol (HTTP) began as an extremely basic protocol, designed to do just one thing: allow a client to send a simple request for a hypertext file and receive it back from the server. Modern HTTP remains at its heart a straight-forward request/reply protocol, but now includes many new features and capabilities to support the growing size of the World Wide Web and the ever-increasing variety of ways that people have found to use it. The best place to start in explaining HTTP is thus by looking at its operation as a whole and how communication takes place between a Web server and a Web client.

In this section I introduce the Hypertext Transfer Protocol by describing its operation in general terms. I begin with a high-level overview of HTTP and discussion of its operational model. I explain the two types of connections that are supported between HTTP clients and servers, and the method by which requests can be pipelined in HTTP/1.1. I then provide more information about how persistent connections are established, managed and terminated in the current version of HTTP.

### **HTTP Operational Model and Client/Server Communication**

The Hypertext Transfer Protocol is the application-layer protocol that implements the World Wide Web. While the Web itself has many different facets, HTTP is only concerned with one basic function: the transfer of hypertext documents and other files from Web servers to Web clients. In terms of actual communication, clients are chiefly concerned with making requests to servers, which respond to those requests.

Thus, even though HTTP includes a lot of functionality to meet the needs of clients and servers, when you boil it down, what you see is a very simple, client/server, request/response protocol. In this respect, HTTP more closely resembles a rudimentary protocol like [BOOTP](#) or [ARP](#) than it does other application-layer protocols like [FTP](#) and [SMTP](#), which all involve multiple communication steps and command/reply sequences.

### ***Basic HTTP Client/Server Communication***

In its simplest form, the operation of HTTP involves only an HTTP client, usually a *Web browser* on a client machine, and an HTTP server, more commonly known as a *Web server*. After a TCP connection is created, the two steps in communication are as follows:

1. **Client Request:** The HTTP client sends a request message formatted according to the rules of the HTTP standard—an *HTTP Request*. This message specifies the resource that the client wishes to retrieve, or includes information to be provided to the server.
2. **Server Response:** The server reads and interprets the request. It takes action relevant to the request and creates an *HTTP Response* message, which it sends back to the client. The response message indicates whether the request was successful, and may also contain the content of the resource that the client requested, if appropriate.

**Figure 315: HTTP Client/Server Communication**

In its simplest form, HTTP communication consists of an HTTP Request message sent by a client to a server, which replies with an HTTP Response.

In HTTP/1.0, each TCP connection involves only one such exchange, as shown in [Figure 315](#); in HTTP/1.1, multiple exchanges are possible, as we'll see in [the next topic](#). Note also that the server may in some cases respond with one or preliminary responses prior to sending the full response. This may occur if the server sends a preliminary response using the “100 Continue” status code prior to the “real” reply. [See the topic on HTTP status codes for more information.](#)

**Key Concept:** HTTP is a client/server-oriented, request/reply protocol. Basic communication consists of an *HTTP Request* message sent by an *HTTP client* to an *HTTP server*, which returns an *HTTP Response* message back to the client.

---

### ***Intermediaries and The HTTP Request/Response Chain***

The simple request/response pair between a client and server becomes more complex when *intermediaries* are placed in the virtual communication path between the client and server. These are devices such as *proxies*, *gateways* or *tunnels* that are used to improve performance, provide security or perform other necessary functions for particular clients or servers. Proxies are particularly commonly used on the Web, because they can greatly improve response time for groups of related client computers.

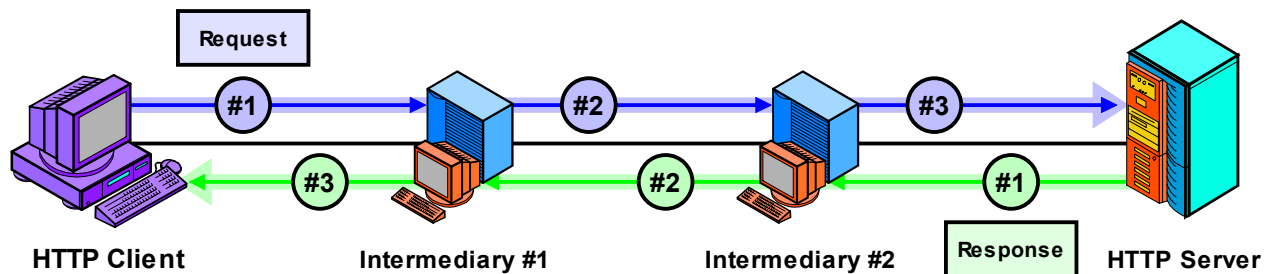

When an intermediary is involved in HTTP communication, it acts as a “middleman”. Rather than the client speaking directly to the server and vice-versa, they each talk to the intermediary. This allows the intermediary to perform functions such as caching, translation, aggregation, or encapsulation. For example, consider an exchange through a single intermediary device. The two-step communication process above would become four steps:

1. **Client Request:** The HTTP client sends a request message to the intermediary device.
2. **Intermediary Request:** The intermediary processes the request, making changes to it if necessary. It then forwards the request to the actual server.
3. **Server Response:** The server reads and interprets the request, takes appropriate action and then sends a response. Since it received its request from the intermediary, its reply goes back to the intermediary.

- 
4. **Intermediary Response:** The intermediary processes the request, again possibly making changes, and then forwards it back to the client.

As you can see, the intermediary acts as if it were a server from the client's perspective, and as a client from the server's viewpoint. Many intermediaries are designed to be able to “intercept” a variety of TCP/IP protocols, by “posing” as the server to a client and the client to a server. Most protocols are unaware of the existence of the interposition of an intermediary in this fashion. HTTP, however, includes special support for certain intermediaries such as [proxy servers](#), providing headers that control how intermediaries handle HTTP requests and replies.

It is possible for two or more intermediaries to be linked together between the client and server. For example, the client might send a request to intermediary 1, which then forwards to intermediary 2, which then talks to the server; see [Figure 316](#). The process is reversed for the reply. The HTTP standard uses the phrase *request/response chain* to refer collectively to the entire set of devices involved in an HTTP message exchange.

**Figure 316: HTTP Request/Response Chain Using Intermediaries**

Instead of being connected directly, an HTTP client and server may be linked using one or more intermediary devices such as proxies. In this example, two intermediaries are present. The *HTTP Request* sent by the client will actually be transferred three times: from the client to the first intermediary, then to the second, and finally to the server. The *HTTP Response* will likewise be created once but transmitted three distinct times. The full set of devices participating in the message exchange is called the request/response chain.

**Key Concept:** The simple client/server operational model of HTTP is complicated when *intermediary devices* such as proxies, tunnels or gateways are inserted in the communication path between the HTTP client and server. HTTP/1.1 is specifically designed with features to support the efficient conveyance of requests and responses through a series of steps from the client through the intermediaries to the server, and back again. The entire set of devices involved in such a communication is called the *request/response chain*.

---

### ***The Impact of Caching on HTTP Communication***

The normal HTTP communication model is changed through the application of *caching* to client requests. Caching is employed by various devices on the Web to store recently-retrieved resources so they can be quickly supplied in reply to a request. The client itself will

---

cache recently-accessed Web documents so that if the user asks for them again they can be displayed without even making a request to a server. If a request is in fact required, any intermediary device can satisfy a request for a file if the file is in its cache.

When a cache is used, the device that has the cached resource requested returns it directly, “short-circuiting” the normal HTTP communication process. In the example above, if intermediary 1 has the file the client needs, it will supply it back to the client directly, and intermediary 2 and the real Web server that the client was trying to reach originally will not even be aware that a request was ever made; [the topic on HTTP caching](#) discusses the subject in much more detail.

**Note:** Most requests for Web resources are made using [HTTP URLs](#) based on a [Domain Name System \(DNS\)](#) host name. The first step in satisfying such requests is to [resolve the DNS domain name into an IP address](#), but this process is separate from the HTTP communication itself.

---

## **HTTP Transitory and Persistent Connections and Pipelining**

The [basic HTTP communication process](#) is a simple “two-step dance”: a client sends a request to a server and the server replies back to the client. Since this was all that HTTP was intended to do, the first version of the protocol was designed so that after a TCP connection was established between the client and server, a single request/response exchange was performed. The request satisfied, the TCP connection would then be terminated.

### ***Transitory Connections***

These connections, called *transitory* due to their short-lived nature, were the only type supported by the original HTTP/0.9, and the same model was maintained in the more widely-deployed HTTP/1.0. The advantage of this connection model is its conceptual simplicity; the problem with it is that it is inefficient when the client needs to make many requests to the same server. This is often the case with modern hypertext documents, which usually carry inline references to images and other media. A typical client request for the home page of a Web site begins with a single request for an HTML file, but then leads to subsequent requests for each of the other related files that go with that document.

With transitory connections, each of these requests made by the client requires a new, distinct [TCP connection](#) to be set up between the client and server. Every connection takes server resources and network bandwidth, so having to establish a new one for each file is woefully inefficient. Suppose that you were having a conversation with someone whom you needed to ask a series of questions. Now imagine that after answering each question, the other person hung up the phone and you had to call them up again! You get the picture.

---

There are some people who consider the temporary nature of HTTP/0.9 and HTTP/1.0 connections to be a “design flaw” of these early versions of HTTP, but I don't think that this is necessarily very fair. In the early days, this model of operation was really not a big issue; it only became problematic when the use of the Web and hypertext evolved.

For the first few years of its existence, hypertext was primarily that: **text**. Having an HTTP session only last long enough for one request/response was generally sufficient since the whole resource was in one file. It was only in the 1990s that hypertext became *hypermedia*, with a heavy emphasis on embedded graphics and other files. When Web pages changed from simple text to multimedia marvels sporting dozens or even hundreds of embedded images, the limitations of HTTP/1.0 really became obvious.

### ***Persistent Connections***

The solution to the inefficiency problem of transitory connections came in HTTP/1.1, which allows an HTTP client and server to set up a *persistent connection*. The basic operation of HTTP is not changed; the main difference is that by default, the TCP connection is kept open after each request/response set, so that the next request and response can be exchanged immediately. The session is only closed when the client is done requesting all the documents it needs.

Keeping the TCP connection between an HTTP client and server alive between requests is probably the single most important way that HTTP/1.1 improves performance over version 1.0. Clients are able to get their files more quickly because they don't have to wait for a TCP connection before each resource is retrieved. Server load is reduced and memory use in busy servers is conserved. Network congestion is reduced through the elimination of unnecessary [TCP handshaking segments](#).

### ***Pipelining***

Persistent connections offer another important performance-enhancing option to HTTP clients: the ability to *pipeline* requests. Suppose the client needs to send a request for files *A*, *B* and *C* to a server. Since the requests for all of these files will be sent in the same TCP session, there is no need for the client to wait for a response to its request for *A* before sending the request for *B*. The client can send requests “rapid-fire”, one after the other. This also improves the efficiency of the server, which will be able to fill the requests in the order in which they are received, as soon as it is able, without having to pause to wait for each new request to be sent.

**Key Concept:** HTTP/0.9 and HTTP/1.0 only supported *transitory connections* between an HTTP client and server, where just a single request and response could be exchanged on a TCP connection. This is very inefficient for the modern Web, where clients frequently need to make dozens of requests to a server. HTTP/1.1 operates by default using *persistent connections*: once a TCP connection is established, the client can send many requests to the server and receive replies to each in turn. This allows files to be retrieved more quickly, and conserves server resources and Internet bandwidth. The client can even *pipeline* its requests, sending the second one immediately, without having to first wait for a reply to the first one. HTTP/1.1 still supports transitory connections for backwards compatibility, when needed.

---

### ***Complications Arising From Persistent Connections and Pipelining***

The obvious advantages of persistent connections make them the default for modern HTTP communication, but they do have one drawback: they complicate the process of sending data from the server to the client. With transitory connections, the client knows that all of the data it receives back from the server is in reply to the one request it sent. Once it has all the bytes the server sent and the TCP session ends, the client knows the file is complete.

With persistent connections, and especially when pipelining is used, the server will typically be sending one file after the other to the client, which must differentiate them. Remember that TCP just sends data as a series of unstructured bytes; the application must take care of specifying where the dividing points are between files. This means that persistent connections and pipelining lead to [data length issues that must be specially addressed in HTTP](#).

To provide compatibility with older versions of the software, HTTP/1.1 servers still support transitory connections, and will automatically close the TCP connection after one response if they receive an HTTP/0.9 or HTTP/1.0 request. HTTP/1.1 clients may also specify that they do not want to use persistent connections in their initial request. The next topic describes how persistent connections are created and managed.

### **HTTP Persistent Connection Establishment, Management and Termination**

The introduction of [persistent connections](#) greatly improved the efficiency of HTTP by cutting out most of the overhead involved in a sequence of HTTP/1.0 requests between a client and server pair. These connections have now become the standard for client/server communication on the Web.

#### ***Connection Establishment***

Like most TCP/IP client/server protocols, the server in HTTP plays the passive role by listening for requests on a particular port number. The default port number for HTTP is [well-known TCP port](#) number 80, and is used by Web browsers for most HTTP requests, unless a different port number is specified in the [URL](#). The client initiates an HTTP connection by opening a TCP connection from itself to the server it wishes to contact.

**Note:** A [DNS name resolution](#) step may precede the entire HTTP connection, since most URLs contain a host name, while HTTP requires that the client know the server's IP address. This can cause confusion, especially since DNS uses [UDP](#) where HTTP uses [TCP](#).

---

Once the TCP connection is active, the client sends its first request message. As we will see in [the next section](#), the request specifies what version of HTTP the client is using. If this is HTTP/0.9 or HTTP/1.0, the server will automatically work in the transitory connection model, and will only send one reply and then close the link. If it is HTTP/1.1, the assumption is that a persistent connection is desired. An HTTP/1.1 client can override this by including the special *Connection: close* header in its initial request, which tells the server it does not want to keep the session active after the request it is sending has been fulfilled.

### ***Persistent Connection Use and Management***

Assuming that a persistent connection is being used, the client may begin pipelining subsequent requests after sending its first request, while waiting for a response from the server to the initial query. As the server starts to respond to requests, the client processes them and takes action such as displaying the data retrieved to the user. The data received from the server may also prompt the client to request more files on the same connection, as in the case of an HTML document that contains references to images.

The server will generally buffer a certain number of pipelined requests from the client. In the case where the client sends too many requests too quickly, the server may “throttle back” the client using the [flow control mechanism built into TCP](#). In theory, the server could also just decide to terminate the connection with the client, but it is better for it to use TCP's existing features. Closing the connection will cause the client to initiate a new connection, potentially exacerbating any overloading problem.

### ***Connection Termination***

The flow of requests and responses continues for as long as the client has requests. The connection can be gracefully terminated by the client by including the *Connection: close* header in the last request it needs to send to the server. All requests are filled in order, so the server will satisfy all outstanding requests and then close the session.

Since HTTP/1.1 supports pipelining of requests, there is usually no need for a client to establish more than one simultaneous connection to the same server. Clients occasionally do this anyway to allow them to get information from a server more quickly. This is considered by many to be “anti-social”, because it can lead to a busy server's resources being monopolized by one client to the exclusion of others that want to access it.

Under special circumstances, either the client or the server may unexpectedly close an active persistent connection. For example, if the client detects that too much time has elapsed since the server last replied, it may conclude that the server has crashed and

---

terminate the connection. Similarly, the server might receive a shutdown command from its administrator or for other reasons end a session with a client abruptly. Servers normally avoid closing down a link during the middle of sending a response.

Both clients and servers must be able to handle abrupt session termination. For servers, there is not much to do; if the client terminates the connection the server simply “cleans up” any resources associated with the connection, and goes on to service the next client.

Clients have more to do when a server prematurely terminates a session, and this is especially the case when requests are pipelined. The client must keep track of all requests sent to the server to ensure that each is filled. If the server closes the session unexpectedly, the client will usually attempt to establish a new connection to retransmit the unfilled requests. Since an abrupt session close is often a sign of a busy server, the HTTP standard specifies that clients use a binary exponential backoff algorithm to wait a variable but increasing amount of time before submitting re-requests for files (similar in concept to the method used to deal with collisions in Ethernet). This helps prevent clients from “piling on” requests to a device that is already overwhelmed.

---

## **HTTP Messages, Message Formats, Methods and Status Codes**

As we saw in [the operational overview of the Hypertext Transfer Protocol](#), HTTP is entirely oriented around the sending of client requests and server responses. These take the form of *HTTP messages* sent between clients and servers. As with all protocols, HTTP uses a special format that dictates the structure of both client request messages and server response messages; understanding how these messages work is a big part of comprehending HTTP as a whole.

In this section I describe the messages used by HTTP and the specific commands and responses issued by clients and servers. I begin with a look at the generic HTTP message format and the major components of every HTTP message. I then discuss the specific formats used for both requests and responses. I explain the different types of HTTP methods (commands) used in client requests, and the HTTP status codes used in server replies.

**Note:** Much of the functionality of HTTP is implemented using *header fields* that appear at the start of each HTTP request and response. Due to the number of headers and their potential complexity, they are covered in detail in [their own section](#).

---

### **HTTP Generic Message Format**

As we've already seen, all of the communication between devices using the Hypertext Transfer Protocol takes place via *HTTP messages*, of which there are only two types: *requests* and *responses*. Clients usually send requests and receive responses, while servers receive requests and send responses. Intermediate devices such as gateways or proxies may send and receive both types of message.

All HTTP messages are created to fit a message structure that the standard calls the *generic message format*. Like most of the other TCP/IP messaging protocols such as [SMTP](#) and [NNTP](#), HTTP messages do not use a binary message format; rather, they are text-based. HTTP messages are based loosely on the electronic mail [RFC 822 and 2822 message standards](#), as well as the [Multipurpose Internet Mail Extensions \(MIME\)](#) standard. I say "loosely" because HTTP messages are similar in construction to e-mail messages but do not strictly follow all of the e-mail or MIME format requirements. For one thing, not all of the RFC 822 and MIME headers are used; there are other differences as well, which we will soon examine.

The HTTP generic message format is as follows:

```
<start-line>
<message-headers>
<empty-line>
[<message-body>]
[<message-trailers>]
```

---

You can see that this is pretty much the same as [the format used for e-mail messages](#) and [for Usenet newsgroup messages](#) too: headers, an empty line and then a message body. All text lines are terminated with the standard “CRLF” control character sequence; the empty line contains just those two characters and nothing else. The headers are always sent as regular text; the body, however, may be either text or 8-bit binary information, depending on the nature of the data to be sent. (This is another way that HTTP does not adhere strictly to the RFC 822 standard; [see the discussion of entities and media types](#) for a full discussion.)

The *start line* is a special text line that conveys the nature of the message. In a request, this line indicates the nature of the request, in the form of a *method*, as well as specifying a URI to indicate the resource that is the object of the request. Responses use the start line to indicate status information in reply to a request. More details on the use of the start line can be found in the next two topics that detail [request messages](#) and [response messages](#) respectively.

### **Header Format**

There are many dozens of message headers defined in HTTP, which are organized into groups by function as we will soon see. Almost all of these are optional; the one exception is the *Host* header, which must be present in each request in HTTP/1.1. Headers may be sent in any order, and all follow the same header format used in e-mail messages:

<header-name>: <header-value>

### **Message Body Contents**

The message body is optional, because it is only needed for certain types of messages. The body may carry a set of information to be communicated between the client and server, such as a detailed error message in a response. More commonly, when present, it carries a file or other resource, which is formally called an *entity* in the HTTP standard. Entities are most often found in the body of a response message, since most client requests ask for a server to send a file or other resource. However, they can also be found in certain requests. HTTP supports many kinds of entities and provides encoding methods to support a wide range of media. Special headers describe the characteristics of the entity, if present. HTTP entities and related issues are described in detail in [their own section of the Guide](#).

**Key Concept:** All HTTP messages conform to a structure called the *generic message format*. This format is based on the RFC 822 and MIME electronic mail message standards, though HTTP does not follow those formats precisely. Each HTTP message begins with a *start line*, then contains a number of *message headers*, followed by an empty line and optionally a *message body*. The body of the message may contain a resource such as a file to be communicated between client and server, called an *entity*.

---

---

## Chunking and Message Trailers

HTTP/1.1 uses persistent connections by default, so messages are sent in a steady stream from client to server and server to client. This requires that some means be used to mark where one message ends and the next begins, which is usually accomplished in one of two ways. The first is using a special header that indicates the length of the message so the receiving device knows when the entire message has been received. The second is a method called “chunking”, where a message is broken into pieces for transmission and the length of each piece indicated in the message body.

When chunking is done, a set of message *trailers* may follow the body of the message. Trailers are in fact the same as headers except for their position in the file, but may only be used for entity headers. [See the topic on data length issues, “chunked” transfers and trailers](#) for more details on all of these matters.

## HTTP Request Message Format

The client initiates an HTTP session by opening a TCP connection to the HTTP server with which it wishes to communicate. It then sends *request messages* to the server, each of which specifies a particular type of action that the user of the HTTP client would like the server to take. Requests can be generated either by specific user action (such as clicking a hyperlink in a Web browser) or indirectly as a result of a prior action (such as a reference to an inline image in an HTML document leading to a request for that image.)

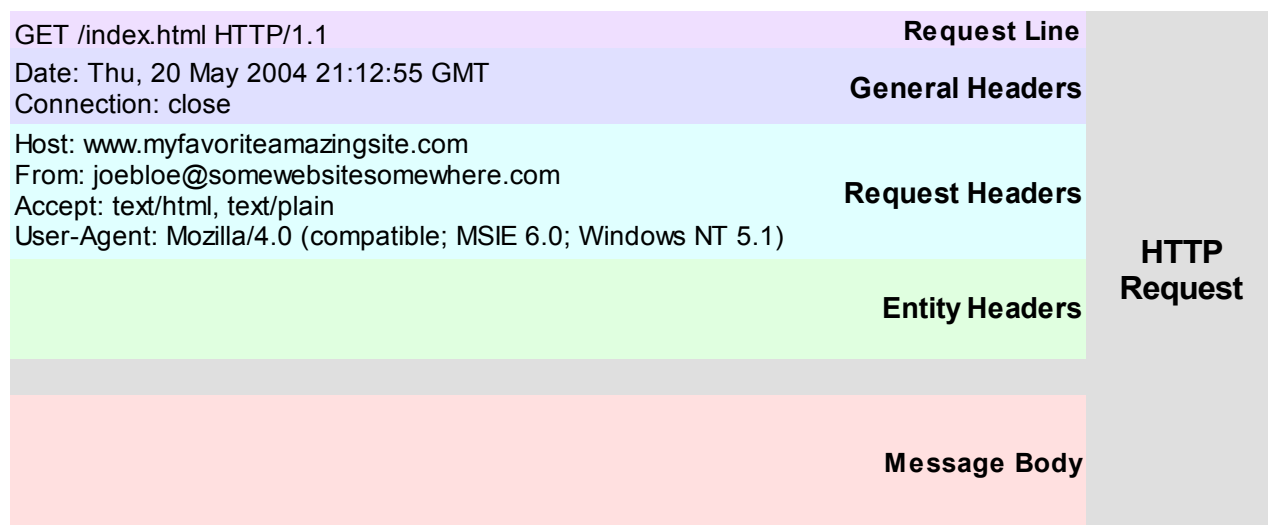

HTTP requests use a message format that is based on the generic message format described in [the preceding topic](#), but specific to the needs of requests. The structure of this format is as follows (see [Figure 317](#)):

```
<request-line>
<general-headers>
<request-headers>
<entity-headers>
<empty-line>
[<message-body>]
[<message-trailers>]
```

### **Request Line**

The generic *start line* that begins all HTTP messages is called a *request line* in request messages. Its has a three-fold purpose: to indicate the command or action that the client wants performed; to specify a resource upon which the action should be taken; and to indicate to the server what version of HTTP the client is using. The formal syntax for the request line is:

```
<METHOD> <request-uri> <HTTP-VERSION>
```

**Figure 317: HTTP Request Message Format**

This diagram shows the structural elements of an HTTP request and an example of the sorts of headers a request might contain. Like most HTTP requests, this one carries no entity, so there are no entity headers and the message body is empty. See [Figure 318](#) for the HTTP response format.

## Method

The *method* is simply the type of action that the client wants the server to take; it is always specified in upper case letters. There are eight standard methods defined in HTTP/1.1, of which three are widely used: *GET*, *HEAD* and *POST*. They are called “methods” rather than “commands” because the HTTP standard uses terminology from object-oriented programming. I explain this and also describe the methods themselves in [the topic describing HTTP methods](#).

## Request URI

The *request URI* is the [uniform resource identifier](#) of the resource to which the request applies. While URIs can theoretically refer to either [uniform resource locators \(URLs\)](#) or [uniform resource names \(URNs\)](#), at the present time a URI is almost always an [HTTP URL that follows the standard syntax rules of Web URLs](#).

Interestingly, the exact form of the URL used in the HTTP request line usually differs from that used in HTML documents or entered by users. This is because some of the information in a full URL is used to control HTTP itself. It is needed as part of the communication between the user and the HTTP client, but not in the request from the client to the server. The standard method of specifying a resource in a request is to include the path and file name in the request line (as well as any optional query information) while specifying the host in the special *Host* header that must be used in HTTP/1.1 requests.

For example, suppose the user enters a URL such as this:

`http://www.myfavoritewebsite.com:8080/chatware/chatroom.php`

---

We obviously don't need to send the "http:" to the server. The client would take the remaining information and split it so the URI was specified as "/chatware/chatroom.php" and the *Host* line would contain "www.myfavoritewebsite.com:8080". Thus, the start of the request would look like this:

```
GET /chatware/chatroom.php HTTP/1.1
Host: www.myfavoritewebsite.com:8080
```

The exception to this rule is when a request is being made to a [proxy server](#). In that case, the request is made using the full URL in its original form, so that it can be processed by the proxy just as the original client did. The request would be:

```
GET http://www.myfavoritewebsite.com:8080/chatware/chatroom.php HTTP/1.1
```

Finally, there is one special case where a single asterisk can be used instead of a real URL. This is for the *OPTIONS* method, which does not require the specification of a resource. (Nominally, the asterisk means the method refers to the server itself.)

## HTTP Version

The *HTTP-VERSION* element tells the server what version the client is using so the server knows how to interpret the request, and what to send and not to send the client in its response. For example, a server receiving a request from a client using versions 0.9 or 1.0 will assume that a [transitory connection is being used rather than a persistent one](#), and will avoid using version 1.1 headers in its reply. The version token is sent in upper case as "HTTP/0.9", "HTTP/1.0" or "HTTP/1.1"—just the way I've been doing throughout my discussion of the protocol.

## Headers

After the request line come any of the headers that the client wants to include in the message; it is in these headers that details are provided to the server about the request. The headers all use the same structure, but are organized into categories based on the functions they serve, and whether they are specific to one kind of message or not:

- ☉ **General Headers:** General headers refer mainly to the message itself, as opposed to its contents, and are used to control its processing or provide the recipient with extra information. They are not particular to either request or response messages, so they can appear in either. They are likewise not specifically relevant to any entity the message may be carrying.
- ☉ **Request Headers:** These headers convey to the server more details about the nature of the client's request, and give the client more control over how the request is handled. For example, special request headers can be used by the client to specify a conditional request—one that is only filled if certain criteria are met. Others can tell the server which formats or encodings the client is able to process in a response message.
- ☉ **Entity Headers:** These are headers that describe the entity contained in the body of the request, if any.

---

Request headers are obviously used only in request messages, but both general headers and entity headers can appear in either a request or a response message. Since there are so many headers and most are not particular to one message type, they are described in detail in [their own complete section](#).

**Key Concept:** *HTTP requests* are the means by which HTTP clients ask servers to take a particular type of action, such as sending a file or processing user input. Each request message begins with a *request line*, which contains three critical pieces of information: the *method* (type of action) the client is requesting; the *URI* of the resource upon which the client wishes the action to be performed, and the version of HTTP that the client is using. After the request line come a set of message headers related to the request, followed by a blank line and then optionally, the message body of the request.

---

## **HTTP Response Message Format**

Up and down; east and west; black and white; yin and yang. Well, you get the idea. Each request message sent by an HTTP client to a server prompts the server to send back a *response message*. Actually, in certain cases the server may in fact send two responses, a preliminary response followed by the real one. Usually though, one request yields one response, which indicates the results of the server's processing of the request, and often also carries an entity (file or resource) in the message body.

Like requests, responses use their own specific message format that is based on the [HTTP generic message format](#). The format, shown in [Figure 318](#), is:

```
<status-line>
<general-headers>
<response-headers>
<entity-headers>
<empty-line>
[<message-body>]
[<message-trailers>]
```

### ***Status Line***

The *status line*—not “response line”, note—is the start line used for response messages. It has two functions: to tell the client what version of the protocol the server is using, and to communicate a summary of the results of processing the client's request. The formal syntax for the status line is:

```
<HTTP-VERSION> <status-code> <reason-phrase>
```

HTTP/1.1 200 OK	Status Line	HTTP Response
Date: Thu, 20 May 2004 21:12:58 GMT	General Headers	
Connection: close		
Server: Apache/1.3.27	Response Headers	
Accept-Ranges: bytes		
Content-Type: text/html	Entity Headers	
Content-Length: 170		
Last-Modified: Tue, 18 May 2004 10:14:49 GMT		
<div>&lt;html&gt; &lt;head&gt; &lt;title&gt;Welcome to the Amazing Site!&lt;/title&gt; &lt;/head&gt; &lt;body&gt; &lt;p&gt;This site is under construction. Please come back later. Sorry!&lt;/p&gt; &lt;/body&gt; &lt;/html&gt;</div>		
		Message Body

**Figure 318: HTTP Response Message Format**

This figure illustrates the construction of an HTTP response, and includes an example of both message headers and body. The status code “200” indicates that this is a successful response to a request; it contains a brief text HTML entity in the message body. See [Figure 317](#) for the HTTP request format.

## HTTP Version

The *HTTP-VERSION* label in the status line serves the same purpose as it does in the [request line of a request message](#); here, it tells the client the version number that the server is using for its response. It uses the same format as in the request line, in upper case as “HTTP/0.9”, “HTTP/1.0” or “HTTP/1.1”. The server is required to return an HTTP version number that is no greater than that the client sent in its request.

## Status Code and Reason Phrase

The *status code* and *reason phrase* provide information about the results of processing the client's request in two different forms. The status code is a three-digit number that indicates the formal result that the server is communicating to the client; it is intended for the client HTTP implementation to process so the software can take appropriate action. The reason phrase is an additional, descriptive text string, which can be displayed to the human user of the HTTP client so he or she can see how the server responded. [I describe status codes and reason phrases later in this section](#), and also list all of the standard codes.

## Headers

The response message will always include a number of headers that provide extra information about it. Response message headers fall into these categories:

- 
- 🕒 **General Headers:** General headers that refer to the message itself and are not specific to response messages or the entity in the message body. These are the same as the generic headers that can appear in request messages (though certain headers appear more often in responses and others are more common in requests).
  - 🕒 **Response Headers:** These headers provide additional data that expands upon the summary result information in the status line. The server may also return extra result information in the body of the message, especially when an error occurs, as discussed below.
  - 🕒 **Entity Headers:** These are headers that describe the entity contained in the body of the response, if any. These are the same entity headers that can appear in a request message, but they are seen more often in response messages. The reason for this is simply that responses more often carry an entity than requests, because most requests are to retrieve a resource.

---

**Note:** Entity headers may appear in a response to describe the resource that is the subject of the request, even if the entity itself is not sent in the message. This occurs when the *HEAD* method is used to request only the headers associated with an entity.

---

Response headers are of course used only in response messages, while the others are general with respect to message type. [See the section describing HTTP headers for more details.](#)

Most response messages contain an entity in the message body. In the case of a successful request to retrieve a resource, this is the resource itself. Responses indicating unsuccessful requests usually contain detailed error information, often in the form of an HTML-formatted error message.

---

**Key Concept:** Each HTTP request sent by a client leads to a server returning one or more *HTTP responses*. Each response message starts with a *status line* that contains the server's HTTP version number, and a numeric *status code* and text *reason phrase* that indicate the result of processing the client's request. The message then contains headers related to the response, followed by a blank line and then the optional message body. Since most HTTP requests ask for a server to return a file or other resource, many HTTP responses carry an entity in the message body.

---

## **HTTP Methods**

A request sent by a client to a server obviously... requests that the server do something. All client/server protocols provide a way for the client to prompt the server to take action, generally by having the client give the server a series of commands. HTTP, in contrast, does not have commands but rather *methods*. Each client [request message](#) begins with the specification of the method that is the subject of the request.

---

What is the difference between a method and a command? In practical terms, nothing; they are the same. So why does HTTP use the term “method” instead of “command”? Good question. ☺ The answer can be found in the abstract of the standard defining HTTP/1.0, RFC 1945. It states, in part, that HTTP is:

“a generic, stateless, object-oriented protocol which can be used for many tasks...”

In highly simplified terms, object-oriented programming is a technique in which software modules are described not as sets of procedures but as *objects* that possess attributes. These modules send messages to each other to communicate, and to cause actions to be performed, where the action taken depends on the nature of the object. In object-oriented programming, the procedures each object can perform are called *methods*.

HTTP is considered to be object-oriented because in many cases, the action taken by a server depends on the object that is the subject of the request. For example, if you ask a server to retrieve a text document, it will send that document, but if you ask for a directory, the server may instead return a default document for that directory. In contrast, a request that specifies the name of a program will result in the program being executed and its output returned (as opposed to the program’s source code being returned.)

### **Common Methods**

Each method allows the client to specify a particular type of action to be taken by the server. Method names are always in upper case letters. There are three methods that are commonly used in HTTP.

#### **GET**

The *GET* method requests that server retrieve the resource specified by the URL on the HTTP request line and send it in a response back to the client. This is the most basic type of request and the one that accounts for the majority of HTTP traffic. When you enter a conventional URL or click on a link to a document or other file, you are usually prompting your Web browser to send a *GET* request.

The handling of a *GET* request depends on a number of factors. If the URL is correct and the server can find the resource, it will of course send back the appropriate response to the client. As mentioned above, the exact resource returned depends on the nature of the object requested. If the request cannot be processed properly, an error message may result. [Caching](#) also comes into play, as a proxy server or even the client itself might satisfy the request before it gets to the server.

It’s important to remember that the meaning of a *GET* request may change if certain headers, such as *If-Modified-Since* or *If-Match* are used—these and other similar headers tell the server to only send the resource if certain conditions are met. A request of this sort is sometimes called a *conditional GET*. Similarly, the *Range* header may be used by the client to request that the server send it only part of a resource; this is usually used for large files. When this header is included, the request may be called a *partial GET*.

---

## **HEAD**

This is identical to the *GET* method, but tells the server to not send the actual body of the message. Thus, the response will contain all of the headers that would have accompanied a reply to the equivalent *GET* message, including [entity headers](#) describing the entity that the server would have sent had the method been *GET*. This method is often used by the client to check the existence, status or size of a file before deciding whether or not it wants the server to send the whole thing.

*HEAD* requests are processed in the same way as *GET* requests, except that only the headers are returned, not the actual resource.

## **POST**

This method allows the client to send an entity containing arbitrary data to the server for processing. It is commonly used to enable a client to submit information such as an interactive HTML form to a program on the server, which then takes action based on that input and sends a response. This capability is now used for all sorts of online programs. The URL in the request specifies the name of the program on the server that is to accept the data.

Contrast this with the *PUT* method below.

## **Other, Less-Common Methods**

The other methods defined by the HTTP standard are not used as often, but I will describe them briefly, as you may still encounter them from time to time.

## **OPTIONS**

Allows the client to request that the server send it information about available communication options. A URI of a resource may be specified to request information relevant to accessing that resource, or an asterisk (“\*”) may be used to indicate that the query is about the server itself. The response includes headers that give the client more details about how the server may be accessed.

## **PUT**

Requests that the server store the entity enclosed in the body of the request at the URL specified in the request line. The difference between a *PUT* and a *POST* is that in a *PUT*, the URI identifies the entity in the request, while in a *POST*, the URI identifies a program intended to **process** the entity in the request. Thus a *PUT* would be used to allow a file to be copied to a server, in the exact complement to how a *GET* requests that a file be copied to the client. A *POST* is used for interactive programs, as explained above.

Now, would you like people to be able to store files on your server in the same way that they request them? Neither would I. This is one primary reason why *PUT* is not often used. It has valid uses, such as uploading content to a Web site, and must be used with authentication in this case. However, generally speaking, storing files on a site is more often accomplished using other means, like FTP.

---

## DELETE

Requests that the specified resource be deleted. This has the same issues as *PUT* and is not often used for similar reasons.

## TRACE

Allows a client to receive back a copy of the request that it itself sent to the server, for diagnostic purposes.

**Note:** In addition to the methods described above, the HTTP standard reserves the method name *CONNECT* for future use. An earlier version of HTTP/1.1, RFC 2068, also defined the methods *PATCH*, *LINK* and *UNLINK*. These were removed in the final version but reference to them is still sometimes seen.

---

**Key Concept:** Each HTTP client request specifies a particular type of action that the server perform; in HTTP, these are called not commands but rather *methods*. The three most common HTTP methods are *GET*, which prompts a server to return a resource; *HEAD*, which returns just the headers associated with a resource; and *PUT*, which allows a client to submit data to a server for processing.

---

## "Safe" and Idempotent Method Categorizations

As we've seen above, methods vary greatly in the type of behavior they cause the server to take. The HTTP standard defines two characteristics that can be used to differentiate methods based on the impact they have on a server:

- 🕒 **"Safe" Methods:** These are methods that an administrator of a server can feel reasonably comfortable permitting a client to send because they are very unlikely to have any negative "side-effects". The methods usually put into this category are *GET*, *HEAD*, *OPTIONS* and *TRACE*. The methods that cause data to be accepted by the server for processing, or lead to changes on the server, are deemed "unsafe": *POST*, *PUT*, and *DELETE*. (The fact that they are "unsafe" doesn't mean a server never allows them, just that they require more care and detail in handling than the others.)
- 🕒 **Idempotent Methods:** Woah, 10-dollar word time. 😊 A method is said to be *idempotent* if repeating the same method request numerous times causes the exact same results as if the method were issued only once. For example, if you load a Web page in your browser, and then type the same URL in again, you get the same result, at least most of the time. In general, all of the methods in HTTP have this property inherently except one: *POST*.

---

The *POST* method is not idempotent because each instance of a *POST* request causes the receiving server to process the data in the request's body. Submitting a *POST* request two or more times can often lead to undesirable results. The classic example is hitting the “submit” button on a form more than once, which can lead to annoyances such as a duplicate message on an Internet forum, or even a double order at an online store.

There are also situations where a method that is normally idempotent may not be. A *GET* request for a simple document is idempotent, but a *GET* for a script can change files on the server and therefore is not idempotent. Similarly, a sequence of idempotent methods can be non-idempotent. For example, consider a situation where a *PUT* request is followed by a *GET* for the same resource. This sequence is non-idempotent because the second request depends on the results of the first.

The significance of non-idempotence is that clients must handle such requests or sequences specially. The client must keep track of them, and make sure that they are filled in order and only once. The HTTP standard also specifies that non-idempotent methods should not be pipelined, to avoid problems if an HTTP session is unexpectedly terminated. For example, if two *POST* requests were pipelined and the server got hung up handling them, the client would need to reissue them but might not know how many of the originals had been successfully processed.

### **HTTP Status Code Format. Status Codes and Reason Phrases**

Every request sent by an HTTP client causes one (or more) responses to be returned by the server that receives it. As we saw in [the topic describing the response message format](#), the first line of the response is a status line that contains a summary of the results of processing the request. The purpose of this line is to communicate quickly whether or not the request was successful, and why.

HTTP status lines contain both a numeric *status code* and a text *reason phrase*. The idea behind this was taken directly from earlier application layer protocols such as [FTP](#), [SMTP](#) and [NNTP](#). The reason for having both a number and a text string is that computers can more easily “understand” the results of a request by looking at a number, and can then quickly respond accordingly. Humans, on the other hand, find numbers cryptic and text descriptions easier to comprehend. ([The topic on FTP reply codes](#) discusses more completely the reasons why numeric reply codes are used in addition to descriptive text.)

---

## Status Code Format

HTTP status codes are three digits in length and follow a particular format where the first digit has particular significance. Unlike FTP and the others, the second digit does not stand for a functional grouping; the second and third digits together just make 100 different options for each of the categories indicated by the first digit. Thus, the general form of an HTTP status code is “xyy”, where the first digit, “x”, is specified as given in [Table 275](#).

**Table 275: HTTP Status Code Format: First Digit Interpretation**

Status Code Format	Meaning	Description
1yy	Informational Message	Provides general information; does not indicate success or failure of a request.
2yy	Success	The method was received, understood and accepted by the server.
3yy	Redirection	The request did not fail outright, but additional action is needed before it can be successfully completed.
4yy	Client Error	The request was invalid, contained bad syntax or could not be completed for some other reason that the server believes was the client's fault.
5yy	Server Error	The request was valid but the server was unable to complete it due to a problem of its own.

In each of these five groups, the code where “yy” is “00” is defined as a “generic” status code for that group, while other two-digit combinations are more specific responses. For example, “404” is the well-known specific error message that means the requested resource was not found by the server, while “400” is the less specific “bad request” error. This system was set up to allow the definition of new status codes that certain clients might not comprehend. If a client receives a strange code, it just treats it as the equivalent of the generic response in the appropriate category. So if a server response starts with the code “491” and the client has no idea what this is, it just treats it as a 400 “bad request” reply.

## Reason Phrases

The reason phrase is a text string that provides a more meaningful description of the error for people who are bad at remembering what cryptic codes stand for (which would be most of us!) The HTTP standard includes “sample” reason phrases for each status code, but these can be customized by the administrators of a server if desired. When a server returns a more detailed HTML error message in the body of its response message, the reason phrase is often used for the “title” tag in that message body.

**Key Concept:** Each HTTP response includes both a numeric *status code* and a text *reason phrase*, both of which indicate the disposition of the corresponding client request. The numeric code allows software programs to easily interpret the results of a request, while the text phrase provides more useful information to human users. HTTP status codes are three digits in length, with the first digit indicating the general class of the reply.

## Status Codes and Reason Phrases

Table 276 lists in numerical order the status codes defined by the HTTP/1.1 standard, along with the “standard” reason phrase and a brief description of each:

**Table 276: HTTP Status Codes (Page 1 of 4)**

Status Code	Reason Phrase	Description
100	Continue	Client should continue sending its request. This is a special status code; see below for details.
101	Switching Protocols	The client has used the <i>Upgrade</i> header to request the use of an alternative protocol and the server has agreed.
200	OK	Generic successful request message response. This is the code sent most often when a request is filled normally.
201	Created	The request was successful and resulted in a resource being created. This would be a typical response to a <i>PUT</i> method.
202	Accepted	The request was accepted by the server but has not yet been processed. This is an intentionally “non-committal” response that does not tell the client whether or not the request will be carried out; the client determines the eventual disposition of the request in some unspecified way. It is used only in special circumstances.
203	Non-Authoritative Information	The request was successful, but some of the information returned by the server came not from the original server associated with the resource but from a third party.
204	No Content	The request was successful, but the server has determined that it does not need to return to the client an entity body.
205	Reset Content	The request was successful; the server is telling the client that it should reset the document from which the request was generated so that a duplicate request is not sent. This code is intended for use with forms.
206	Partial Content	The server has successfully fulfilled a partial GET request. <a href="#">See the topic on methods</a> for more details on this, as well as <a href="#">the description of the Range header</a> .
300	Multiple Choices	The resource is represented in more than one way on the server. The server is returning information describing these representations, so the client can pick the most appropriate one, a process called <a href="#">agent-driven negotiation</a> .

**Table 276: HTTP Status Codes (Page 2 of 4)**

Status Code	Reason Phrase	Description
301	Moved Permanently	The resource requested has been moved to a new URL permanently. Any future requests for this resource should use the new URL.  This is the proper method of handling situations where a file on a server is renamed or moved to a new directory. Most people don't bother setting this up, which is why URLs "break" so often, resulting in 404 errors as discussed below.
302	Found	The resource requested is temporarily using a different URL. The client should continue to use the original URL. See code 307.
303	See Other	The response for the request can be found at a different URL, which the server specifies. The client must do a fresh <i>GET</i> on that URL to see the results of the prior request.
304	Not Modified	The client sent a conditional <i>GET</i> request, but the resource has not been modified since the specified date/time, so the server has not sent it.
305	Use Proxy	To access the requested resource, the client must use a proxy, whose URL is given by the server in its response.
306	(unused)	Defined in an earlier (draft?) version of HTTP and no longer used.
307	Temporary Redirect	The resource is temporarily located at a different URL than the one the client specified.  Note that 302 and 307 are basically the same status code. 307 was created to clear up some confusion related to 302 that occurred in earlier versions of HTTP (which I'd rather not get into!)
400	Bad Request	Server says, "huh?" ☹ Generic response when the request cannot be understood or carried out due to a problem on the client's end.
401	Unauthorized	The client is not authorized to access the resource. Often returned if an attempt is made to access a resource protected by a password or some other means without the appropriate credentials.
402	Payment Required	This is reserved for future use. Its mere presence in the HTTP standard has caused a lot of people to scratch their chins and go "hmm..." ☹
403	Forbidden	The request has been disallowed by the server. This is a generic "no way" response that is not related to authorization. For example, if the maintainer of Web site blocks access to it from a particular client, any requests from that client will result in a 403 reply.
404	Not Found	The most common HTTP error message, returned when the server cannot locate the requested resource. Usually occurs due to either the server having moved/removed the resource, or the client giving an invalid URL (misspellings being the most common cause.)
405	Method Not Allowed	The requested method is not allowed for the specified resource. The response includes an <i>Allow</i> header that indicates what methods the server will permit.

**Table 276: HTTP Status Codes (Page 3 of 4)**

Status Code	Reason Phrase	Description
406	Not Acceptable	The client sent a request that specifies limitations that the server cannot meet for the specified resource. This error may occur if an overly-restrictive list of conditions is placed into a request such that the server cannot return any part of the resource.
407	Proxy Authentication Required	Similar to 401, but the client must first authenticate itself with the <a href="#">proxy</a> .
408	Request Timeout	The server was expecting the client to send a request within a particular time frame and the client didn't send it.
409	Conflict	The request could not be filled because of a conflict of some sort related to the resource. This most often occurs in response to a <i>PUT</i> method, such as if one user tries to <i>PUT</i> a resource that another user has open for editing, for example.
410	Gone	The resource is no longer available at the server, which does not know its new URL. This is a more specific version of the 404 code that is used only if the server knows that the resource was intentionally removed. It is seen rarely (if ever) compared to 404.
411	Length Required	The request requires a <a href="#">Content-Length header field</a> and one was not included.
412	Precondition Failed	Indicates that the client specified a precondition in its request, such as the use of an <i>If-Match</i> header, which evaluated to a false value. This indicates that the condition was not satisfied so the request is not being filled. This is used by clients in special cases to ensure that they do not accidentally receive the wrong resource.
413	Request Entity Too Large	The server has refused to fulfill the request because the entity that the client is requesting is too large.
414	Request-URI Too Long	The server has refused to fulfill the request because the URL specified is longer than the server can process. This rarely occurs with properly-formed URLs but may be seen if clients try to send gibberish to the server.
415	Unsupported Media Type	The request cannot be processed because it contains an entity using a media type the server does not support.
416	Requested Range Not Satisfiable	The client included a <i>Range</i> header specifying a range of values that is not valid for the resource. An example might be requesting bytes 3,000 through 4,000 of a 2,400-byte file.
417	Expectation Failed	The request included an <i>Expect</i> header that could not be satisfied by the server.
500	Internal Server Error	Generic error message indicating that the request could not be fulfilled due to a server problem.
501	Not Implemented	The server does not know how to carry out the request, so it cannot satisfy it.
502	Bad Gateway	The server, while acting as a gateway or proxy, received an invalid response from another server it tried to access on the client's behalf.

---

**Table 276: HTTP Status Codes (Page 4 of 4)**

Status Code	Reason Phrase	Description
503	Service Unavailable	The server is temporarily unable to fulfill the request for internal reasons. This is often returned when a server is overloaded or down for maintenance.
504	Gateway Timeout	The server, while acting as a gateway or proxy, timed out while waiting for a response from another server it tried to access on the client's behalf.
505	HTTP Version Not Supported	The request used a version of HTTP that the server does not understand.

### ***The 100 (Continue) Preliminary Reply***

Phew. Now, let's go back to the top, status code 100. Normally, a client sends a complete request to the server, and waits for a response to it (while optionally [pipelining additional requests](#)). In certain circumstances, however, the client might wish to check in advance if the server is willing to accept the request before it bothers sending the whole message. This is not a common occurrence, because most requests are quite small, which makes it not worth the bother. However, in cases where a user wants to submit a very large amount of data to an online program, or use *PUT* to store a large file, for example, checking with the server first can be a useful optimization.

In this situation, the client sends a request containing the special header “*Expect: 100-continue*”. Assuming that the server supports the feature, it will process the request's headers and immediately send back the “*100 Continue*” preliminary reply. This tells the client to continue sending the rest of the request. The server then processes it and responds normally. If the server doesn't send the 100 response after a certain amount of time, the client will typically just send the rest of the request anyway.

**Note:** In some cases, servers send these preliminary replies even when they are not supposed to, so clients must be prepared to deal with them (they are simply discarded, since they contain no information).

---

---

## HTTP Message Headers

HTTP communication takes place through the relatively simple [exchange of request and response messages](#). There are only a small number of [methods \(commands\)](#) supported by the protocol, which might give one the impression that the protocol is quite limited. Looks can be deceiving, however. Much of the functionality in HTTP is actually implemented in the form of *message headers*, which convey important details between clients and servers.

Some headers can appear in only [HTTP requests](#), some in only [HTTP responses](#), and some in either type of message. Since they are so important, there are literally dozens of them, and many apply to both requests and responses, I decided to describe them in detail in a separate section rather than try to summarize them too much in the course of describing the message formats

In this section I provide a description of each of the many headers used in HTTP request and response messages. The section contains four topics, each of which covers one of the four basic types of HTTP headers: general headers, request headers, response headers and entity headers.

**Background Information:** I assume here that you have already read [the preceding section describing HTTP message formats](#).

---

**Note:** For the purpose of determining how Web caches treat HTTP messages, HTTP headers are categorized as either *end-to-end* or *hop-by-hop* headers. The former are meaningful only to the ultimate recipient of a message, while the latter are relevant to each device in the [chain of devices](#) (such as [proxies](#)) connecting a client and server. To avoid unnecessary complication I have not categorized the headers in this section using these categories; [see the topic on caching](#) for more information. In the descriptions of the individual headers, I indicate which headers are hop-by-hop; all others are end-to-end.

---

## HTTP General Headers

HTTP *general headers* are so named because unlike the other three categories, they are not specific to any particular kind of message or message component (request, response or message entity). General headers are used primarily to communicate information about the message itself, as opposed to what content it carries. They provide general information and control how a message is processed and handled.

---

Despite not being specific to either requests or replies, some general headers are used either mostly or entirely in one or the other type of message. There are also some general headers that can appear in either a request or a reply, but have a somewhat different meaning in each.

## Cache-Control

Specifies directives that manage how caching is performed either for an HTTP request or response. These directives affect the handling of a request or response by all devices in the [request/response chain](#) from the HTTP client, through any present intermediaries, to the HTTP server (or the other way, from the server, through intermediaries, to the client). They override any default caching behavior performed by a device. [See the topic on caching for a full exposition of the subject.](#)

There are a dozen individual directives that can appear in this header, the full details of which can be found in RFC 2616. Even though this is a general header, some directives can appear only in a request or a response. Some also include an additional parameter, such as a number of seconds, that control their interpretation. [Table 277](#) provides a brief summary of the different *Cache-Control* options and how they are used.

Note that only one directive may appear in a *Cache-Control* header, but more than one such header can appear in a message.

**Table 277: HTTP *Cache-Control* Directives (Page 1 of 2)**

Cache-Control Directive	HTTP Message Type	Description
<b><i>no-cache</i></b>	<i>Request or Response</i>	When present, forces a caching device to forward any subsequent requests for the same content to the server for revalidation. That is, the cache must check with the server to ensure that the cached data is still valid.  Also see the <i>Pragma</i> header description, for an alternative way of accomplishing the same thing.
<b><i>public</i></b>	<i>Response</i>	Indicates that the response may be cached by any cache, including a shared one (a cache used by many clients). <a href="#">See the topic on caching for more details on shared caches.</a>
<b><i>private</i></b>	<i>Response</i>	Specifies that the response is intended for only a particular user and should not be placed into a shared cache.
<b><i>no-store</i></b>	<i>Request or Response</i>	Specifies that the entire request or response should not be stored in a cache. This is used sometimes to prevent the storing of sensitive documents in caches where unauthorized people might be able to access them. However, as the HTTP standard points out, this is really a very rudimentary security measure and should not be trusted a great deal (since a malicious cache operator could simply ignore the directive.)
<b><i>max-age</i></b>	<i>Request or Response</i>	In a request, indicates that the client is willing to accept a response whose age is no greater than the value specified. In a response, indicates the maximum age of the response before it is considered “stale”—this is an alternative to the use of the <i>Expires</i> header and takes precedence over it.

**Table 277: HTTP Cache-Control Directives (Page 2 of 2)**

Cache-Control Directive	HTTP Message Type	Description
<b><i>s-max-age</i></b>	<i>Response</i>	If present, this directive specifies the maximum age for shared caches receiving the response. Private caches (ones that serve only a single client) use the <i>max-age</i> value described just above.
<b><i>min-fresh</i></b>	<i>Request</i>	Specifies that the client wants a response that is not only not stale at the time the request is received, but that will remain “fresh” for the specified number of seconds.
<b><i>max-stale</i></b>	<i>Request</i>	If sent without a parameter, indicates that the client is willing to accept a stale reply (one that has expired). If a numeric parameter is included, it indicates how stale, in seconds, the response may be.
<b><i>only-if-cached</i></b>	<i>Request</i>	Used only in special circumstances, this directive forces the reply to come from a cache only; the content may not come from the actual specified HTTP server.
<b><i>must-revalidate</i></b>	<i>Response</i>	Instructs a cache to revalidate its cache entry for the given response with the original server after it becomes stale. This is used to prevent problems with certain types of transactions that can occur if stale cache entries are sent to a client (perhaps as a result of the client using the <i>max-stale</i> directive.)
<b><i>proxy-revalidate</i></b>	<i>Response</i>	Similar to <i>must-revalidate</i> , but applies only to proxies that service many users. Private caches, such as those on individual client computers, are not affected.
<b><i>no-transform</i></b>	<i>Request or Response</i>	Some caches will, by default, change the form in which certain cached entries are stored, to save space or improve performance. In cases where this might cause problems, the client or server can use this directive to request that this transformation not be performed.

## Connection

Contains instructions that pertain only to this particular connection, and must not be retained by proxies and used for further connections. The most common use of this header is with the parameter “close”, as follows:

Connection: close

This overrides the default [persistent connection](#) behavior of HTTP/1.1, forcing the connection to terminate after the server's response. *Connection* is a hop-by-hop header.

## Date

Indicates the date and time when the message originated. This is the same as the *Date* header in the [RFC 822 e-mail format](#). A typical example would be:

Date: Wed, 06 Aug 2003 16:43:50 GMT

---

## ***Pragma***

Used to enable implementation-specific directives to be applied to all devices in the request/response chain. One common use of this header is to suppress caching by including “*Pragma: no-cache*” in a message. This has the same meaning as a “*Cache-Control: no-cache*” header, and is included in HTTP/1.1 for backward compatibility with HTTP/1.0 (which supports *Pragma* but not *Cache-Control*).

## ***Trailer***

When “[chunked](#)” transfers are used, certain headers may be placed as trailers, after the data being sent. In this case, the *Trailer* header is included before the data, and lists the names of the headers that are actually trailers in that message. This warns the recipient to look for them after the data. *Trailer* is a hop-by-hop header.

## ***Transfer-Encoding***

Indicates what encoding has been used for the body of the message, to ensure that it is able to be transferred properly between devices. This header is most often used with the “chunked” transfer method. Note that this header describes encoding applied to an entire message, and is thus not the same as the *Content-Encoding* [entity header](#), which specifically describes the entity carried in a message. [See the topic on content and transfer encodings](#) for a full discussion. This header applies only to a single transfer, so it is a hop-by-hop header.

## ***Upgrade***

Allows a client device to specify what additional protocols it supports. If the server also supports one of the protocols the client listed, the server may agree to “upgrade” the connection to the alternative protocol. It indicates the protocol to which it is upgrading by including an *Upgrade* header in a 101 (“*Switching Protocols*”) response to the client. This is a hop-by-hop header.

## ***Via***

Included by intermediary devices to indicate to the recipient what gateways, proxies and/or tunnels were used in conveying a request or response. This header allows easy tracing of the path a message took over a potentially complex chain of devices between a client and server.

## ***Warning***

Used when needed to provide additional information about the status of a message. Many of the defined warning header types are related to caching. More than one *Warning* header may appear in a message, and each typically includes a three-digit numeric code as well as a plain text message—the same basic format used in [HTTP response status codes](#).

---

Table 278 briefly lists the warnings defined in RFC 2616.

**Table 278: HTTP *Warning* Header Codes**

Warning Code	Warning Text	Description
110	Response is stale	Must be included when a response provided by a cache is stale (that is, has passed the expiration time set for it.)
111	Revalidation failed	A cache attempted to revalidate a cached entry but was unsuccessful, so it returned its (stale) cached entry.
112	Disconnected operation	The cache is disconnected from the rest of the network.
113	Heuristic expiration	Included if the cache chose a freshness lifetime of more than 24 hours, and the age of the response is also greater than 24 hours.
199	Miscellaneous warning	Catch-all code for other, non-specific warnings.
214	Transformation applied	Warns the recipient that an intermediate cache or proxy applied a transformation of some type to change the <a href="#">content coding</a> or <a href="#">media type</a> of the message or message body.
299	Miscellaneous persistent warning	Similar to code 199 but indicates a persistent warning.

**Key Concept:** HTTP *general headers* can appear in either an *HTTP Request* or *HTTP Response* message. They are used to communicate information about the message itself, as opposed to its contents. General headers are used for functions such as specifying the date and time of a message, controlling how the message is cached, and indicating its transfer encoding method.

---

## **HTTP Request Headers**

HTTP *request headers*, as you might imagine, are used only in HTTP [request messages](#), and serve a number of functions in them. First, they allow the client to provide information about itself to the server. Second, they give additional details about the nature of the request that the client is making. Third, they allow the client to have greater control over how its request is processed and how (or even if) a response is returned by the server or intermediary.

This is the largest of the four categories of HTTP headers, comprising over a dozen different types.

### ***Accept***

Allows the client to tell the server what Internet media types it is willing to accept in a response. The header may list several different MIME media types and subtypes that the client knows how to deal with. Each may be prepended with a “quality value” (“q”

---

parameter) to indicate the client's preference. If this header is not specified, the default is for the server to assume any media type may be sent to the client. See the topics on [entity media types](#) and [content negotiation](#) for more information on how this header is used.

### ***Accept-Charset***

Similar to *Accept*, but specifies what character sets the client is willing to accept in a response, rather than what media types. Again, the listed charsets may use a “q” value, and again, the default if the header is omitted is for the client to accept any character set.

### ***Accept-Encoding***

Similar to *Accept* and *Accept-Charset*, but specifies what content encodings the client is willing to accept. This is often used to control whether or not the server may send content in compressed form. (Remember that [content codings are not the same as transfer encodings](#).)

### ***Accept-Language***

Similar to the preceding *Accept*-type headers, but provides a list of *language tags* that indicate what languages the client supports or expects the server to use in its response.

### ***Authorization***

Used by the client to present authentication information (called “credentials”) to the server to allow the client to be authenticated. This is required only when the server requests authentication, often by sending a 401 (“*Unauthorized*”) response to the client's initial request. This response will contain a *WWW-Authenticate* header providing the client with details on how to authenticate with the server. [See the topic on security and privacy](#).

### ***Expect***

Indicates certain types of actions that the client is expecting the server to perform. Usually the server will accept the indicated parameters; if not, it will send back a 417 (“*Expectation Failed*”) response. The most common use of this field is to control when the server sends a 100 (“*Continue*”) response. The client indicates that it wants the server to send this preliminary reply by including the “*Expect: 100-continue*” header in its request. ([See the end of the topic on status codes](#) for details.)

### ***From***

Contains the e-mail address of the human user making the request. This is optional, and since it is easily spoofed, should be used only for informational purposes, and not for any type of access rights determination or authentication.

---

## **Host**

Specifies the Internet host as a [DNS domain name](#), and may also contain a port number specification as well (typically, only if a port other than the HTTP default of 80 is to be used). This header is used to allow multiple domains to be served by the same Web server on a particular IP host. It has the distinction of being the only **mandatory** header—it must be present in all HTTP/1.1 requests.

## **If-Match**

Makes a method conditional by specifying the *entity tag* (or tags) corresponding to the specific entity that the client wishes to access. This is usually used in a *GET* method, and the server responds with the entity only if it matches the one specified in this header. Otherwise, a 412 (*Precondition Failed*) reply is sent.

## **If-Modified-Since**

Makes a method conditional by telling the server to return the requested entity only if it has been modified since the time specified in this header. Otherwise, the server sends a 304 (*Not Modified*) response. This is used to check if a resource has changed since it was last accessed, to avoid unnecessary transfers.

## **If-None-Match**

This is the opposite of *If-Match*; it creates a conditional request that is only filled if the specified tag(s) do **not** match the requested entity.

## **If-Range**

This header is used in combination with the *Range* header to effectively allow a client to both check for whether an entity has changed and request that a portion of it be sent in a single request. (The alternative is to first issue a conditional request, which if it fails would then require a second request.) When present, *If-Range* tells the server to send to the client the part of the entity indicated in the *Range* header if the entity has not changed. If the entity **has** changed, the entire entity is sent in response.

## **If-Unmodified-Since**

The logical opposite of the *If-Modified-Since* header; the request is filled only if the resource has **not** been modified since the specified time; otherwise a 412 reply is sent.

## **Max-Forwards**

Specifies a limit on the number of times a request can be forwarded to the next device in the request chain. This header is used with the *TRACE* or *OPTIONS* methods only, to permit diagnosis of forwarding failures or looping. When present in one of these methods, each time a device forwards the request, the number in this header is decremented. If a device

---

receives a request with a *Max-Forwards* value of 0, it must not forward it but rather respond back to the client. (In a way, this is somewhat analogous to how the *Time To Live* field is used in the [Internet Protocol datagram format](#).)

### ***Proxy-Authorization***

This is like the *Authorization* header, but is used to present credentials to a [proxy server](#) for authentication, rather than the end server. It is created using information sent by a proxy in a response containing a *Proxy-Authenticate* header. This is a hop-by-hop header, sent only to the first proxy that receives the request. If authentication is required with more than one proxy, multiple *Proxy-Authorization* headers may be put in a message, with each proxy in turn “consuming” one of the headers.

### ***Range***

Allows the client to request that the server send it only a portion of an entity, by specifying a range of bytes in the entity to be retrieved. If the requested range is valid, the server sends only the indicated part of the file, using a 206 (“*Partial Content*”) status code; if the range requested cannot be filled, the reply is 416 (“*Requested Range Not Satisfiable*”).

### ***Referer [sic]***

Tells the server the URL of the resource from which the URL of the current request was obtained. Typically, when a user clicks a link on one Web page to load another, the address of the original Web page is put into the *Referer* line when the request for the clicked link is sent. This allows tracking and logging of how the server is accessed. If a human user manually enters a URI into a Web browser, this header is not included in the request. Since this header provides information related to how Web pages are used, it has certain [privacy implications](#).

The proper spelling of this word is “referrer”. It was misspelled years ago in an earlier version of the HTTP standard, and before this was noticed and corrected, became incorporated into so much software that the IETF chose not to correct the spelling in HTTP/1.1.

### ***TE***

Provides information to the server about how the client wishes to deal with transfer encodings for entities sent by the server. If extensions to the standard HTTP transfer encodings are defined, the client can indicate its willingness to accept them in this header. The header “*TE: trailers*” can also be used by the client to indicate its ability to handle having headers sent as trailers following data when “[chunking](#)” of data is done. This is a hop-by-hop header and applies only to the immediate connection.

---

## User-Agent

Provides information about the client software. This is normally the name and version number of the Web browser or other program sending the request. It is used for server access statistic logging and also may be used to tailor how the server responds to the needs of different clients. Note that proxies do not modify this field when forwarding a request; rather, they use the *Via* header.

**Key Concept:** HTTP *request headers* are used only in *HTTP Request* messages. They allow a client to provide information about itself to a server, and provide more details about a request and control over how it is carried out.

---

## HTTP Response Headers

The counterpart to [request headers](#), *response headers* appear only in [HTTP responses](#) sent by servers or intermediaries. They provide additional data that expands upon the summary information that is present in the status line at the beginning of each server reply. Many of the response headers are sent only in response to the receipt of specific types of requests, or even particular headers within certain requests.

There are nine response headers defined for HTTP/1.1.

### Accept-Ranges

Tells the client whether or not the server accepts partial content requests using the *Range* request header, and if so, what type. Typical examples include “*Accept-Range: bytes*” if the server accepts byte ranges, or “*Accept-Range: none*” if range requests are not supported.

Note that this header is different from the other “Accept-” headers, which are used in [HTTP requests](#) to perform [content negotiation](#).

### Age

Tells the client the approximate age of the resource, as calculated by the device sending the response.

### ETag

Specifies the entity tag for the entity included in the response. This value can be used by the client in future requests to uniquely identify an entity, using the *If-Match* request header or similar.

---

## **Location**

Indicates a new URL that the server is instructing the client to use in place of the one the client initially requested. This header is normally used when the server redirects a client request to a new location, using a 301, 302 or 307 reply. It is also used to indicate the location of a created resource in a 201 (“Created”) response to a *PUT* request.

Note that this is not the same as the *Content-Location* [entity header](#), which is used to indicate the location of the originally-requested resource.

## **Proxy-Authenticate**

This is the proxy version of the *WWW-Authenticate* header (see below). It is included in a 407 (“*Proxy Authentication Required*”) response, to indicate how the proxy is requiring the client to perform authentication. The header specifies an authentication method as well as any other parameters needed for authentication. The client will use this to generate a new request containing a *Proxy-Authorization* header. This is a hop-by-hop header.

## **Retry-After**

This header is sometimes included in unsuccessful requests—such as those resulting in a 503 (“*Service Unavailable*”) response—to tell the client when it should try its request again. It may also be used with a redirection response such as 301, 302 or 307, to indicate how long the client should wait before sending a request for the redirected URL. The *Retry-After* header may specify either a time interval to wait (in seconds) or a full date/time when the server suggests the client try again.

## **Server**

This is the server's version of the *User-Agent* [request header](#); it identifies the type and version of the server software generating the response. Note that proxies do not modify this field when forwarding a response; they put their identification information into a *Via* header instead.

## **Vary**

Specifies which request header fields fully determine whether a cache is allowed to use this response to reply to subsequent requests for the same resource without revalidation. A caching device inspects the *Vary* header to determine which other headers it needs to examine to determine whether or not it can respond with a cached entry, when the client makes its next request for the resource in this reply. Yeah, this one's a bit confusing.

## **WWW-Authenticate**

This header is included in a 401 (“*Unauthorized*”) response, to indicate how the server wants the client to authenticate. The header specifies an authentication method as well as any other parameters needed for authentication. The client will use this to generate a new request containing an *Authorization* header.

**Key Concept:** HTTP *response headers* appear in *HTTP Response* messages, where they provide additional information about HTTP server capabilities and requirements, and the results of processing a client request.

---

## **HTTP Entity Headers**

Last but not least, we come to the fourth group of HTTP headers: *entity headers*. These headers provide information about the resource carried in the body of an HTTP message, called an *entity* in the HTTP standards. They serve the overall purpose of conveying to the recipient of a message the information it needs to properly process and display the entity, such as its type and encoding method.

The most common type of entity is a file or other set of information that has been requested by a client, and for this reason, entity headers most often appear in HTTP responses. However, they can also appear in HTTP requests, especially those using the *PUT* and *POST* methods, which are the ones that transfer data from a client to a server.

At least one entity header should appear in any HTTP message that carries an entity. However, they may also be present in certain responses that do not have an actual entity in them. Most notably, a response to a *HEAD* request will contain all the entity headers associated with the resource specified in the request; these are the same headers that would have been included with the entity, had the *GET* method been used instead of *HEAD* on the same resource. Entity headers may also be present in certain error responses, to provide information to help the client make a successful follow-up request.

**Note:** Many of the entity headers have the same names as certain MIME headers, but they are often used in different ways. [See the topic on HTTP Internet media types](#) for a full discussion of the relationship between HTTP and MIME.

---

The following are the entity headers defined in HTTP/1.1:

### ***Allow***

Lists all the [methods](#) that are supported for a particular resource. This header may be provided in a server response as a guide to the client regarding what methods it may use on the resource in the future. The header **must** be included when a server returns a 405 (“*Method Not Allowed*”) response to a request containing an unsupported method.

### ***Content-Encoding***

Describes any optional method that may have been used to encode the entity. This header is most often used when transferring entities that have been compressed; it tells the recipient what algorithm has been used so the entity can be uncompressed. Note that this

---

header only describes transformations performed on the entity in a message; the *Transfer-Encoding* header describes encodings done on the message as a whole. [See the topic on content codings and transfer codings](#) for more details.

### ***Content-Language***

Specifies the natural (human) language intended for using the entity. This is an optional header, and may not be appropriate for all resource types. Multiple languages may be specified, if needed.

This header is intended to provide guidance so the entity can be presented to the correct audience; thus, the language should be selected based on who would best use the material, which may not necessarily include all of the languages used in the entity. For example, a German analysis of Italian operas would probably best tagged only with the language “de”. (They do have German analyses of Italian operas, don’t they? ☺)

### ***Content-Length***

Indicates the size of the entity in octets. This header is important, as it is used by the recipient to determine the end of a message. However, it may only be included in cases where the length of a message can be fully determined prior to transmitting the entity. This is not always possible in the case of dynamically-generated content, which complicates message length calculation; [the discussion of data length and the “chunked” transfer encoding](#) contains a full exploration of this issue.

### ***Content-Location***

Specifies the resource location of the entity, in the form of an absolute or relative uniform resource locator (URL). This is an optional header, and is normally included only in cases where the entity has been supplied from a location different from the one specified in the request. This may occur if a particular resource is stored in multiple places.

### ***Content-MD5***

Contains an MD5 digest for the entity, used for message integrity checking.

### ***Content-Range***

Sent when a message contains an entity that is only part of a complete resource; for example, a fragment of a file sent in response to an HTTP *GET* request containing the *Range* header. The *Content-Range* header indicates what portion of the overall file this message contains, as well as the total size of the resource. This information is given as a byte range, with the first byte numbered 0; for example, if the entity contains the first 1,200 bytes of a 2,000-byte file, this header would have a value of “0-1199/2000”.

---

## **Content-Type**

Specifies the media type and subtype of the entity, in a manner very similar to [how this header is used in MIME](#). See the topic describing HTTP entities and Internet media types for a full discussion.

## **Expires**

Specifies a date and time after which the entity in the message should be considered “stale”. This may be used to identify certain entities that should be held in HTTP caches for longer or shorter periods of time than usual.

This header is ignored if a *Cache-Control* header containing the “max-age” directive is present in the message.

## **Last-Modified**

Indicates the date and time when the server believes the entity was last changed. This header is often used to determine if a resource has been modified since it was last retrieved. For example, suppose a client machine already contains a copy of a very large file that was obtained two months ago, and its user wants to check if an update to the file is available. The client can send a *HEAD* request for the file, and compare the value of the returned *Last-Modified* header to the date of the copy of the file it already has. Then it needs only to request the entire file if it has changed.

Note the use of the word “believe” in the description above. The reason for this wording is that the server cannot always be certain of the time that a resource was modified. With files this is fairly simple—it is usually the last-modified time stored for the file by the operating system. For other more complex resources such as database records or virtual objects, however, it may be more difficult to ascertain when the last change occurred to a particular piece of information. In the case of dynamically-generated content, the *Last-Modified* date/time may be the same as that of the message as a whole, as specified in the *Date* field.

**Key Concept:** HTTP *entity headers* appear in either request or response messages that carry an entity in the message body. They describe the nature of the entity, including its type, language and encoding, to facilitate the proper processing and presentation of the entity by the device receiving it.

---

---

## **HTTP Entities, Transfers, Coding Methods and Content Management**

[HTTP message headers](#) are very important, because they are the mechanism that HTTP uses to allow devices to specify the details of client requests and server responses. These headers, however, are only the means to an end, which is the transfer of resources such as files, form input and program output from one device to another. When a resource is carried in the body of an HTTP message, it is called an *entity*. HTTP defines special rules for how these entities are identified, encoded and transferred.

In this section, I take a detailed look at how HTTP handles entities. I begin with a discussion of entities in general terms, and a look at how their contents are identified; this includes an examination of the relationship between HTTP and MIME. I discuss the issues behind the transfer of entities between clients and servers, and the difference between content encodings and transfer encodings. I describe the special issues associated with identifying the length of entities in HTTP messages, and detail the special “chunked” transfer coding and message trailers. Finally, I describe the methods by which devices can perform content negotiation, and how quality values allow clients to intelligently select different variations of a resource.

### **HTTP Entities and Internet Media Types**

The presence of the word “text” in the name “Hypertext Transfer Protocol” is a reminder of the legacy of HTTP. As I explained in my [brief history of the World Wide Web](#), it was originally created to allow text documents to be linked together. This made sense, because at the time that the Web was being created, most computing was still being done with text. Accordingly, the first version of HTTP (HTTP/0.9) supported only one type of message body: a plain ASCII text document.

In the early 1990s, the rapid increase in computing power and networking performance transformed the world of information technology from text to multimedia. These were also the World Wide Web’s formative years, and it did not take long before many users wanted to exploit the power of the Web to share not only text files but also pictures, drawings, sound clips, movies and much more. Thus, HTTP had to evolve as well; starting with HTTP/1.0, significant changes were made to allow the protocol to transport and process much more than just text. Today, HTTP really would be better described as dealing with *hyper-media* than hypertext, though the name of the protocol was never changed.

One drawback of supporting many types of files in HTTP is added complexity. Where before every message recipient knew the body contained ASCII text, now any message can contain any of many kinds of data. When HTTP was expanded to support flexible media, it needed a system that would address two specific issues: encoding entities of various types into an HTTP message body, and clearly identifying the entity’s characteristics for the recipient of the message.

At the same time that HTTP was being changed to support non-text entities, another important TCP/IP application was also moving away from its decades-long role as a text-messaging medium, to one that could transport multimedia: [electronic mail](#). This was accomplished using a technology called [Multimedia Internet Mail Extensions \(MIME\)](#), which

---

define a mechanism for encoding and identifying non-text data—exactly what HTTP needed to do. Since TCP/IP developers wisely reuse technologies that work, the creators of HTTP borrowed many concepts from MIME, including many of the [MIME e-mail headers](#) that are used to identify the contents of a MIME message.

### ***Media Types and Subtypes***

The most important concept that HTTP adopted from MIME was the use of standardized Internet media types, which describe the contents of an HTTP entity. Each media type consists of a top-level media type that defines its general nature, and a more specific subtype that indicates its form or structure. Additional parameters may also be supplied in some cases to provide more information to help a recipient interpret the entity. The formal syntax of an HTTP media type is the same as that used in MIME:

`<type>/<subtype> [; parameter1 ; parameter2 ... ; parameterN ]`

To understand the difference between a top-level media type and a subtype we need only take a couple of examples. Text documents use the general type “text”; within this, subtypes exist such as “plain” for regular unformatted text and “html” for HTML documents. So, an HTML document of the type commonly transported using HTTP will be identified with a media type of “text/html”. Similarly, “image” is a top-level media type, and has subtypes such as “jpeg”, “gif” and “tiff”. Photographs usually use “image/jpeg”, while line drawings are often seen as “image/gif”.

### ***HTTP's Use of Media Types***

In HTTP, media types are most often seen in a special *Content-Type* [entity header](#), which is present in any HTTP message that carries an entity. This header uses the same format as the header of the same name in MIME:

`Content-Type: <type>/<subtype> [; parameter1 ; parameter2 ... ; parameterN ]`

The other place where media types are used in HTTP is in the *Accept* [request header](#), which may appear in an HTTP request sent by a client. If present, the purpose of this header is to tell the server what sorts of media types the client can handle, so the server will not send a response that cannot be processed. For example, if a client can only process text documents, it might send a request specifying this in an *Accept* header. This is part of the overall [content negotiation process](#) supported by HTTP.

When a media type is specified in an *Accept* header, either the subtype, or both the type and subtype, can be replaced by the “\*” wildcard to represent “any acceptable”. For example, in an *Accept* header, the specification “text/html” refers to an HTML document, while “text/\*” means “any text type”. The string “\*/\*” means any type of media; this is usually used in combination with a “q” value as explained in the topic on the HTTP [content negotiation process](#).

**Related Information:** I provide a more complete description of both the *Content-Type* header and Internet media types, including a description of many types and subtypes, in [the topic on media types in the MIME section](#). HTTP can also support [composite media types](#), such as the multipart media type.

---

**Key Concept:** While HTTP is naturally most often associated with hypertext, its messages can transport a large variety of different types of files, including images, audio, video and much more. To indicate the type of entity contained in an HTTP message, its sender must identify its media *type* and *subtype*. This is done using the HTTP *Content-Type* header, which was borrowed from the Multipurpose Internet Mail Extensions (MIME) specification.

---

### ***Other MIME Constructs Used In HTTP***

In addition to media types, HTTP also borrows from MIME in several other ways. These include the notion of [content codings](#) and [the use of a header to indicate the length of an entity](#). It's important to recognize, however, that even though HTTP's handling of Internet media is very similar to that of MIME, it is not identical. In fact, my understanding is that there was an early proposal that HTTP use MIME exactly as defined, but a specific decision was made not to do this. We will explore a possible reason why in [the next topic](#).

The bottom line, however, is that HTTP's developers chose to adopt concepts from MIME that made sense, and left other parts out. As a result, HTTP messages are not MIME compliant, even though you may see several headers in HTTP messages starting with MIME's "Content-" prefix. For example, even though HTTP has a *Content-Encoding* header, its use is quite different from that of MIME's, as we will again see in the next topic. Confirmation of the difference between HTTP and MIME can be found in the fact that HTTP does not use the *MIME-Version* header that is required in MIME messages.

**Key Concept:** Even though HTTP borrows several concepts and header types from MIME, the protocol is not MIME-compliant.

---

### **HTTP Data Transfer. Content Encodings and Transfer Encodings**

In [the previous topic](#), I mentioned two specific issues that HTTP had to address in order to carry a wide variety of media types in its messages: encoding the data and identifying its type and characteristics. HTTP borrows from [MIME](#) the notion of media types and the *Content-Type* header to handle type identification, as we have already seen. It similarly borrows concepts and headers from MIME to deal with the encoding issue. Here, however, we run into some of the important differences between HTTP and MIME.

---

Encoding was a significant issue for MIME, because it was created for the specific purpose of sending non-text data using the old [RFC 822 e-mail message standard](#). RFC 822 imposes several significant restrictions on the messages it carries, the most important of which is that data must be encoded using 7-bit ASCII. RFC 822 messages are also limited to lines of no more than 1000 characters that end in a “CRLF” sequence.

These limitations mean that arbitrary binary files, which have no concept of lines and consist of bytes which can each contain a value from 0 to 255, cannot be sent using RFC 822 in their native format. In order for MIME to transfer these files, they must be encoded using a [method such as base64](#), which converts three 8-bit characters to a set of four 6-bit characters that can be represented in ASCII. When this sort of transformation is done, the MIME *Content-Transfer-Encoding* header is included in the message so the recipient can reverse the encoding to return the data to its normal form.

Now, while this technique works, it is less efficient than sending the data directly in binary, because base64 encoding increases the size of the message by 33% (three bytes are encoded using four ASCII characters, each of which takes one byte to transmit). HTTP messages are transmitted directly between client and server over a TCP connection, and do not use the RFC 822 standard. Thus, binary data can be sent between HTTP clients and servers without the need for base64 encoding or other transformation techniques. Since it is more efficient to send the data unencoded, this may be one reason why HTTP’s developers decided to not make the protocol strictly MIME compliant.

### ***HTTP’s Two-Level Encoding Scheme***

This would seem to be an area where HTTP was simpler than MIME—since there is no need to encode the entity, there is no need for the *Content-Transfer-Encoding* header, and we have one less thing to worry about. Ha, nice try! ☺ It is true that HTTP **could** have simply been designed so that all entities were just sent one byte at a time with no need to specify encodings. But the developers of the protocol recognized that this would have made the protocol inflexible. There are situations where it might be useful to transform or encode an entity or message for transmission, and then reverse the operation upon receipt.

This effort to make HTTP flexible resulted in a system of representing encodings that is actually more complicated than MIME’s. The key to understanding it is to recognize that HTTP/1.1 actually splits MIME’s notion of a “content transfer encoding” into two different encoding levels:

- ☉ **Content Encoding:** This is an encoding that is applied specifically to the entity carried in an HTTP message, to prepare or package it prior to transmission. Content encodings are said to be “end-to-end”, because the encoding of the entity is done once before it sent by the client or server, and only decoded upon receipt by the ultimate recipient: server or client. When this type of encoding is done, the method is identified in the special *Content-Encoding entity header*. A client may also specify what content encodings it can handle, using the *Accept-Encoding* header, as we will see in [the topic on content negotiation](#).

- 
- ☛ **Transfer Encoding:** This is an encoding that is done specifically for the purpose of ensuring that data can be safely transferred between devices. It is applied across an entire HTTP message, and not specifically to the entity. This type of encoding is “hop-by-hop” because a different transfer encoding may be used for each hop of a message that is transmitted through many intermediaries in the [request/response chain](#). The transfer encoding method, if any, is indicated in the *Transfer-Encoding* [general header](#).

### ***Use of Content and Transfer Encodings in HTTP***

Since the two encodings are applied at different levels, it is possible for both to be used at the same time. A content encoding may be applied to an entity and then placed into a message. On some or all of the hops that are used to move the message containing that entity, a transfer encoding may be applied to the entire message (of course including the entity). The transfer encoding is removed first, and then the content encoding.

Okay, so what are these used for in practice? Not a great deal. The HTTP standard defines a small number of content and transfer encodings, and specifies that additional methods may be registered with the [IANA](#). As of the time that I write this, however, only the ones defined in the HTTP/1.1 standard are in use.

Content encodings are currently used only to implement compression. This is a good example of an encoding that while not strictly necessary, can be useful since it improves performance—for some types of data, dramatically. The RFC 2616 defines three different encoding algorithms: *gzip* (the compression used by the UNIX *gzip* program, and described in RFC 1952); *compress* (again, representing the compression method used by the UNIX program of that name) and *deflate* (a method defined in RFCs 1950 and 1951).

**Note:** It is also possible to apply compression to an entire HTTP message as a transfer encoding. Obviously, if the entity is already compressed using content encoding, this will result in some duplication of effort. Since the size of HTTP headers is not that large compared to some entities that HTTP messages carry, it is usually simpler just to compress the entity using content encoding.

---

Since transfer encodings are intended to be used to make data safe for transfer, and we’ve already discussed the fact that HTTP can handle arbitrary binary data, this suggests that transfer encodings are not really necessary. As it turns out, however, there is one situation where “safe transport” does become an issue: the matter of identifying the end of a message. This issue is the subject of [the next topic](#).

**Key Concept:** HTTP supports two levels of codings for data transfer. The first is *content encoding*, which is utilized in certain circumstances to transform the entity carried in an HTTP message; the second is *transfer encoding*, which is used to encode an entire HTTP message to assure its safe transport. Content encodings are often employed when entities are compressed to improve communication efficiency; transfer encoding is used primarily to deal with the problem of identifying the end of a message.

---

## **HTTP Data Length Issues, "Chunked" Transfers and Message Trailers**

Two different levels of encodings are used in HTTP: *content encodings*, which are applied to HTTP entities, and *transfer encodings*, which are used over entire HTTP messages. Content encodings are used for convenience to package entities for transmission, where transfer encodings are hop-specific, and are intended for use in situations where data needs to be made “safe” for transfer.

However, [we’ve already seen in the previous topic](#) that HTTP can transport arbitrary binary data, so unlike the situation where MIME had to make binary data “safe” for RFC 822, this is not an issue. Therefore, why are transport encodings needed at all? In theory they are not, and HTTP/1.0 did not even have a *Transfer-Encoding* header (though it did use content encodings). The concept of transfer encoding became important in HTTP/1.1 due to another key feature of that version of HTTP: [persistent connections](#).

Recall that HTTP uses the [Transmission Control Protocol \(TCP\)](#) for connections. One of the key characteristics of TCP is that it [transmits all data as a stream of unstructured bytes](#). TCP itself does not provide any way of differentiating between the end of one piece of data and the start of the next; this is left up to each application.

In HTTP/1.0 (and HTTP/0.9) this was not a problem, because those versions used only transitory connections. Each HTTP session consisted of only one request and one response; since client and server only each sent one piece of data, there was no need to worry about differentiating HTTP messages on a connection. HTTP/1.1’s persistent connections improve performance by letting devices send requests and responses one after the other over a single TCP connection. However, the fact that messages are sent in sequence makes differentiating them a concern.

### ***Using The Content-Length Header***

There are two usual approaches to dealing with this sort of data length issue: either using an explicit delimiter to mark the end of the message, or including a length header or field to tell the recipient how long each message is. The first approach could not really have been done easily while maintaining compatibility with older versions of the protocol. This left the second approach; since HTTP already had a *Content-Length* [entity header](#), the solution was to use this to indicate the length of each message at transmission time.

---

This method works fine in cases where the size of the entity to be transferred is known in advance, such as when a static file such as a text document, image or executable program needs to be transmitted. However, there are many types of resources that are generated dynamically; the total size of such a resource is not known until it has been completely processed. While not typical in HTTP's early days, these account for a large percentage of World Wide Web traffic today.

Many Web pages are often not static HTML files, but rather are created as output from scripts or programs based on user input; discussion forums would be a good example. Even HTML files today are often not static. They usually contain program elements such as *server-side includes (SSIs)* that cause code to be generated on-the-fly, so their exact size is cannot be determined in advance.

### ***Using "Chunked" Transfers***

The problem of unknown message length could be resolved by buffering the entire resource before transmission. However, this would be wasteful of server memory and would delay the transmission of the entity unnecessarily—no part could be sent until the entire entity was ready. Instead, a special transfer encoding method was developed to handle this particular problem of “unsafe” transport: not knowing the length of a file. The method is called *chunking*.

When this technique is used, instead of sending an entity as a raw sequence of bytes, it is broken into, well, chunks. ☺ This allows HTTP to send a dynamically-generated resource, such as output from a script, a piece at a time as the data becomes available from the software processing it. To indicate that this method has been used, the special header “*Transfer-Encoding: chunked*” is placed in the message. A special format is also used for the body of the HTTP message to delineate the chunks:

```
<chunk-1-length>
<chunk-1-data>
<chunk-2-length>
<chunk-2-data>
...
0
<message-trailers>
```

Basically, instead of putting the whole entity in the body and indicating its length in a *Content-Length* header, each chunk is placed in the body sequentially, each preceded by the length of the chunk. The length is specified in hexadecimal, and represented using ASCII characters. All chunk lengths and chunk data are terminated with a “CRLF” sequence. The recipient knows it has received the last chunk when it sees a chunk-length of zero.

**Key Concept:** Since HTTP/1.1 uses persistent connections that allow multiple requests and responses to be sent over a TCP connection, clients and servers need some way to identify where one message ends and the next begins. The easier solution is to use the *Content-Length* header to indicate the size of a message, but this only works when the length of a message can be easily determined in advance. For dynamic content or other cases where message length cannot be easily computed before sending the data, the special *chunked* transfer encoding can be used, where the message body is sent as a sequence of chunks, each preceded by the length of the chunk.

---

## Message Trailers

When chunked transfer encoding is used, the sender of the message may also choose to specify one or more *message trailers*. These are the same as [entity headers](#), describing the contents of the message body, but appear after the entity instead of before it. They provide flexibility in the same way that chunking itself does—they allow a device to include an HTTP header that may contain information that was not available when the HTTP message transmission began. A good example would be an integrity check field calculated based on the byte values of the entire entity.

Trailers are optional, and not always be needed. When they are used, they are processed just like regular entity headers. To give the recipient of a message a “heads up” that trailers have been used, the special *Trailer* header should be included at the start of the message, which lists the names of each header that appears as a trailer.

## Example Using the Content-Length Header and “Chunking”

Yes, I really did say that headers can actually be trailers, in which case a header called *Trailer* lists each header that is actually a trailer. Perhaps an example would help clarify matters somewhat? Suppose we have a server that contains a program that, when supplied with a file name, returns a simple HTML response that contains the size and last modification date of the file. This is obviously dynamic content, so the length of the response cannot be determined in advance.

If the server were to buffer the entire output of this program (since it is small) it could construct a conventional HTTP response using the *Content-Length* header, as shown in the sample output of [Table 279](#). Instead, chunking allows the server to send out parts of the response as soon as they become available from the program. The equivalent output of that example using chunked transfers is shown in [Table 280](#); notice that the *Expires* header is now a trailer, so it can be calculated based on the output of the program, and this is

---

indicated by the “*Trailer: Expires*” header. Remember that the *Content-Length* header specifies the length as a decimal number while chunking specifies chunk lengths in hexadecimal; the chunks in this example are 41, 5, 35, 29 and 19 bytes, respectively.

**Table 279: Example HTTP Response Using Content-Length Header**

```
HTTP/1.1 200 OK
Date: Mon, 22 Mar 2004 11:15:03 GMT
Content-Type: text/html
Content-Length: 129
Expires: Sat, 27 Mar 2004 21:12:00 GMT

<html><body><p>The file you requested is 3,400 bytes long and was
last modified: Sat, 20 Mar 2004 21:12:00 GMT.</p></body></html>
```

**Table 280: Example HTTP Response Using Chunked Transfer Encoding**

```
HTTP/1.1 200 OK
Date: Mon, 22 Mar 2004 11:15:03 GMT
Content-Type: text/html
Transfer-Encoding: chunked
Trailer: Expires

29
<html><body><p>The file you requested is
5
3,400
23
bytes long and was last modified:
1d
Sat, 20 Mar 2004 21:12:00 GMT
13
.</p></body></html>
0
Expires: Sat, 27 Mar 2004 21:12:00 GMT
```

**Note:** An HTTP/1.1 client can specify that it does not want to use persistent connections by including the “*Connection: close*” header in its request. In this case, the server does not have to use chunking in its response—since it will close the connection after the first response message, the client knows that everything it receives from the server is part of that response. However, some servers may use chunked transfers anyway, even in this situation.

---

**Key Concept:** When chunked transfer encoding is used, the sender of the message may move certain headers from the start of the message to the end, where they are known as *trailers*. They are interpreted in the same way as normal headers by the recipient. The special *Trailer* header is used in such messages to tell the recipient to look for trailers after the body of the message.

---

## **HTTP Content Negotiation and "Quality Values"**

Many Internet resources have only one representation, meaning a single way in which they are stored or made available. In this situation, a client request to a server is an “all or nothing” proposition. The client may specify conditions under which it would like the server to send the resource, using the “*If-*” series of [request headers](#). If the condition is met, the resource will be sent in the server’s response in the one form in which it exists; if the condition is not met, no entity will be returned.

Other resources, however, may have multiple representations. The most common example would be a document that is available in multiple languages, or that is stored using more than one character set. Similarly, a graphical image might exist in two different formats: one a Tagged Image File Format (TIFF) file for those wanting maximum image quality despite the large size of TIFF images; and a more compact JPEG file for those who need to see the image quickly and don’t care as much about its quality level.

### ***Content Negotiation Techniques***

To provide flexibility in allowing clients to obtain the best version of resources that exist in multiple forms, HTTP/1.1 defines a set of features that are collectively called *content negotiation*. The standard defines two basic methods by which this negotiation may be performed:

- 🕒 **Server-Driven Negotiation:** In this technique, the client includes headers in its request that provide guidance to the server about its desired representation for the resource. The server uses an algorithm that processes this information and provides the version of the resource that it feels best matches the client’s preferences.
- 🕒 **Agent-Driven Negotiation:** This method puts the client in charge of the negotiation process. It first sends a preliminary request for the resource to the server. If the resource is available in multiple forms, the server typically sends back a 300 (“*Multiple Choices*”) response, which contains a list of the various representations in which the resource is available. The client then sends a second request for the one that it prefers.

### ***Comparing Negotiation Methods***

To draw an analogy, suppose a co-worker offers to go out at lunch-time to pick up lunch for the two of you, at a new restaurant where neither of you have eaten before. You could provide him with some parameters regarding what you like to eat—“I like roast beef sandwiches, fish & chips, and pizza, but not chicken”—and then trust him to pick something

---

you will like. Or, he could go to the restaurant, call you on his cell phone, and read the menu to you and let you make a selection. This first is like server-driven negotiation; the second, like agent-driven negotiation.

I think this is a good analogy not only because it (hopefully) helps you see the differences between the two methods, but it also highlights the key advantages and disadvantages of each. Trusting your co-worker with your lunch selection is simple and efficient, but not foolproof. It's possible that the restaurant may not have any of the items you specified, or that your friend may get you something containing another ingredient that you don't like but that you forgot to mention. Similarly, server-based negotiation is a "best-guess" process that does not guarantee that the client will receive the resource in the format it wants. This is exacerbated by the fact that there are only so many ways for the client to specify its preferences using a handful of request headers.

Agent-based negotiation, on the other hand, allows the client to select exactly what it wants from the available choices, just as you can choose your favorite dish from the menu of the restaurant. The problem here is that it is inefficient, because two requests and responses are required for each resource access. (Would **you** really want to read a restaurant's menu over the phone to someone so they could choose their ideal dish? ☺)

**Key Concept:** HTTP includes a feature called *content negotiation* that allows the selection of a particular variation of a resource that has more than one representation. There are two negotiation techniques: *server-driven*, where the client includes headers in its request that indicate what it wants and the server does its best to select the most appropriate variant; and *agent-driven*, where the server sends the client a list of the available resource alternatives and the client chooses one.

---

### ***Server-Based Negotiation in HTTP***

In practice, server-based negotiation is the type that is most commonly used today. The client specifies its preferences using a set of four [request headers](#) that indicate what it would prefer in the representation of the resource. The headers each represent one characteristic of a resource: *Accept* (media type); *Accept-Charset* (character set); *Accept-Encoding* (content encoding); and *Accept-Language* (resource language). Any or all of these may be included in the request.

Each "*Accept-*" header contains a list of acceptable values that is appropriate to the characteristic that it specifies, separated by a comma. For example, the *Accept* header lists [media types](#) the client considers acceptable, while *Accept-Language* contains language tags. Suppose you have a friend who is trilingual in English, French and Spanish. She can read a particular document in any of these languages, so she might instruct her browser to include the following header in her requests:

Accept-Language: en, fr, sp

---

## Weighting Preferences with "Quality Values"

Even better than simple acceptance lists, HTTP allows the client to *weight* each of the items in such a list, to indicate which is preferred of the alternatives. This is done by adding a decimal quality value after each parameter using the syntax "q=<value>", which represents the relative priority of that parameter relative to others. The highest priority is 1 and the lowest is 0; the default if no value is indicated is 1, while a value of 0 means the client is specifically saying it is **not** willing to accept documents with that characteristic.

This is best illustrated by an example, so let's take our trilingual friend again. This time, let's say she knows English, French and Spanish, but her French is a bit rusty (she hasn't used it in a while). Furthermore, she may need to share this document with a friend of hers who only knows a little Spanish, so it would be best if she got the document in English. Finally, she knows there is a German version of the resource that she definitely does not want. This could be represented as follows:

Accept-Language: en, fr;q=0.3, sp;q=0.7, de;q=0

Translated to English, this means "I prefer if you sent me the document in English. If not, Spanish is okay, or French if that is all you have, but definitely don't send it in German".

Incidentally, the name "quality value" is the one used in the HTTP standard, but is really a poor choice of terminology (which, to be fair, is also mentioned in the standard!) These values do not really have anything to do with quality; for all we know, the German version of this document may be the original and the others could be lousy translations. The "q" values only specify the relative preference of the client making the request.

Finally, the "\*" wildcard can be used in the Accept family of headers to represent "any value", or "everything else". This is often used to tell the server "if you can't find what I specifically asked for, then here's my preference level on the alternatives". Let's take an example using the *Accept* header:

Accept: text/html, text/\*;q=0.6, \*/\*;q=0.1

This header represents the client saying "My preference (q=1) is an HTML text document. If not available, I would prefer some other type of text document. Failing that, you may send me any other type of document relevant to the requested resource."

**Key Concept:** Server-driven content negotiation is the type most often used in HTTP. A client sending a request can include up to four different headers that provide information about how the server should fill its request. These may include optional *quality values* that specify the client's relative preference amongst a set of alternative resource characteristics such as media type, language, character set or encoding.

---

---

## **HTTP Features, Capabilities and Issues**

The first four subsections of the large section covering the Hypertext Transfer Protocol were meant to give you a good understanding of the fundamental concepts and basic operation of the protocol. Modern HTTP, however, goes beyond the simple mechanics by which HTTP requests and responses are exchanged. It includes a number of features and capabilities that extend the basic protocol to improve performance and meet the various needs of organizations using modern TCP/IP internetworks.

In this section, I complete my description of HTTP by discussing several important matters that are essential to the operation of the modern World Wide Web. I begin with an overview of HTTP caching, which is the single most important feature that promotes efficiency in Web transactions. I discuss the different uses of proxies in HTTP and some of the issues associated with them. I briefly examine the issues related to security and privacy in HTTP, and conclude with a discussion of the matter of state management, and how it is implemented despite HTTP being an inherently stateless protocol.

**Background Information:** This section assumes that you have already covered the preceding ones in this larger section on HTTP. If you are not already familiar with concepts such as the [HTTP request/reply chain](#), [HTTP message structure](#) and [HTTP headers](#), you should review those materials first.

---

## **HTTP Caching Features and Issues**

The explosive growth of the World Wide Web was a marvel for its users, but a nightmare for networking engineers. The biggest problem that the burgeoning Web created was an overloading of the internetworks over which it ran. Many of the features that were added to HTTP/1.1 were designed specifically to improve the efficiency of the protocol and reduce unnecessary bandwidth consumed by HTTP requests and responses. Arguably the most important of these is a set of features designed to support *caching*.

The subject of caching comes up again and again in discussions of computers and networking, because of a phenomenon that is widely observed in these technologies: whenever a user, hardware device or software process requests a particular piece of data, there is a good chance it will ask for it again in the near future. Thus, by storing recently-retrieved items in a cache, we can eliminate duplicated effort. This is why caching plays an important role in the efficiency of protocols such as [ARP](#) and [DNS](#).

### ***The Significance of Caching to HTTP***

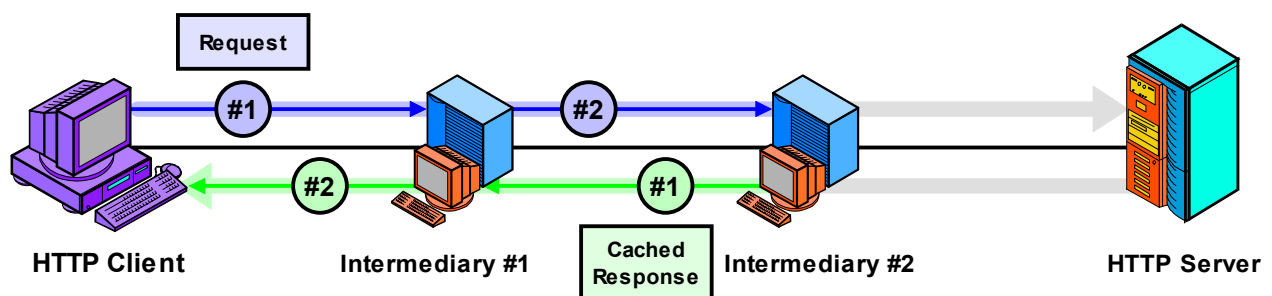

Caching is important to HTTP because Web users tend to request the same documents over and over again. For example, in writing this section on HTTP, I made reference to RFC 2616 many, many times. Each time, I loaded it from a particular Web server. Since the document never changes, it would be more efficient to just load it from a local cache rather than having to retrieve it from the distant Web server each time.

---

However, caching is even more essential to HTTP than to most other protocols or technologies where it is used. The reason is that Web documents tend to be structured so that a request for one resource leads to a request for many others. Even if I load a number of **different** documents, they may each refer to common elements that do not change between user requests. Thus, caching can be of benefit in HTTP even if a user never asks for the same document twice, or if a single document changes over time so that caching the document itself would be of little value.

For example, suppose that each morning I load up CNN's Web site to see what is going on in the world. Obviously, the headlines will be different every day, so caching of the main CNN.com Web home page won't be of much value. However, many of the graphical elements on the page (CNN's logo, dividing bars, perhaps a "breaking news" graphic) will be the same, every day, and these can be cached. Another example would be a set of discussion forums on a Web site. As I load up different topics to read, each one is different, but they have common elements (such as icons and other images) that would be wasteful to have to retrieve over and over again.

Caching in HTTP yields two main benefits. The first is reduced bandwidth use, by eliminating unneeded transfers of requests and responses. The second, equally important, is faster response time for the user loading a resource. Consider that on many Web pages today, the image files are much larger than the HTML page that references them. Caching these graphics will allow the entire page to load far more quickly. [Figure 319](#) illustrates how caching reduces bandwidth and speeds up resource retrieval by "short-circuiting" the request/response chain.

**Figure 319: Impact of Caching on HTTP Request/Response Chain**

This diagram illustrates the impact of caching on the request/response chain of [Figure 316](#). In this example, intermediary #2 is able to satisfy the client's request from its cache. This "short-circuits" the communication chain after two transfers, which means the client gets its resource more quickly, and the HTTP server is spared the need to process the client's request.

The obvious advantages of caching have made it a part of the Web since pretty much the beginning. However, it was not until HTTP/1.1 that the importance of caching was really recognized in the protocol itself, and many features added to support it. Where the HTTP/1.0 standard makes passing mention of caching and some of the issues related to it, HTTP/1.1 devotes 26 full pages to caching (over 20% of the main body of the document!) I obviously cannot go into that level of detail here, but I will discuss HTTP caching in general terms to give you a feel for the subject.

---

## Tradeoffs in Cache Location

HTTP caching can be implemented in a variety of places in the request/response chain. The location of the cache must be chosen based on a fundamental trade-off that always occurs in caching: proximity versus universality. Simply put, the closer the cache is to the requestor of the information, the more savings that result when data is pulled from the cache rather than being fetched from the source. However, the further the cache is from the requestor (and thus closer to the source), the greater the number of devices that can benefit from the cache. Let's see how this manifests itself in the three classes of devices where caches may be found.

### Web Client Caching

The cache with which most Internet users are familiar is that found on the local client. It is usually built into the Web browser software, and for this reason called a *Web browser cache*. This cache stores recent documents and files accessed by a particular user, so that they can be made quickly available if that user requests them again.

Since the cache is in the user's own machine, a request for an item that the cache contains is filled instantly, resulting in no network transaction and "instant gratification" for the user. However, that user is the only one who can benefit from the cache, which is for this reason sometimes called a *private cache*.

### Intermediary (Proxy) Caching

Devices such as [proxy servers](#) that reside between Web clients and servers are also often equipped with a cache. If a user wants a document not in his or her local client cache, the intermediary may be able to provide it, as shown in [Figure 319](#). This is not as efficient as retrieving from the local cache, but far better than going back to the Web server. However, the intermediary has the advantage that all devices using it can benefit from its cache, which may be termed *public* or *shared*. This can be useful, because members of an organization often access similar documents.

For example, in an organization developing a hardware product to be used on Apple computers, many different people might be accessing documents on Apple's Web site. With a shared cache, a request from user A would often result in items being cached that could be used by user B.

### Web Server Caching

Web servers themselves may also implement a cache. While it may seem a bit strange to have a server maintain a cache of its own documents, this can be of benefit in some circumstances. A resource might require a significant amount of server resources to create; for example, consider a Web page that is generated using a complex database query. If this page is retrieved frequently by many clients, there can be a large benefit to creating it periodically and caching it rather than generating it on the fly for each request.

---

Since the Web server is “farthest” from the users, this results in the least savings for a cache hit, as the client request and server response must still travel the full path over the network between client and server. However, this distance from the client also means that all users of the server can benefit from it.

**Key Concept:** The most important feature that improves the efficiency of operation of HTTP is *caching*—the storing of recently-requested resources in a temporary area. If the same resource is then needed again a short time later, it can be retrieved from the cache rather than requiring a fresh request to the server, resulting in a savings of both time and bandwidth. Caching can be performed by Web clients, servers and intermediaries. The closer the cache is to the user, the greater the efficiency benefits; the farther from the user, the greater the number of users that can benefit from the cache.

---

## **Cache Control**

The control of caching in clients and servers is accomplished in the same manner that most other types of control are implemented in HTTP: through the use of special headers. The most important of these is the Cache-Control [general header](#), which has a number of directives that allow the operation of caches to be managed. There are other important caching-related headers, including *Expires* and *Vary*. For a great deal of more specific information related to HTTP caching, please consult RFC 2616, section 13.

## **Important Caching Issues**

While the performance advantages of caching make it a “no-brainer”, there is no denying that caching has one significant drawback: it complicates the operation of HTTP in a number of ways. Below is a description of some of the more important issues that HTTP/1.1 clients, servers and intermediaries need to deal with. As long as it is, this list is not exhaustive, which gives you an idea of what is involved with caching in HTTP (as well as why the standard needed 26 pages to cover the subject!)

### **Cache Aging and “Staleness”**

When a user retrieves a document directly from its original source on the server, he or she always is assured of getting the current version of that resource. When caching is used, that is no longer the case. While many resources change infrequently, almost all will change at some point in time. To take the example above of CNN’s Web site, it is probable that the CNN logo won’t change very often, but it’s possible that the site may be redesigned periodically and the logo modified in some way, such as its size or color.

For this reason, a device cannot keep items in an HTTP cache indefinitely. The longer an item is held in a cache—a process called *aging*—the more likely it is that the resource on the server has changed and the cache has become “stale”. To make matters even more complex, some resources become stale more quickly than others. As a result, much of the caching-related functionality of HTTP is related to dealing with this matter of cache aging.

---

## Cache Expiration and Validation

One of the ways that HTTP deals with the cache aging issue is through headers and logic that allow caches, clients and servers to specify how long items should be cached before they expire and must be refreshed. A process of validation is also defined that allows a cache to check with a server at appropriate times to see if an item it has stored has been modified.

## Communication of Cache Status to the User

In most cases, the fact that an item has been retrieved from a cache rather than its source is transparent to the user (though he or she may notice that the resource loads faster than expected!) In certain cases, however, the user may need to be informed that a resource came from a cache and not its original source. This is especially true when a cached item may be stale, in which case the client should warn the user that the information might be out of date.

## Header Caching

Caching in HTTP is complicated by the fact that it can occur in multiple places, and some HTTP headers are treated differently than others. HTTP headers are divided into two general categories: *end-to-end headers* that are intended to accompany a resource all the way to its ultimate recipient, and *hop-by-hop headers* that are used only for a particular communication between two devices (be they client, server, or intermediary device). End-to-end headers must be stored with a cached resource, where hop-by-hop headers only have meaning for a particular transfer and are not cached.

## Impact of Resource Updates

Some [HTTP methods](#) will automatically cause cache entries to become invalidated, because they inherently cause a change to the underlying resource. For example, if a user performs a *PUT* on a resource that was previously retrieved using *GET*, any cached copies of that resource should be automatically invalidated to prevent the old version from being supplied from the cache.

## Privacy Concerns

In the case of shared caches (such as might exist in a proxy) there are potential privacy issues to be concerned with. While in most cases having user *A*'s cached resource be made available to user *B* is advantageous, we must be careful not to cache any items that might be specific to user *A*, which user *B* should not see.

## HTTP Proxy Servers and Proxying

In my overview of [the HTTP operational model](#), I described how HTTP was designed to support not just communication between a client and server, but also the inclusion of intermediaries that may sit in the communication path between them. One of the most important types of intermediary is a device called a *proxy server*, or more simply, just a *proxy*.

---

A proxy is a “middleman” that acts as both a client and a server. It accepts requests from a client as if it were a server, then forwards them (possibly modifying them) to the real server, which sees the proxy as a client. The server responds back to the proxy, which forwards the reply back to the client. Proxies can be either *transparent*, meaning that they do not modify requests and responses, or *non-transparent*, if they do so in order to provide a particular service.

---

**Note:** The term “transparent proxy” can also be used to refer to a proxy that is interposed automatically between a client and server—such as an organization-wide firewall—as opposed to one that a user manually configures.

---

## **Benefits of Proxies**

Since proxies have the ability to fully process all client requests and server responses, they can be extremely useful in a number of circumstances. They can be used to implement or enhance many important capabilities.

### **Security**

Proxies can be set up to examine both outgoing requests and incoming responses, to address various security concerns. For example, filtering can be set up to prevent users from requesting “objectionable” content, or to screen out harmful replies such as files containing hidden viruses.

### **Caching**

As I mentioned in [the previous topic](#), it can be advantageous to set up a “shared cache” that is implemented on an intermediary, so resources requested by one client can be made available to another. This can be done within a proxy server.

### **Performance**

In some circumstances, the existence of a proxy server can significantly improve performance, particularly by reducing latency. An excellent example of this is the proxy server that is used by my own satellite Internet connection.

Due to the distance from the earth to the satellite, it takes over 500 milliseconds for a round trip request/response cycle between my PC and an Internet server. If I load a Web page containing images, I would have to wait 500+ milliseconds to get the HTML page, at which point my browser would then have to generate new requests for each graphical element, meaning another 500+ millisecond delay for each.

Instead, my ISP has a proxy server to which I send my requests for Web pages. It looks through the HTML of these pages and automatically requests any elements such as graphics for me. It then sends them straight back to my machine, cutting the time required to display a full Web page drastically.

**Key Concept:** One of the most important types of intermediary devices in HTTP is a *proxy server*, which acts as a middleman between the client and server, handling both requests and responses. A proxy server may either transport messages unchanged or may modify them to implement certain features and capabilities. Proxies are often used to increase the security and/or performance of Web access.

---

### ***Comparing Proxies and Caches***

Proxying and caching are concepts that have a number of similarities, especially in terms of the impact that they have on basic HTTP operation. Like caching, proxying has become more important in recent years, and also complicates HTTP in a number of ways. The HTTP/1.1 standard includes a number of specific features to support proxies, and also addresses a number of concerns related to proxying.

The fact that both proxying and caching represent ways in which basic HTTP client/server communication is changed, combined with the ability of proxies to perform caching, sometimes leads people to think caches and proxies are the same, when they are not. A proxy is actually a separate element that resides in the HTTP request/response chain, where caches can be implemented within any device in that chain, including a proxy.

Another key way that caches and proxies differ is that caches are used “automatically” when they are enabled, where proxies are not. To use a proxy, client software must be told to use the proxy, and supplied with its IP address or domain name. The client then sends all requests to the proxy rather than to the actual server that the user specifies.

**Note:** Most of my explanations here have focused on hardware proxy servers, but proxies are also commonly implemented as software in a client device. A software proxy performs the same tasks of processing requests and responses; it is much cheaper to implement than a hardware proxy, but cannot be shared by many devices.

---

### ***Important Proxying Issues***

As I mentioned above, there are a few different issues that come into play when proxies are used in HTTP. Here are some of the more important ones, and how HTTP deals with them. Again, for much more information on proxying, please refer to your trusty copy of RFC 2616.

#### **Capability Inconsistencies:**

Issues arise when a client and server don't use the same version of HTTP, or don't support the same features; for example, some servers may not support all of the methods that a client may try to use. This is made all the more complex when a proxy enters the picture. Of

---

particular concern is the situation where a client and server may agree on a particular feature that the proxy does not. The proxy must make sure that it passes along headers or other elements that it may not comprehend.

### Authentication Issues

The use of proxy servers often introduces new authentication or security requirements. In addition to authenticating with an end server, the proxy may specify that the client needs to present separate authentication credentials to it as well. This is done using the *HTTP Proxy-Authorization* and *Proxy-Authenticate* headers; [see the topic on HTTP security](#) for details.

### Caching Interaction

Not only do both caching and proxying both complicate HTTP, they can complicate each other. Many of [the issues in handling caching](#), such as header caching, expiration and validation, become more complex when proxies are involved. Some of the *Cache-Control* [general header](#) directives are specific to proxying.

Another issue is that the use of proxying and caching together can lead to distortions in the apparent number of times that a Web resource is accessed. This is important in situations where Web pages are supported by advertising, based on the number of times the page is accessed. Sometimes in this situation, special codes are placed in URLs called “cache busters” are used to force pages not to be stored in shared caches.

### Encodings

[Content encodings](#) are applied end-to-end and so should not be affected by proxies. Transfer encoding is done hop-by-hop, so a proxy may use different encodings in handling different transfers of a single request or response.

### Tracing Proxy Handling

It is useful in some circumstances, especially when multiple proxies may be in the request/response chain, to be able to trace what proxies have processed a particular message. To this end, HTTP/1.1 requires that each proxy that handles a message identify itself in the *Via* header.

### HTTP Security and Privacy

There are a number of different protocols in this Guide where I address security considerations. Usually, I start out by saying something to the effect that the protocol doesn’t include much in the way of security, because when it was first developed, the Internet was small and used by a tight-knit group, so security wasn’t a big concern. Today, the Internet is globe-spanning and used by millions of strangers, making security a big deal indeed, blah blah blah. ☺

---

Well, in the case of the World Wide Web this is true, but the issue is even more important due to the significance of the changes in the **content** of what HTTP messages carry. HTTP has become the vehicle for transporting any and every kind of information, including a large amount of personal data. HTTP was initially designed to carry academic documents such as memos about research projects, but today is more likely to carry someone's mortgage application, credit card details or medical details. Thus, not only does HTTP have the usual security issues such as preventing unauthorized access, it needs to deal with privacy concerns as well.

### **HTTP Authentication Methods**

The main HTTP/1.1 standard, RFC 2616, also does not deal extensively with security matters. These are addressed in detail instead in the companion document, RFC 2617, which explains the two methods of HTTP authentication. Highly summarized, they are:

- ☉ **Basic Authentication:** This is a conventional user/password type of authentication. When a client sends a request to a server that requires authentication to access a resource, the server sends a response to the client's initial request that contains a *WWW-Authenticate* header. The client then sends a new request containing the *Authorization* header, which carries a [base64-encoded](#) username and password combination.
- ☉ **Digest Authentication:** Basic authentication is not considered strong security because it sends credentials "in the clear", which means that they can be intercepted. Digest authentication uses the same headers as basic authentication, but employs more sophisticated techniques, including encryption, that protect against a malicious person "snooping" credentials information. Digest authentication is not considered as strong as public key encryption, but is a lot better than basic authentication. It's also a darn sight more complicated. The full details of how it works are in RFC 2617.

### **Security and Privacy Concerns and Issues**

Both RFC 2616 and 2617 also address some of the specific security concerns and threats that can potentially affect HTTP clients and servers. These include actions such as spoofing, counterfeit servers, replay attacks and much more. One concern addressed is the potential for "man-in-the-middle" attacks, where an attacker interposes between the client and server. Since proxies are inherently "men in the middle", they represent a security concern in this area. The same authentication methods used for servers can also be applied to authentication with proxies. The *Proxy-Authenticate* and *Proxy-Authorization* headers are used instead of *WWW-Authenticate* and *Authorization*.

The standards also discuss a number of privacy issues. Some that are worthy of note:

- ☉ **Handling of Sensitive Information:** The HTTP protocol can carry any type of information, and it does not inherently protect the privacy of data in HTTP message entities. To ensure the privacy of sensitive information, other techniques must be used (which we will discuss shortly).

- 
- ☉ **Privacy of Information in URLs:** One issue that sometimes arises in HTTP is that poorly-designed Web sites may inadvertently encode private information into URLs. These URLs may be recorded in Web logs, where they could fall into the hands of people who could abuse them. An example of this would be a Web site that submits a user login and password to a server by encoding them as parameters of a *GET* request such as this:

GET http://www.somesite.com/login?name=xxx&password=yyy”

The *POST* method should be used instead for this sort of functionality, because it transmits its data in the body of the message instead of putting it into the URL.

- ☉ **Private Information in Accept Headers:** While this may seem strange at first, it is possible that private information about the user could be transmitted through the use of certain “*Accept-*” headers used for [content negotiation](#). For example, some users might not want others to know what languages they speak, so they may be concerned about who looks at the *Accept-Language* header.
- ☉ **Information Obtained From the Referer Header:** The Referer [sic] [request header](#) is a double-edged sword; it can be very useful to those who operate Web sites because it lets them see the sources of links to their resources. At the same time, it can be abused by those who might employ it to study users’ Web access patterns. There are also potential privacy issues that the HTTP standard raises. For example, a user might not want the name of a private document that references a public Web page to be transmitted in a Referer header.

### ***Methods for Ensuring Privacy in HTTP***

As mentioned earlier, HTTP does not include any mechanism to protect the privacy of transmitted documents or messages. There are two different methods by which this is normally accomplished. The simplest way is to encrypt the resource on the server and supply valid decryption keys only to authorized users; even if the entire message is intercepted, the entity itself will still be secured. The level of protection here depends on the quality of the encryption.

Another more common method is to use an “add-on” protocol designed specifically to ensure the privacy of HTTP transactions. The one often used today is called *Secure Sockets Layer (SSL)*. Servers employ SSL to protect sensitive resources, such as those associated with financial transactions. They are accessed by using the [URL scheme](#) “https” rather than “http” in a Web browser that supports the protocol. SSL was originally developed by Netscape and is now widely used across the World Wide Web.

### **HTTP State Management Using “Cookies”**

Even though the modern Hypertext Transfer Protocol has a lot of capabilities and features, it is still, at its heart, a simple request/reply protocol. One of the unfortunate problems that results from this is that HTTP is entirely *stateless*. This means that each time a server receives a request from a client, it processes the request, sends a response, and then forgets about the request. The next request from the client is treated as independent of any previous ones.

**Note:** The [persistent connection feature](#) of HTTP/1.1 does not change the stateless nature of the protocol. Even though multiple requests and responses can be sent on a single TCP connection, they are still not treated as being related in any way.

---

So why is this a problem? Isn't this what we would expect of a protocol designed to allow a client to quickly and efficiently retrieve resources from a server? Well, this is, yet again, another place where HTTP's behavior was well-suited to its original intended uses, but not to how the Web is used today. Sure, if all we want to do is to say "hey server, please give me that file over there", then the server doesn't have to care about whether or not it may have previously provided that client with any other files in the past. This is how HTTP was originally intended to be used.

Today, as most of us know, the Web is much more than a simple resource-retrieval protocol. If you go to an online store, you want to be able to select a number of items to put into a "shopping cart", and have the store's server remember them. You might also want to participate in a discussion forum, which requires you to provide a user name and password in order to post a message. Ideally, the server should let you log in once and then remember who you are so you can post many messages without having to enter your login information each and every time. (I have used forums where the latter is required—it gets old very quickly, believe me.)

### ***Cookies: Storing HTTP State Information***

For these and other interactive applications, the stateless nature of HTTP is a serious problem. The solution was the addition of a new technology, called *state management*, that allows the state of a client session with a server to be maintained across a series of HTTP transactions. Initially developed by Netscape, this technique was later made a formal Internet standard in RFC 2109, later revised in RFC 2965 ([HTTP State Management Mechanism](#)). Note that this feature is actually not part of HTTP; it is an optional element, but one that has been implemented in pretty much all Web browsers due to its usefulness.

The idea behind state management is very simple. When a server implements a function that requires state to be maintained across a set of transactions, it sends a small amount of data to the Web client called a "cookie". The cookie contains important information relevant to the particular Web application, such as a customer name, items in a shopping cart, or a user name and password. The client stores the information in the cookie, and then uses it in subsequent requests to the server that set the cookie. The server can then update the cookie based on the information in the new request and send it back to the client. In this manner, state information can be maintained indefinitely, allowing the client and server to have a "memory" that persists over a period of time.

**Note:** “Cookie” may seem an odd term, but is used in a few contexts to refer to a small piece of significant data—another example is found in the [BOOTP/DHCP message format](#). Today, most knowledgeable Web users would blink at you if you mentioned the “HTTP state management mechanism” but they usually know what “cookies” are.

---

## ***Issues with Cookies***

Cookies sound like a great idea, right? Well they are—and they aren’t. On the positive side, cookies are absolutely essential for many of the applications that make the Web the powerhouse it is today, the examples of online shopping and discussion forums being only two of many. Most of the time, cookies are used for these sorts of useful and benign purposes. Unfortunately, like every good idea, there are those who have found a way to turn cookies to the “dark side” by finding ways to abuse them. There can even be potential problems with them when there is no nefarious intent. For this reason, cookies are rather controversial.

Some of the issues with cookies:

- ☛ **Transmission of Sensitive Information:** Suppose you use an online banking system. You log in to the server, which then stores your login and password (which controls access to your account) in a cookie. If the application is not implemented carefully, the message containing that cookie could be intercepted, giving someone access to your account. Even if it is not, someone knowledgeable who gained access to your computer could retrieve the information from the file where cookies are stored.
- ☛ **Undesirable Use of Cookies:** In theory, cookies should be a help to the user, not a hindrance. However, any server can set a cookie for any reason. In some cases, a server could set a cookie for the purpose of tracking the sites that a user visits, which some people consider a violation of their privacy. Since some Web browsers do not inform the user when a cookie is being set, they may not even be aware that this is happening.
- ☛ **Third-Party or “Unintentional” Cookies:** While most people think of cookies as being set in the context of a resource they specifically request, a cookie may be set by **any** server to which a request is sent, whether the user realizes it or not. Suppose you send a request to “<http://www.myfavoritesite.com/index.htm>” and that page contains a reference to a tiny image that is on the server “<http://www.bigbrotherishere.com>”. The second site can set a cookie on your machine even though you never intended to visit it at all. This is called a “third-party cookie”.

## ***Managing Cookie Use***

The RFCs describing the cookie state management technique deal extensively with these and other issues, but there is no clear-cut resolution to these concerns. Like most security and privacy matters, the most important determinant of how significant potential cookie abuse may be is your own personal comfort level. Millions of people browse the Web every day letting any and all sites set whatever cookies they want, and never have a problem. Others consider cookies an offensive idea and disable all cookies, which eliminates the

---

privacy concerns but can cause problems with useful applications like interactive Web sites. As usual, the best approach is usually something in the middle, where you choose when and how you will allow cookies to be set.

The degree to which “cookie control” is possible depends greatly on the quality and feature-set of your Web client software. Many browsers do not provide a great deal of control in how and when cookies are set, where others are much better in this regard. Some allow cookies to be disabled, but come with them turned on by default, and since many people are not even aware of the issues I have mentioned above, they will not even realize when cookies are being sent. Most notable in this regard is the most popular browser in the world, Microsoft’s Internet Explorer, which normally comes set by default to accept all cookies without complaint or even comment.

Internet Explorer does allow you to disable cookies, but you have to do it yourself. It also allows you to differentiate between first-party and third-party cookies, but again, you must turn this on. Other browsers have more sophisticated settings, which will let you dictate conditions under which cookies may be set and others when they may not. Some will even let you allow certain sites to send cookies while prohibiting them from others. Better ones will also let you visually inspect cookies, and selectively clear the ones you do not want on your machine.

**Key Concept:** HTTP is an inherently *stateless* protocol, because a server treats each request from a client independently, forgetting about all prior requests. This characteristic of HTTP is not an issue for most routine uses of the World Wide Web, but is a problem for interactive applications such as online shopping where the server needs to keep track of a user’s information over time. To support these applications, most HTTP implementations include an optional feature called *state management*. When enabled, a server sends to a client a small amount of information called a *cookie*, which is stored on the client machine. The data in the cookie is returned to the server with each subsequent request, allowing the server to update it and send it back to the client again. Cookies thus enable a servers to remember user data between requests. However, they are controversial, because of certain potential privacy and security concerns related to their use.

---

---

## **Gopher Protocol (Gopher)**

Let's suppose that I told you I was going to describe a TCP/IP application layer protocol designed for the specific purpose of distributed document search and retrieval. This protocol uses a [client/server model of operation](#), where servers provide links to related resources such as files or programs that users access with client software that displays options for the user to select. You might think that I was talking about the [World Wide Web](#), and for good reason. However, in this case I am actually talking about one of the Web's predecessors: the *Gopher Protocol*.

A good place to start our discussion of this protocol is with its name, which is well-chosen for a number of reasons. The Gopher Protocol was developed at the University of Minnesota, whose sports teams are called the "Golden Gophers" (Minnesota is known as the "Gopher State"). This is the direct origin of the name, but it is also appropriate because the rodent that shares it is known for burrowing, just as the protocol is designed to "burrow" through the Internet. And of course, the term "gopher" also applies to a person who performs errands, such as retrieving documents (they "go fer" this, and "go fer" that). ☺

The Gopher Protocol was developed in the late 1980s to provide a mechanism for organizing documents for easy access by students and faculty at the university. The core principle that guided the development of the system was *simplicity*. Gopher is designed on the basis of a small number of core principles, and uses a very straight-forward mechanism for passing information between client and server devices. It is described in RFC 1436, published in March 1993.

### ***Information Storage on Gopher Servers***

Information accessible by Gopher is stored as files on *Gopher servers*. It is organized in a hierarchical manner similar to the file system tree of a computer such as a Windows PC or UNIX workstation. Just as a file system consists of a top-level directory (or folder) that contains files and subdirectories (subfolders), Gopher servers present information as a top-level directory that contains resources such as files, and/or subdirectories containing additional resources. Resources on different servers can be linked together using by having them mentioned in each others' resource hierarchies. It is also possible for "virtual" resources to be created that act as if they were files, such as programs that allow Gopher servers to be searched.

### ***Gopher Client/Server Operation***

Typical use of Gopher begins with a user on a client machine creating a TCP connection to a Gopher server using [well-known TCP port](#) number 70. After the connection is established, the server waits for the client to request a particular resource by sending the server a piece of text called a *selector string*. Often, when a user first accesses a server, he or she does not know what resource to request, so a null (empty) selector string is sent. This causes the server to send back to the client a list of the resources available at the top (root) directory of the server's file system tree.

---

## Directory Listing Structure

A directory list sent by the server consists of a set of lines, each of which describes one available resource in that directory. Each line contains the following elements, each of which is separated by a "<Tab>" character:

- ☛ **Type Character and Resource Name:** The first character of the line tells the client software what sort of resource the line represents. The most common type characters are "0" for a file, "1" for a subdirectory and "7" for a search service. The rest of the characters up to the first "<Tab>" contain the name of the resource to be presented to the user.
- ☛ **Selector String:** The string of text to be sent to the server to retrieve this resource.
- ☛ **Server Name:** The name of the server where the resource is located.
- ☛ **Server Port Number:** The port number to be used for accessing this resource's server; normally 70.

Each line ends with a "<CR><LF>" character sequence consistent with the [Telnet Network Virtual Terminal \(NVT\)](#) specification. Upon sending the directory listing (or any other response) the connection between the client and server is closed.

## Menus and User Resource Selection

After receiving this sort of directory list, the Gopher client software will display a menu to the user containing all the resource names the server provided. The user then selects his or her desired item from the menu, and the client retrieves it by making a connection to the appropriate server and port number and sending the selector string of that resource. If this itself represents a subdirectory, a new directory listing for that subdirectory will be sent by the server; if some other type of resource, it will be accessed according to the requirements of the resource type.

For example, suppose this line were sent from the server to the client:

```
0Gopher Introduction<Tab>intro<Tab>gopher.someserver.org<Tab>70
```

This would be presented to the user as the file called "Gopher Introduction" in a menu containing other options. If the user chose it, the client would initiate a connection to the gopher server "gopher.someserver.org" at port 70, and then send the selector string "intro" to that server to retrieve the document.

## Important Differences Between Gopher and The Web

As I hinted at the start of this discussion, both Gopher and the World Wide Web are intended for the same basic purpose: providing access to repositories of information, with links between related documents and resources. However, they take a very different approach to how that information is accessed, especially in two key areas: user interface and resource linking.

---

Gopher's presentation to the user is entirely oriented around its hierarchical file system. As a result, Gopher is inherently menu-based, and the user interface usually based on a simple text presentation of those menus. In contrast, information on World Wide Web servers can be organized in any manner, and presented to the user in whatever form or fashion the owner of the server desires. The Web is much more "free form", and there is no need to use a directory structure unless that is advantageous in some way.

Linking in the World Wide Web is done directly between documents, most often using [Hypertext Markup Language \(HTML\)](#) tags. When someone writing document *A* mentions something relevant to document *B*, he or she puts a link to *B* right into document *A* itself. Gopher, on the other hand, is not designed to use links in this way. Instead, linking is intended to be done using the directory tree we described earlier.

### ***Gopher's Role in the Modern Internet***

There are some people who believe that Gopher is technically superior to the Web in a number of respects. They consider it cleaner to have linking be done by servers, rather than having links embedded in documents. An argument can also be made that the text orientation of Gopher is efficient, better able to ensure compatibility between platforms, and also more suited to special needs situations such as low-bandwidth links and access by those with visual impairment. Some Gopher enthusiasts thus consider it to be a "purer" hypertext system than the World Wide Web.

However, history shows us that despite Gopher predating the World Wide Web, the Web overtook it in popularity in only a few short years. Today, the Web is the 900 pound gorilla of the Internet, while most people have never even **heard** of Gopher. What happened?

I believe the main reason why Gopher lost out to the Web is that the Web is far more *flexible*. Gopher's use of text hyperlinks and server directory structures may be efficient, but it is limiting. In contrast, the Web allows information to be presented in a wide variety of ways. The open, unstructured nature of the Web made it an ideal vehicle for the creativity of information providers and application developers. In the mid-1990s, the Web was also perfectly poised to support the transition of computing from text to graphics, and Gopher really was not.

Simply put, you can do more with the Web than you can with Gopher, and more people care about functionality and breadth of options than straight efficiency. Once the Web started to gain momentum, it very quickly snowballed, as I discuss in [the topic on the Web's history](#). It took only a couple of years before Web use was well-entrenched, and Gopher was unable to compete.

For its part, the University of Minnesota likely hastened Gopher's demise with its controversial decision to charge licensing fees to companies that wanted to use Gopher for commercial purposes. I do not believe there was anything nefarious about this: the university was on a limited budget and wanted companies that could afford it, to pay a small fee to support development of Gopher software. However, computing history has shown time and time again that there is no faster way to kill a protocol or standard than to try to charge licensing or royalty fees for it, no matter what the reason.

---

By the late 1990s, Gopher was well on its way to obsolescence. As use of the protocol dwindled, many organizations could no longer justify the cost of continuing to run Gopher servers. Even the University of Minnesota itself eventually shut down its own Gopher servers due to low utilization. The final “nail in the coffin” for Gopher occurred in 2002, when a security vulnerability related to Gopher was discovered in Internet Explorer, and Microsoft chose to simply remove Gopher support from the product rather than fix the problem. Today, Gopher is still around, but is a niche protocol used only by a relatively small group of enthusiasts and a handful of organizations that have a past history of using it.

**Key Concept:** The Gopher Protocol is a distributed document search and retrieval protocol that was developed at the University of Minnesota in the late 1980s. Resources are stored on Gopher servers, which organize information using a hierarchical directory structure. Gopher clients access servers to retrieve directory listings of available resources, which are presented to the user as a menu from which an item may be selected for retrieval. Gopher’s chief advantage is simplicity and ease of use, but it lacks flexibility in presentation and the ability to effectively present graphics and multimedia. For this reason, despite Gopher predating the World Wide Web, the Web has almost entirely replaced it, and Gopher is now a niche protocol.

---

---

## **TCP/IP Interactive and Remote Application Protocols**

When it comes to TCP/IP applications, [file and message transfer applications](#) such as [electronic mail](#), [FTP](#) and the [World Wide Web](#) get the most attention, because they are the ones used most often on modern internetworks. Another category of TCP/IP application protocols that is less-well-known is the group that allows users to interactively access and use other computers directly over an internetwork, such as the public Internet. These applications are not often employed by end-users today but are still important—both from a historical perspective, and because of their usefulness in certain circumstances, especially to network administrators.

In this section, I provide a brief description of the “classical” interactive and remote application protocols used in TCP/IP. The first subsection describes the Telnet Protocol, one of the earliest and most important application protocols in TCP/IP, still used today both for remote device access and as the basis of communication of many other protocols. The second describes the Berkeley remote access family, often called the “r” commands or protocols because their command names begin with that letter. Finally, I provide a brief overview of the Internet Relay Chat (IRC) protocol, the original interactive chat application of the Internet and one still used widely today.

---

## **Telnet Protocol**

In the very earliest days of internetworking, one of the most important problems that computer scientists needed to solve was how to allow someone operating one computer to access and use another as if he or she were connected to it locally. The protocol created to meet this need was called *Telnet*, and the effort to develop it was tied closely to that of the Internet and TCP/IP as a whole. Even though most Internet users today never invoke the Telnet protocol directly, they use some of its underlying principles indirectly all the time. Every time you send a piece of e-mail, use FTP to transfer a file, or load a Web page, you are using technology based on Telnet. For this reason, the Telnet protocol can make a valid claim to the title of the most historically important application protocol in TCP/IP.

In this section, I describe the operation of the Telnet protocol. I begin with an overview and history of the protocol and a discussion of the standards that define it. I describe the general operation of Telnet clients and servers and how connections are made and maintained. I then explain the important concept of the Network Virtual Terminal (NVT), Telnet's protocol commands, and how interrupts are handled using Telnet's special synch function. I conclude with a detailed look at Telnet's options and how they are negotiated.

**Background Information:** A basic comprehension of the [Transmission Control Protocol \(TCP\)](#), especially its [sliding window mechanism](#) and [flow control feature](#), will be helpful in understanding this section.

---

## **Telnet Overview, History and Standards**

The description of internetworking protocol suites such as TCP/IP is most often done from the lower layers working upward, just as I have done in this Guide. While this makes sense for a number of reasons—most notably, the protocols are easier to understand this way—this does not reflect the history of how many protocol suites were developed. Applications in fact often come first: they are defined to meet the needs of users, and the rest of the suite is developed to enable the application to run. Telnet and TCP/IP represent a good example of this “top-down” process.

The history of Telnet actually goes back over a decade before the modern TCP/IP protocol suite that we know today. As I mentioned in [my overview of the File Transfer Protocol \(FTP\)](#), the early developers of TCP/IP internetworking technologies identified two overall application needs for networks to fill: enabling *direct access* and *indirect access* to resources. FTP was created for indirect access, by allowing a user to retrieve a resource from a remote host, use it locally, and if desired, copy it back to its source. Telnet was designed for direct access: to let a user access a remote machine and use it as if he or she were connected to it locally.

---

## ***The Motivation for Telnet's Development***

Understanding why Telnet was needed requires us to remember the nature of computing at the time the protocol was initially developed: the late 1960s. This was well before the era of the small personal computers that so many of us use exclusively today. All computers of that period were large and usually shared by many users. To work on a computer, you had to access a physical terminal connected to that machine, which was usually specially tailored to the needs and requirements of the host.

There were two specific issues that resulted from this situation. The first was that if you had several different computers in an organization, each user would need a separate terminal to access each computer he or she needed to use. This was expensive and inefficient; I can recall reading a quote from a book that compared this situation to having a room containing a number of television sets, each of which could only display a single channel.

The second and perhaps more significant issue was the difficulty in allowing a user at one site to access and use a machine at another. The only method at the time for accomplishing this was to install a dedicated data circuit from the site of the computer to the site of the user, to connect the user's terminal to the remote machine. Again, each circuit would only enable access to one machine. Every combination of user and computer would have required a separate, expensive circuit to be installed and maintained.

The solution to both of these issues was to create a more general way of allowing any terminal to access any computer. The underlying internetwork would provide the mechanism for communicating information between computers; this became the physical network connecting sites and the TCP/IP protocol suite connecting networks. On top of this would run an application protocol that allowed a user to establish a session to any networked computer and use it: the *Telnet* protocol.

## ***Telnet History***

Telnet was the first application protocol demonstrated on the fledgling ARPAnet, in 1969. The first RFC specifically defining Telnet was RFC 97, *First Cut at a Proposed Telnet Protocol*, published in February 1971. Development of Telnet continued throughout the 1970s, with quite a number of different RFCs devoted to revisions of the protocol and discussions of issues related to it. It took many years to refine Telnet and resolve all the difficulties that were associated with its development.

The final version of the protocol, *Telnet Protocol Specification*, was published as RFC 854 in May 1983. Over the years other RFCs have been published to clarify the use of the protocol and address various issues such as authentication. There are also a number of other RFCs that define [Telnet options](#), as we will see later in this section.

## ***Fundamental Telnet Concepts***

At first glance, it may be surprising that Telnet took so long to develop, because in theory, it should be a very simple protocol to define: all it needs to do is send keystrokes and program output over the network like any other protocol. This would be true if every terminal

---

and computer used the same communication method, but they do not. Telnet becomes complicated because it needs to allow a terminal from one manufacturer to be able to talk to a computer that may use a very different data representation.

Telnet solves this problem by defining a method that ensures compatibility between terminal types and computers while allowing special features to be used by computers and terminals that agree to support them. The protocol is built upon a foundation of three main concepts:

- ☉ **The Network Virtual Terminal (NVT):** Telnet defines a standardized, fictional terminal called the *Network Virtual Terminal (NVT)* that is used for universal communication by all devices. A Telnet client takes input from a user and translates it from its native form to the NVT format to send to a Telnet server running on a remote computer; the server translates from NVT to whatever representation the computer being accessed requires. The process is reversed when data is sent from the remote computer back to the user. This system allows clients and servers to communicate even if they use entirely different hardware and internal data representations. Special Telnet commands are interspersed with the data to allow the client and server devices to perform various functions needed to manage the operation of the protocol.
- ☉ **Options and Option Negotiation:** Having Telnet clients and servers act as NVTs avoids incompatibilities between devices, but does so by stripping all terminal-specific functionality to provide a common base representation that is understood by everyone. Since there are many cases where more intelligent terminals and computers may wish to use a more advanced communication feature or service, Telnet defines a rich set of options and a mechanism by which a Telnet client and server can negotiate their use. If the client and server agree on the use of an option it can be enabled; if not, they can always fall back on the NVT to ensure basic communication.
- ☉ **Symmetric Operation:** While Telnet is a client/server protocol, it is specifically designed to not make assumptions about the nature of the client and server software. Once a Telnet session is established, they can each send and receive data as equals. They can also each initiate the negotiation of options. This makes the protocol extremely flexible, and has led to its use in a variety of places, as we will discuss in a moment.

## **Telnet Applications**

Telnet is most often associated with remote login, which is its most common traditional use. A user typically uses a Telnet client program to open a Telnet connection to a remote server, which then treats the Telnet client like a local terminal, allowing the user to log in and access the server's resources as if he or she were using a directly-attached terminal. Telnet is still used this way quite extensively by UNIX users, who often need to log in to remote hosts from their local machines; I myself use Telnet in this manner every day to access a machine hundreds of miles away. However, this use of Telnet is not nearly as common amongst the majority of Internet users who work on Windows or Apple computers where network resources are accessed not through direct login but by other means.

However, while remote login is a big part of what Telnet is about, it's important to note that the protocol was not inherently designed for that specific function. When Telnet is used to access a remote device, the protocol itself is only used to set up the connection between the client and server machines, encode data to be transmitted according to the rules of the

---

Telnet NVT, and facilitate the negotiation and use of options. It is the client and server devices themselves that decide whether Telnet is used for remote access or for some other purpose.

### ***Telnet's Legacy***

Telnet's flexibility, combined with its age in the TCP/IP suite, has led to Telnet being adopted for a variety of other protocols. Since Telnet doesn't make assumptions about what a client is and what a server is, any program or application can use it. Many of the file and message transfer applications, including [FTP](#), [SMTP](#), [NNTP](#) and [HTTP](#), communicate through the sending of text commands and messages, and use the Telnet's NVT specification to ensure the compatibility of communication between devices. They don't actually establish Telnet sessions or use features like option negotiation, they just send data in a manner consistent with how Telnet works.

Thus, even though modern Internet users may never intentionally invoke Telnet specifically, they use it indirectly every time they send or receive e-mail or browse the Web. Administrators can even use Telnet client software to access devices such as FTP and HTTP servers and send them commands manually.

**Key Concept:** *Telnet* is one of the oldest protocols in the TCP/IP suite, first developed in the 1960s to allow a user on one computer system to directly access and use another. It is most often used for remote login, with Telnet client software on a user's machine establishing a session with a Telnet server on a remote host to let the user work with the host as if connected directly. To ensure compatibility between terminals and hosts that use different hardware and software, communication between Telnet client and server software is based on a simplified, fictional data representation that can be enhanced through the negotiation of options.

---

## **Telnet Connections and Client/Server Operation**

Telnet's overall function is to define a means by which a user or process on one machine can access and use another machine as if it were locally connected. This makes Telnet inherently client/server in operation, like so many other application protocols in TCP/IP. Usually, the Telnet client is a piece of software that acts as an interface to the user, processing keystrokes and user commands and presenting output from the remote machine. The Telnet server is a program running on a remote computer that has been set up to allow remote sessions.

### ***TCP Sessions and Client/Server Communication***

Telnet is used for the interactive communication of data and commands between client and server over a prolonged period of time, and is thus strongly based on the concept of a *session*. For this reason, Telnet runs over the connection-oriented [Transmission Control Protocol \(TCP\)](#). Telnet servers listen for connections on [well-known TCP port](#) number 23.

---

When a client wants to access a particular server, it initiates a TCP connection to the appropriate server, which responds to set up a TCP connection using the standard [TCP three-way handshake](#).

The TCP connection is maintained for the duration of the Telnet session, which can remain alive for hours, days, or even weeks at a time. The [quality of service features of TCP](#) guarantee that data is received reliably and in order, and ensures that data is not sent at too high a rate for either client or server. A machine offering Telnet service can support multiple simultaneous sessions with different users, keeping each distinct by [identifying it using the IP address and port number of the client](#).

Since TCP is a [full-duplex protocol](#), both client and server can send information at will over the Telnet session. By default, both devices begin by using the standard [Telnet Network Virtual Terminal \(NVT\)](#) method for encoding data and control commands. They can also negotiate the use of [Telnet options](#) to provide greater functionality for the session. While option negotiation can occur at any time, it is normal for there to be a “burst” of such option exchanges when a Telnet session is first established, and only occasional option command exchanges thereafter.

With the TCP connection in place and the Telnet session active, the client and server software begin their normal jobs of interfacing the user to the remote host. To the user, the Telnet session appears fundamentally the same as sitting down at a terminal directly connected to the remote host. In most cases, the server will begin the user’s session by sending a login prompt to ask for a user name and password. The Telnet client will accept this information from the user and send it to the server. Assuming the information is valid, the user will be logged in and can use the host in whatever manner his or her account authorizes.

As mentioned in [the Telnet overview](#), even though the protocol is classically intended for remote login, it need not be used in this manner. The administrator of the computer that is running the Telnet server determines how it is to be used on that machine. As just one example, a Telnet server can be interfaced directly to a process or program providing a service. I can recall years ago using an Internet server that provided weather information to the public using Telnet. After using the protocol to connect to that machine, you would be presented not with a login prompt, but a menu of weather display options. Of course today, [the Web](#) has replaced most of such facilities, as it is far better-suited to this type of information retrieval.

**Key Concept:** Telnet is a client/server protocol that uses TCP to establish a session between a user terminal and a remote host. The Telnet client software takes input from the user and sends it to the server, which feeds it to the host machine’s operating system. The Telnet server takes output from the host and sends it to the client to display to the user. While Telnet is most often used to implement remote login capability, there is no concept specifically pertaining to logins in the protocol, which is general enough to allow it to be used for a variety of functions.

---

---

## ***Use of Telnet To Access Other Servers***

The Telnet NVT representation is used by a variety of other protocols such as SMTP and HTTP. This means that the same Telnet client that allows you to access a Telnet server can be used to directly access other application servers. All you need to do is specify the port number corresponding to the service. For example, this command will allow you to directly interface to a Web server:

```
telnet www.someserversomewhere.org 80
```

You will not receive a login prompt, but instead the server will wait for you to send an [HTTP Request message](#), as if you were a Web browser. If you enter a valid request, the server will send you an [HTTP Response message](#). Used in this way, Telnet can be very valuable as a diagnostic tool.

**Key Concept:** The Telnet Network Virtual Terminal (NVT) data representation has been adopted by a host of other TCP/IP protocols as the basis for their messaging systems. Telnet client software can thus be used not only to connect to Telnet servers, but also to servers of protocols such as SMTP and HTTP, which is useful for diagnostic purposes.

---

## **Telnet Communications Model and the Network Virtual Terminal (NVT)**

At its heart, Telnet is a rather simple protocol. Once a TCP connection is made and the Telnet session begins, the only real task that the client and server software has is to capture input and output, and redirect it over the network. So, when the user types a key on his local terminal, the Telnet client software captures it and sends it over the network to the remote machine. There, the Telnet server software sends it to the operating system, which treats it as if it had been typed locally. When the operating system produces output, the process is reversed: Telnet server software captures the output and sends it over the network to the user's client program, which displays it on the printer or monitor.

To invoke two well-known clichés, I could say that this “looks good on paper”, but that “the devil is in the details”. This simplified implementation would only work if every computer and terminal used the exact same hardware, software and data representation. Of course, this is far from the case today, and was even worse when Telnet was being developed.

### ***The Problem of Differing Representations***

Computers back in the “good old days” were highly proprietary, and not designed to interoperate. They differed in numerous ways, from the type of keyboard a terminal used and the keystrokes it could send, to the number of characters per line and lines per screen on a terminal, to the character set used to encode data and control functions. In short, computer *A* was designed to accept input in a particular form from its own terminals, and not those of Computer *B*.

---

This is actually a fairly common issue in the world of networking, and one to which we can draw a real-world analogy to help explain the problem and how it may be solved. Suppose that an important international conference was attended by 30 ambassadors from different nations, each of which had one assistant. Every ambassador and assistant pair spoke only their own language and thus could only speak to each other—just like a computer and terminal designed to interface only to each other.

To allow the assistant from one country to speak to the ambassador from the others, one solution would be to train the assistants to speak the languages of all the other attending nations. Back in the computing world, this would be like defining the Telnet protocol so that every Telnet client software implementation understood how to speak to every computer in existence. In both cases, this would work, but would be quite impractical and difficult to do.

An alternative approach is to define a single common language and have all the ambassadors and assistants learn it. While this would require some work, it would be a lot less than requiring people to learn dozens of languages. Each ambassador and assistant would speak both his or her native language and this chosen common language. Each could communicate with all of the others using this common language, without having to know all of the languages that might be used by anyone at the conference. Even more importantly, if an ambassador and assistant showed up at the conference speaking a new, 31st language, all the other delegates wouldn't need to learn it.

### ***The Network Virtual Terminal***

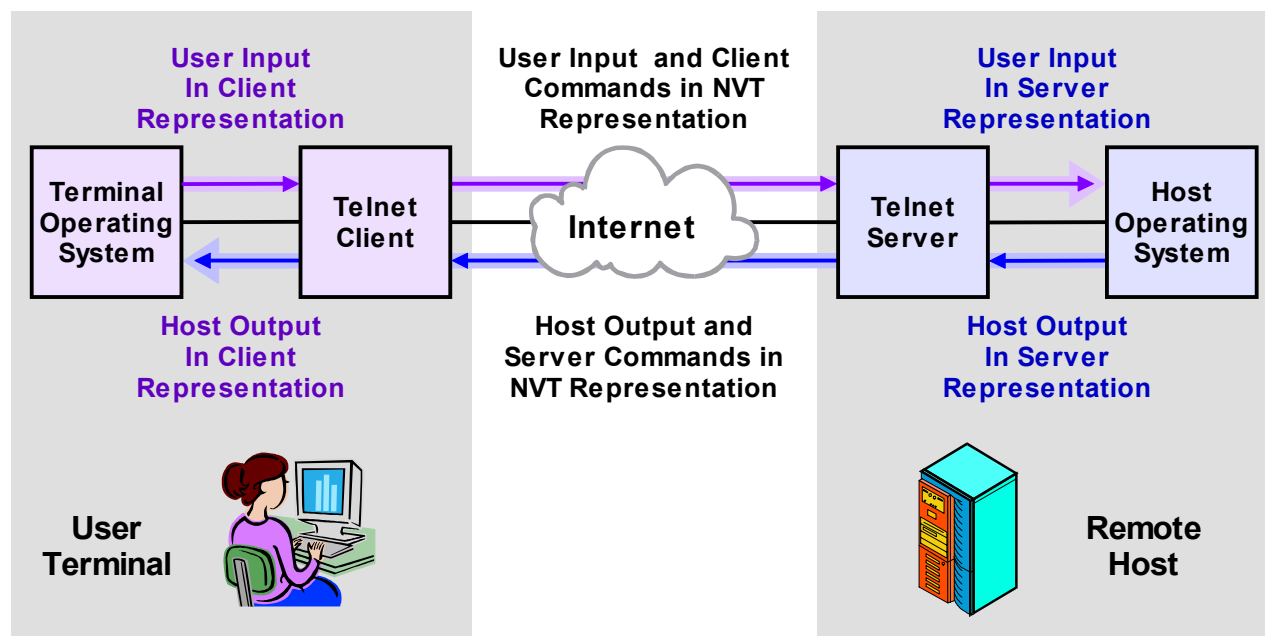

Telnet uses an approach similar to the analogy described above for dealing with its problem of hardware and software compatibility. Rather than having terminals and hosts communicate using their various native “languages”, all Telnet clients and servers agree to send data and commands that adhere to a fictional, “virtual” terminal type call the *Network Virtual Terminal (NVT)*. The NVT defines a set of rules for how information is formatted and sent, such as character set, line termination, and how information about the Telnet session itself is sent.

Each Telnet client running on a terminal understands both its native language and NVT. When information is entered by the user on his or her local terminal, it is converted to NVT for transmission over the network in NVT form. When the Telnet server receives this information, it translates it from NVT to the format that the remote host expects to receive it. The identical process is performed for transmissions from the server to the client, in reverse. This is illustrated in [Figure 320](#).

**Key Concept:** The Telnet *Network Virtual Terminal (NVT)* is a uniform data representation that ensures the compatibility of communication between terminals and hosts that may use very different hardware, software and data formats. The Telnet client translates user input from the terminal's native form to NVT for transport to the Telnet server, where it is converted to the host's internal format. The process is reversed for output from the host to the user.

---

**Figure 320: Telnet Communication and the Network Virtual Terminal (NVT)**

Telnet uses the Network Virtual Terminal (NVT) representation to allow a user terminal and remote host that use different internal formats to communicate.

The NVT is defined to consist of a logical “keyboard” for input and a logical “printer” for output (the age of the protocol is reflected in these terms; decades ago there were no monitors, all output was on paper). NVT uses the 7-bit *United States ASCII* (*USASCII*) character set. Each character is encoded using one 8-bit byte. Note however that a client and server can use [Telnet options](#) to negotiate other data representations, including the transmission of either extended ASCII or even full 8-bit binary data.

### ***NVT ASCII Control Codes***

Regular ASCII consists of 95 regular, “printable” characters (codes 32 through 126) and 33 control codes (0 through 31 and 127). The Telnet standard specifies that the output device must be able to handle all the printable characters, and it mandates how several of the other common ASCII control codes should be interpreted. Of these codes, three (0, 10 and

13) are required to be accepted by all Telnet software; five others are optional, but if supported, must be interpreted in a manner consistent with the Telnet specification. They are all described in [Table 281](#).

**Table 281: Interpretation of Standard Telnet NVT ASCII Control Codes**

ASCII Value (Decimal)	ASCII Character Code	ASCII Character	Description	Support Optional / Mandatory
0	NUL	Null	No operation (no effect on output).	Mandatory
7	BEL	Bell	Produces an audible or visible signal on the output without moving the print head. This notification may be used to get the user's attention, as in the case of an error.	Optional
8	BS	Back Space	Moves the print position one character to the left.	Optional
9	HT	Horizontal Tab	Moves the printer to the next horizontal tab stop. The standard does not specify how devices agree on tab stop positions; this can be negotiated using Telnet options.	Optional
10	LF	Line Feed	Moves the printer to the next line, keeping the print position the same.	Mandatory
11	VT	Vertical Tab	Moves the print line to the next vertical tab stop. As with the "HT" character, devices must use an option to come to an agreement on vertical tab stop positions.	Optional
12	FF	Form Feed	Moves the printer to the top of the next page (or on a display, clears the screen and positions the cursor at the top.)	Optional
13	CR	Carriage Return	Moves the printer to the left margin of the current print line.	Mandatory

### ***End-of-Line Representations***

The Telnet NVT scheme defines the combination of the carriage return ("CR") and line feed ("LF") characters to represent the end of a line of ASCII text. The literal meaning of these two characters is "return to the left margin" (from the "CR") and "go to the next line" (from the "LF"). However, NVT treats the "CR+LF" sequence as more than just two independent characters; they are taken collectively to define a *logical* "end of line" character. This is necessary because not all terminal types define an end of line using both "CR" and "LF". Translation of end-of-line characters between the native and NVT formats is one of the functions that Telnet client and server software must perform to ensure compatibility between terminals and hosts.

**Key Concept:** The Telnet NVT format is based on 7-bit US ASCII, with each byte carrying one character. The standard specifies that devices must handle all standard printable ASCII characters, as well as three mandatory control characters. Two of these are the carriage return (“CR”) and line feed (“LF”) characters; when combined, these define the logical end of a line of text. The Telnet standard also describes the interpretation of five other optional ASCII control characters.

---

### ***Half-Duplex and Full-Duplex Modes***

Another artifact of the age of Telnet is that for maximum compatibility, the Network Virtual Terminal specification is designed under the assumption of [half-duplex operation](#): only one device can transmit at a time. A device that is sending data is supposed to end its transmission with the special Telnet *Go Ahead* command, telling the other device that it may now transmit ([the next topic describes Telnet protocol commands](#)). This is similar to how people using walkie-talkies end each transmission with “over” to tell their partner that they may now respond.

Of course, modern networks operate in a full-duplex mode, and using half-duplex communication would be needlessly inefficient. In most cases the Telnet client and server agree to use an option (*Suppress Go Ahead*) that eliminates the need to send this command. However, having this as the default is a good example of how NVT acts as a “least common denominator” in Telnet, in case the simpler operating mode is needed by either device.

### **Telnet Protocol Commands**

Most of the input that a user enters at a terminal takes the form of data and commands that are sent to the application program he or she is using. However, computer systems also provide a means by which a user can instruct the terminal to send certain commands that control how the terminal itself operates, and how it interacts with the computer to which it is connected. The best example of this is the command to interrupt a process, which is usually sent by pressing a special key or key combination on the user terminal.

Telnet needs to have a way to allow such commands to be entered by the user. However, here we run into the same problem that we saw in [the last topic](#), when we talked about the communication of data between terminals and computers: a lack of uniformity in representation. While all terminals and computers support the ability to interrupt a running program, for example, they may each use a different keystroke to represent it. For example, on most UNIX systems, the key combination “<Ctrl>+C” interrupts a program, but typing this on a Windows system will not (it usually represents instead the “copy data” function!)

### ***Defining a Universal Representation for Standard Command Functions***

Since the problem is the same as the one we ran into in representing data flow, it’s not too surprising that the solution is the same: the use of a universal representation for a set of standard commands to be passed between the terminal and host computer. All keystrokes

---

that represent these commands are translated to the standard Telnet codes for transmission, and then translated to the specific needs of the host computer. So to take our example again, if a user presses “<Ctrl>+C” on a UNIX terminal where this is defined as the interrupt function, then instead of sending that exact keystroke, the Telnet client sends the special Telnet *Interrupt Process* command, which is translated by the Telnet server to the command code appropriate for the connected host.

The Telnet standard includes a number of these special codes to allow a user to control the operation of the remote computer. It also defines a set of commands that are specific to the Telnet protocol itself; these let the Telnet client and Telnet server software communicate. Collectively, these are called Telnet *protocol commands*.

### ***Escaping Commands and the Interpret As Command (IAC) Character***

All Telnet commands are sent in the same communication stream as regular data; they are represented using special byte values in the range from 240 to 254. To differentiate between data bytes of these values and Telnet commands, every command is preceded by a special *escape character*, given the name *Interpret As Command (IAC)*. IAC has a value of 255; when the recipient sees this character, it knows the next byte is a command and not data. So, since the Telnet *Interrupt Process* command has the value 244, to send this command the Telnet client would transmit the byte 255 and then 244. If the actual data byte value 255 needs to be sent, it is transmitted as two 255 bytes. Some Telnet commands also include additional bytes data, which are sent after the command code itself; a good example is the use of parameters in [Telnet option negotiation](#).

You may be wondering at this point why the IAC character is needed at all. After all, Telnet uses US ASCII, which is 7-bit data in the byte range of 0 to 127, and the Telnet commands have values higher than 127. One general rationale for using the IAC escape is to be explicit that a command is being sent. A more specific reason is to accommodate the optional sending of 8-bit binary data over Telnet, which the client and server can negotiate. If this mode were enabled and commands were not preceded by the IAC character, this would require all data bytes with values from 240 to 255 to be somehow marked so they would be interpreted as data and not commands. It is more efficient to include an extra byte for commands than data, since they are sent less frequently. By escaping commands, only data byte value 255 requires two bytes to be sent.

**Key Concept:** The Telnet protocol defines a set of *protocol commands* that are used for two purposes: first, to represent standard control functions that need to be sent between a terminal and host, such as the command to interrupt a process; and second, to enable protocol communication between the Telnet client and server software. Protocol commands are sent in the normal data communication stream over the Telnet session’s TCP connection. Each is represented by a byte value from 240 to 254, and is preceded by the *Interpret As Command (IAC)* command, byte value 255, which tells the recipient that the next byte in the stream is a command.

---

---

## Telnet Protocol Command Codes

Table 282 lists the Telnet protocol commands in numerical byte value order, showing for each its command code and name and describing its meaning and use.

**Table 282: Telnet Protocol Commands (Page 1 of 2)**

Command Byte Value (Decimal)	Command Code	Command	Description
240	<i>SE</i>	Subnegotiation End	Marks the end of a Telnet option subnegotiation, used with the <i>SB</i> code to specify more specific option parameters. <a href="#">See the topic on Telnet options for details.</a>
241	<i>NOP</i>	No Operation	Null command; does nothing.
242	<i>DM</i>	Data Mark	Used to mark the end of a sequence of data that the recipient should scan for urgent Telnet commands. <a href="#">See the topic on Telnet interrupt handling for more information.</a>
243	<i>BRK</i>	Break	Represents the pressing of the “break” or “attention” key on the terminal.
244	<i>IP</i>	Interrupt Process	Tells the recipient to interrupt, abort, suspend or terminate the process currently in use.
245	<i>AO</i>	Abort Output	Instructs the remote host to continue running the current process, but discard all remaining output from it. This may be needed if a program starts to send unexpectedly large amounts of data to the user.
246	<i>AYT</i>	Are You There	May be used to check that the remote host is still “alive”. When this character is sent the remote host returns some type of output to indicate that it is still functioning.
247	<i>EC</i>	Erase Character	Instructs the recipient to delete the last undeleted character from the data stream. Used to “undo” the sending of a character.
248	<i>EL</i>	Erase Line	Tells the recipient to delete all characters from the data stream back to (but not including) the last end of line (“CR”+“LF”) sequence.
249	<i>GA</i>	Go Ahead	Used in Telnet half-duplex mode to signal the other device that it may transmit.
250	<i>SB</i>	Subnegotiation	Marks the beginning of a Telnet option subnegotiation, used when an option requires the client and server to exchange parameters. <a href="#">See the topic on Telnet options for a full description.</a>
251	<i>WILL</i>	Will Perform	In <a href="#">Telnet option negotiation</a> , indicates that the device sending this code is willing to perform or continue performing a particular option.

**Table 282: Telnet Protocol Commands (Page 2 of 2)**

Command Byte Value (Decimal)	Command Code	Command	Description
252	<i>WON'T</i>	Won't Perform	In <a href="#">Telnet option negotiation</a> , indicates that the device sending this code is either not willing to perform a particular option, or is now refusing to continue to perform it.
253	<i>DO</i>	Do Perform	In <a href="#">Telnet option negotiation</a> , requests that the other device perform a particular option or confirms the expectation that the other device will perform that option.
254	<i>DON'T</i>	Don't Perform	In <a href="#">Telnet option negotiation</a> , specifies that the other party not perform an option, or confirms a device's expectation that the other party not perform an option.
255	<i>IAC</i>	Interpret As Command	Precedes command values 240 through 254 as described above. A pair of IAC bytes in a row represents the data value 255.

Perhaps ironically, the Telnet command are not used as much today as they were when Telnet was in its early days, because many of the compatibility issues that we discussed earlier no longer exist. ASCII has become the standard character set of the computing world, so many of the functions such as aborting output or interrupting a process no longer require the use of Telnet commands. They are still widely used, however, for internal Telnet operations such as option negotiation.

## **Telnet Interrupt Handling Using Out-Of-Band Signaling: The Telnet Synch Function**

All the bytes of data sent from a Telnet client to a server are received in the order that they were sent, and vice-versa. This is, of course, the way we expect an application to operate; in fact, ensuring that data is not received out-of-order is one of the jobs that we assume of [the reliable transport protocol TCP](#), over which Telnet runs. However, this can cause a problem for Telnet because of the way the protocol sends both data and commands over the same connection.

### ***The Problem: Sending an Interrupt Command***

The most important case where the issue of all data being received in order arises is when a user needs to interrupt a process. Suppose as an example that you are using Telnet to run an interactive program that takes user input, processes it, and then produces output. You are merrily typing away when you notice that you haven't seen any output from the program for a while. It has apparently hung up due to a programming error or other glitch.

---

If you were using the program on a directly-connected terminal, you would simply use the key or keystroke command appropriate to that terminal to interrupt or kill the process and restart it. Instead, you are using Telnet, so you enter the appropriate keystroke, which gets converted to the special Telnet *Interrupt Process* command code (byte value 244, preceded by the Telnet *Interpret As Command* code, 255).

Since Telnet uses only a single stream for commands and data, that code is placed into the [TCP data stream](#) to be sent over to the Telnet server. Since you were entering data for a while, that Telnet *Interrupt Process* code will be sitting behind a bunch of regular data bytes. Now, the remote process has stopped reading this data, which means the TCP receive buffer on the server will start to fill up. The *Interrupt Process* command will thus remain stuck in the buffer, waiting to be read. In fact, if the number of data bytes in front of the command is high enough, the TCP buffer on the server may fill entirely, causing the server to [close the client's TCP send window](#). This means the *Interrupt Process* command will wait in the client's outgoing TCP queue and never even be sent to the remote host at all!

Obviously, what we need here is some way to be able to flag the *Interrupt Process* command, so that it can be sent to the remote host regardless of the number of data bytes outstanding in front of it. If you've already perused [the large section of this Guide devoted to TCP](#), you may now be thinking that you have already read about a feature of that protocol that seems ideally suited for this exact problem... and you'd be correct! The TCP "urgent" [function](#) allows an important piece of data to be marked so that it is given priority over regular data, a process sometimes called *out-of-band signaling* (because the signal is "outside" the normal data stream). Telnet makes use of this feature of TCP to define what it calls the *synch function*.

### ***The Synch Function***

When needed, as in the example just described, the synch function is invoked by the client sending the special *Telnet Data Mark (DM)* protocol command, while instructing its TCP layer to mark that data "urgent". The *URG* bit in the [TCP segment](#) carrying this command causes it to bypass TCP's normal flow control mechanism so it is sent over to the remote host. The Telnet server software, seeing the synch in the data stream, then searches through all of the data in its buffer looking only for Telnet control commands such as *Interrupt Process*, *Abort Output* and *Are You There*. These commands are then executed immediately. The server continues to search for important commands up to the point where the *Data Mark* command is seen. All intervening data is discarded; it will need to be retransmitted. After the *Data Mark* is processed, the server returns to normal operation.

It is also possible for the server to use the synch function in communication with the user on the client device. For example, if the user sends the *Abort Output* command to the server, he or she is telling the server to discard all remaining output from the current process. The server will stop sending that output, and can also use the synch function to clear all outstanding data that is waiting in buffers to be sent to the client machine (since it causes data to be discarded as mentioned above).

**Key Concept:** Telnet protocol commands are sent in the same stream with user data, which means a problem with the remote host that stops the flow of data might cause user commands to become backed up and never received by the host. Since this may include commands issued by the user to try to fix the problem on the host, this can be a serious problem. To alleviate this situation, Telnet includes the *synch* function, which uses TCP's urgent data transmission feature to force the receipt of essential commands even when regular data is not being processed.

---

## **Telnet Options and Option Negotiation**

The basic [Telnet Network Virtual Terminal \(NVT\)](#) specification solves the problem of compatibility between different terminal and computer types by defining a common representation for data and commands that every Telnet client and server uses. The price for this universal representation, however, is very high: all of the advanced or special capabilities of terminals and hosts is stripped off. The result is a language that everyone can speak, but that is not capable of much more than basic conversation.

The creators of Telnet recognized that while it was important to define NVT as a common base to ensure cross-device compatibility, it was also essential that some means be provided by which clients and servers could agree to use more advanced means of communication. They defined a set of *Telnet options*, and a mechanism by which a Telnet client and server can *negotiate* which options they want to use.

Most Telnet options are used for the purpose of improving the efficiency of how data is transferred between devices. For example, by default the NVT assumes half-duplex operation with each device needing to use the *Go Ahead* command after each transmission. However, virtually all hardware now supports full-duplex communication, so devices will usually agree to use the *Suppress Go Ahead* option to eliminate the need to send this character. Similarly, it is possible for devices to negotiate the sending of 8-bit binary data instead of the standard 7-bit ASCII of the Telnet NVT.

The process of Telnet option negotiation is described in the main Telnet standard document, RFC 854, as well as a companion document, RFC 855 ([Telnet Option Specifications](#)). The options themselves are described in a separate set of Internet standards. Several of these were published at the same time as RFCs 854 and 855; others were defined earlier as part of previous versions of Telnet, and still others have been added over the years. There are now several dozen different Telnet options in existence; a master list is maintained by [IANA](#) (like all other TCP/IP parameters).

**On The Web:** An up-to-date listing of all Telnet options can be found on the IANA Web site at: <http://www.iana.org/assignments/telnet-options>

---

---

## Common Telnet Options

Each Telnet option is identified using a decimal byte code with a possible value of 0 to 254; the value 255 is reserved to extend the option list should more than 255 options ever be needed. Each option also has a text code string associated with it, which is often used as a symbol in place of the code number in both protocol discussions and diagnostic output.

[Table 283](#) lists some of the more interesting Telnet options and provides a brief description of each.

**Table 283: Common Telnet Options (Page 1 of 2)**

Option Number	Option Code	Option Name	Description	Defining RFC
0	<b>TRANSMIT-BINARY</b>	<b>Binary Transmission</b>	Allows devices to send data in 8-bit binary form instead of 7-bit ASCII.	856
1	<b>ECHO</b>	<b>Echo</b>	When you press a key on a terminal, you also expect to see the character you entered appear on the terminal screen as output; this is called <i>echoing</i> the input. Echoing is a significant issue in terminal applications because it can be implemented in a number of different ways. This option allows devices to negotiate any of a variety of different echo modes.	857
3	<b>SUPPRESS-GO-AHEAD</b>	<b>Suppress Go Ahead</b>	Allows devices not operating in half-duplex mode to no longer need to end transmissions using the Telnet <i>Go Ahead</i> command.	858
5	<b>STATUS</b>	<b>Status</b>	Lets a device request the status of a Telnet option.	859
6	<b>TIMING-MARK</b>	<b>Timing Mark</b>	Allows devices to negotiate the insertion of a special timing mark into the data stream, which is used for synchronization.	860
10	<b>NAOCRD</b>	<b>Output Carriage-Return Disposition</b>	Lets the devices negotiate how carriage returns will be handled.	652
11	<b>NAOHTS</b>	<b>Output Horizontal Tab Stops</b>	Allows the devices to determine what horizontal tab stop positions will be used for output display.	653
12	<b>NAOHTD</b>	<b>Output Horizontal Tab Stop Disposition</b>	Allows the devices to negotiation how horizontal tabs will be handled and by which end of the connection.	654
13	<b>NAOFFD</b>	<b>Output Formfeed Disposition</b>	Allows the devices to negotiation how form feed characters will be handled.	655
14	<b>NAOVTS</b>	<b>Output Vertical Tabstops</b>	Used to determine what vertical tab stop positions will be used for output display.	656

**Table 283: Common Telnet Options (Page 2 of 2)**

Option Number	Option Code	Option Name	Description	Defining RFC
15	<b>NAOVT</b>	<b>Output Vertical Tab Disposition</b>	Lets devices negotiation the disposition of vertical tab stops.	657
16	<b>NAOLFD</b>	<b>Output Linefeed Disposition</b>	Allows devices to decide how line feed characters should be handled.	658
17	<b>EXTEND-ASCII</b>	<b>Extended ASCII</b>	Lets devices agree to use extended ASCII for transmissions and negotiate how it will be used.	698
24	<b>TERMINAL-TYPE</b>	<b>Terminal Type</b>	Allows the client and server to negotiate the use of a specific terminal type. If they agree, this allows the output from the server to be ideally customized to the needs of the particular terminal the user is working on.	1091
31	<b>NAWS</b>	<b>Negotiate About Window Size</b>	Permits communication of the size of the terminal window.	1073
32	<b>TERMINAL-SPEED</b>	<b>Terminal Speed</b>	Allows devices to report on the current terminal speed.	1079
33	<b>TOGGLE-FLOW-CONTROL</b>	<b>Remote Flow Control</b>	Allows flow control between the client and the server to be enabled and disabled.	1372
34	<b>LINEMODE</b>	<b>Linemode</b>	Allows the client to send data one line at a time instead of one character at a time. This improves performance by replacing a large number of tiny TCP transmissions with a smaller number of larger ones.	1184
37	<b>AUTHENTICATION</b>	<b>Authentication</b>	Lets the client and server negotiate a method of authentication to secure connections.	1416

**Key Concept:** The Telnet NVT specification ensures that all devices using Telnet can talk to each other, but accomplishes this by boiling down communication to the simplest of representations. To allow the use of more sophisticated formats and services, Telnet defines a number of *options*. If a client and server both implement a particular option, they can enable its use through a process of *negotiation*.

### **Enabling Options Using Negotiation**

The first stage in Telnet option negotiation is for the client and server to decide whether or not they want to enable a particular option. One of the aspects of Telnet's symmetry of operation is that either device may choose to initiate the use of an option. The initiating

---

device may either specify that it wants to start using an option, or that it wants the other device to start using it. The responding device may either agree or disagree in either case; an option can only be enabled if both devices agree to its use.

This negotiation is performed using four Telnet protocol commands, as follows:

- ☛ ***WILL:*** Sent by the initiator to indicate that it wants to start using a particular option. There are two possible replies by the responding device:
  - ☛ ***DO:*** Sent to indicate agreement that the initiator should use the option; it is then considered enabled.
  - ☛ ***DONT:*** Sent to specify that the initiator must not use the option.
- ☛ ***DO:*** Sent by the initiator to request that the other device start using an option. That device may respond in two ways:
  - ☛ ***WILL:*** Sent to specify that the responding device will agree to use the option; the option is enabled.
  - ☛ ***WONT:*** Sent to tell the initiator that the responder will not use the option requested.

The symmetry of Telnet, combined with the fact that both *DO* and *WILL* can be used either to initiate a negotiation or respond to one, make Telnet's option negotiation potentially complicated. Since either device can initiate negotiation of an option at any time, acknowledgment loops could potentially arise if both devices were to try to enable an option simultaneously, or get into a situation where each kept responding to the other's replies.

For this reason, the Telnet standard specifies restrictions on when the *WILL* and *DO* commands are used. One is that a device may only send a negotiation command to request a change in the status of an option; it cannot send *DO* or *WILL* just to confirm or reinforce the current state of the option. Another is that a device receiving a request to start using an option it is already using should not acknowledge it using *DO* or *WILL*.

### ***Disabling Options***

Since an option may only be activated if both devices agree to use it, either may disable the use of an option at any time by sending either of these commands:

- ☛ ***WONT:*** Sent by a device to indicate that it is going to stop using an option. The other device must respond with *DONT* as a confirmation.
- ☛ ***DONT:*** Sent by a device to indicate that it wants the other device to stop using an option. The other device must respond with *WONT*.

**Key Concept:** Either device may choose to negotiate the use of a Telnet option. The initiator uses the *WILL* command to specify that it wants to start using a particular option; if the other device agrees, it responds with *DO*; otherwise, it sends *DONT*. Alternately, the initiator can use the *DO* command to indicate that it wants the other device to start using an option; that device responds with *WILL* if it agrees to do so, or *WONT* if it does not. Either device may disable the use of an option at any time by sending the other a *WONT* or *DONT* command.

---

### ***Option Subnegotiation***

All of the *DO/DONT/WILL/WONT* stuff above only serves to enable or disable an option. Some options are only either off or on, in which case the negotiation above is sufficient. An example would be the binary transmission option, *TRANSMIT-BINARY*. Others require that after they are enabled, the client and server exchange parameters to control how the option works. For example, the *TERMINAL-TYPE* option requires some way for the client to send the server the name of the terminal.

Telnet allows the client and server to send an arbitrary amount of data related to the option using a process called *option subnegotiation*. A device begins this process by sending a special sequence of Telnet protocol commands and data. First the command *SB* is sent, followed by the option number and parameters as defined by the particular option; the end of the subnegotiation data is marked by the protocol command *SE*. Of course, both *SB* and *SE* must be preceded by the *Interpret As Command (IAC)* command byte.

So, let's take the terminal type option again as an example. Suppose the server supports this option and would like the client to use it. It will send:

IAC DO TERMINAL-TYPE

**Note:** I am showing the text mnemonics for convenience; this would really be sent as the three decimal bytes 255 253 24.

---

Assuming the client agrees, it will respond with:

IAC WILL TERMINAL-TYPE

Now the terminal type option is in effect, but the server still doesn't know what terminal the client is using. It can prompt the client to provide that information by sending this:

IAC SB TERMINAL-TYPE SEND IAC SE

---

The client, receiving this “subnegotiation” command, will respond with:

IAC SB TERMINAL-TYPE IS <some\_terminal\_type> IAC SE

**Key Concept:** The *WILL* and *DO* commands only turn on a Telnet option that a client and server agree to use. In some cases, an option requires additional information to be sent between the client and server device for it to function properly. This is accomplished through a process of *option subnegotiation*. Either device sends the other a set of data relevant to the option, bracketed by the *SB* (*subnegotiation*) and *SE* (*end subnegotiation*) Telnet protocol commands.

---

---

## **Berkeley Remote ("r") Commands**

TCP/IP has achieved success in large part due to its universality: it has been implemented on virtually every major computing platform. While the suite is thus not specific to any operating system, there is no denying that its history is closely tied to a particular one—UNIX. Most of the computers on the early Internet used UNIX, and the development of TCP/IP has paralleled that of UNIX in a number of respects.

One of the most important organizations involved in the development of UNIX, and thus TCP/IP indirectly, was the University of California at Berkeley. Their well-known *Berkeley Software Distribution (BSD)* UNIX has been in widespread use for over 20 years. A set of commands was developed for BSD UNIX to facilitate various remote operation functions over a TCP/IP internetwork. Each of these programs begins with the letter “r” (for “*remote*”), so they have come to be known as both the *Berkeley remote commands* (or utilities) and also simply the “r” *commands*. Since their initial creation, they have been adopted for most variations of UNIX, and some other operating systems as well.

In this section I provide a brief description of the Berkeley remote protocols and how they are used. I begin with a discussion of the main protocol in this group, *rlogin*, and how it is used to enable remote host access. I then describe the remote shell program, *rsh*, and how it allows a command to be executed on a network host. I conclude with a brief summary of the other members of the “r” protocol family: *rcp*, *ruptime* and *rwho*.

**Background Information:** This section will probably make much more sense to those who have some understanding of the UNIX operating system than those who do not. I also make some reference to [Telnet](#) in this section so you may wish to have at least basic familiarity with that protocol.

---

## **Berkeley Remote Login (rlogin)**

The “head” of the Berkeley remote protocol family is the remote login command, *rlogin*. As the name clearly implies, the purpose of this program is to allow a user on a UNIX host to log in to another host over a TCP/IP internetwork. Since Telnet is also often used for remote login, *rlogin* and Telnet are sometimes considered alternatives to each other for TCP/IP remote login. While they can be used in a very similar way, however, they are quite different in a few respects.

From a conceptual standpoint, Telnet is designed as a protocol to enable terminal/host communication. As I mentioned in [the Telnet overview topic](#), the protocol was not designed specifically for the purpose of remote login. In contrast, *rlogin* **was** intended for that specific purpose, and this is reflected in its operation.

---

## ***rlogin Operation***

The protocol requires *rlogin* server software to be running on the host that is going to allow remote access; it is usually called *rlogind* (for *rlogin daemon*, the latter word being the standard UNIX term for a background server process). The server listens for incoming connection requests on TCP port 513. A user who wants to remotely log in to the server runs the *rlogin* command on his or her local host, and specifies the name of the server. The client makes a TCP connection to the server, and then sends to the server a string containing the following information:

- ☉ The login name of the user on the client machine.
- ☉ The login name that the user wants to use on the server (which is often the same as the user's login name on the client, but not always.)
- ☉ Control information such as the type and speed of the terminal.

The server processes this information and begins the login process. It will normally prompt the user for a password to log in to the remote host. Assuming the password is correct, the user will be logged in to the remote host and can use it as if he or she were locally connected.

## ***Comparing rlogin to Telnet***

From a practical standpoint, the *rlogin* command is much simpler than Telnet; it does not support Telnet's full [command structure](#), nor capabilities such as [option negotiation](#). It does include a small set of commands, however. The client is able to send to the server one key piece of information: the current size of the terminal window in use. The server is able to tell the client to turn on or off flow control, request that the client send it the current window size, or flush pending output that the server has sent, up to a certain point in the data stream.

## ***Automating rlogin***

In some organizations, many different UNIX hosts are used every day and needing to type passwords all the time when using *rlogin* was deemed to be somewhat of a chore. On these systems, it is possible for administrators to set up control files that specify combinations of host names, user names and passwords. If set up correctly, this enables an authorized user to utilize *rlogin* to remotely access a host automatically, without having to enter either a login name or password, which can be a time savings.

## ***rlogin Security Concerns and slogind***

As originally designed, *rlogin* is a classic example of a protocol from the early days of TCP/IP: it emphasizes simplicity and usability over security. This is especially true of the automated login process just described. The original schemes used by *rlogin* for authentication are considered inadequate for modern TCP/IP internetworks, especially those connected to the Internet. Later versions of *rlogin* have been enhanced with more secure

---

authorization methods. There is also a newer program called *slogin* (for *secure login*) that uses stronger authentication and encryption, and is intended to replace *rlogin* on newer systems.

**Key Concept:** The Berkeley remote or “r” commands facilitate remote operations between UNIX hosts on a TCP/IP internetwork. The base command of the family is the *remote login* command, *rlogin*, which allows a device on one host to access and use another as if he or she were locally connected to it. *rlogin* is often used as an alternative to Telnet, but is simpler both conceptually and practically.

---

## **Berkeley Remote Shell (rsh)**

The Berkeley [remote login command \(rlogin\)](#) allows a user to easily access a remote UNIX host over a TCP/IP internetwork. A user would normally use *rlogin* when he or she needs to log in to a server to perform a number of tasks. There are some situations, however, where a user needs to only enter one command on a remote host. With *rlogin*, the user would have to log in to the host, execute the command, and then log back out again.

This isn’t exactly an earth-shattering amount of inconvenience, especially when the correct configuration files are set up to allow automatic login. Over the course of time, however, all the extra logging in and out can become tedious. As a convenience, a variation of *rlogin* was created called *remote shell (rsh)*, which allows a user to access a remote host and execute a single command upon it without requiring the login and logout steps.

**Note:** “Shell” is the standard term used in UNIX to refer to the user interface that accepts commands from the user and displays output on the screen.

---

## ***rsh* Operation**

The *rsh* command is based on *rlogin* and really works in much the same way, except that it is oriented around executing a command rather than establishing a persistent login session. The server process on the remote host is usually called *rshd* (*remote shell daemon*) and listens for incoming *rsh* requests. When one is received, the user is logged in through the same mechanism as *rlogin*. The command is then run on the remote host and the user is automatically logged out.

## ***Automated Use of rsh by Programs***

*rsh* is most useful when automatic login is employed, so that the program can be run without the need for the user to enter a login name or password. In that case, it is possible to have programs use *rsh* to automatically run commands on remote hosts without the need for human intervention, which opens up a number of possibilities for UNIX users. The

---

normal UNIX user interface concepts of *standard input (stdin)*, *standard output (stdout)* and *standard error (stderr)* also apply to *rsh*, so you can use it to execute a remote command and redirect the output to a local file. For example, this command would let a user get a listing of his or her home directory on the server “<somehost>” and store it in the local file “remotelist”:

```
rsh <somehost> ls -l >remotelist
```

**Key Concept:** The *remote shell* or *rsh* command is similar to the Berkeley *rlogin* command, but instead of opening a login session on a remote host, it executes a single, user-provided command. *rsh* can be helpful for users who need to perform a quick operation on a remote host, and can also be employed by other programs to automate network tasks.

---

### ***rsh* Security Concerns and *ssh***

Since *rsh* is based on *rlogin*, all of the concerns that apply to *rlogin* are also relevant here, especially with regard to security. (We no more want an unauthorized user running commands on our servers than logging in to them!) As with *rlogin*, newer versions of *rsh* support more advanced authentication options than the original software. Also, just as *slogin* is a newer, more secure version of *rlogin*, there is a program called *ssh* (*secure shell*) that replaces *rsh* on many systems.

**Note:** On some systems, if *rsh* is entered without a command specified to execute, then an interactive remote session is established, exactly as if the *rlogin* command had been entered instead of *rsh*.

---

### **Other Berkeley Remote ("r") Commands (*rcp*, *ruptime*, *rwho*)**

The *rlogin* and *rsh* commands are the generic members of the Berkeley “r” family of programs that allow remote access to a host. To complement these, a small number of specific remote commands were also defined. These are essentially remote versions of some of the more common UNIX functions—instead of the command being applied to only one system, however, it is used between two systems or across all systems on a TCP/IP network.

All of these commands are based on *rlogin* the same way that *rsh* is. They work in the same way, but instead of opening up a session or passing a user-specified command to the remote host, they execute a particular function. The following are the most common of these remote commands and briefly, how each is used:

- 
- ☉ **Remote Copy (*rcp*):** This is the remote version of the UNIX copy (*cp*) command; it allows a file to be copied between the local host and the remote host, or between two remote hosts. The usual syntax is basically the same as the regular *cp* command, but the source and/or destination is specified as being on a remote host.

The *rcp* command can be used in a manner similar to [FTP](#), but is much simpler and less capable. Or to put it another way: *rcp* is to FTP, what *rlogin* is to [Telnet](#). (That's not a perfect analogy, but it's pretty close.)

- ☉ **Remote Uptime (*ruptime*):** The UNIX command *uptime* is used to display how long a computer has been running since it was last booted, along with information related to its current load. *ruptime* is the remote version of this command; it displays the current status of each machine on the network (up or down), how long each up machine has been up since its last boot, and its load statistics.
- ☉ **Remote Who (*rwho*):** This is the remote version of the *who* command. Where *who* shows all the users logged on to the host where it is run, *rwho* shows all users logged on to all machines on the network.

The *ruptime* and *rwho* commands both rely on the presence of the *rwhod* (*remote who daemon*) running in the background on networked machines. These processes routinely share information with each other about host uptime and who is logged on to each system, so it can be quickly displayed when either *ruptime* or *rwho* is run.

On some operating systems, other remote commands may also be implemented. As with *rlogin* and *rsh*, security issues may apply to these commands, and there may be efficiency concerns with others (such as *rwho*). For these reasons, on many networks these commands are no longer used.

---

## Internet Relay Chat Protocol (IRC)

The primary advantage that [electronic mail](#) offers over conventional mail is *speed*. Instead of having to wait for days or weeks for a message to be delivered, it usually arrives in minutes or even seconds. This makes electronic mail far more useful than the regular postal service for most types of information transfer. There are some cases, however, where speed of delivery is not sufficient to make electronic mail an ideal mechanism for communication. One such case is where a *dialog* is required between two parties.

Consider that even though electronic mail may be delivered very quickly, it uses a [decoupled model of communication](#). When person *A* sends an e-mail to person *B*, the message may show up in *B*'s inbox in a matter of seconds, but *B* may not in fact be around to read it at the time it arrives. *B* might not see the message until hours later; he would then send a response to *A*, who in turn might not see it for a while. If the subject they are discussing requires several dozen iterations of this sort, it could take a very long time before the exchange is completed.

In the real world, of course, most of us would never use mail for such a conversation, preferring instead that high-tech communication device that we call... the telephone. ☺ Many people using computers realized that it would be useful to have a way for two or more people to interactively discuss issues in a manner similar to a telephone conversation. In the online world, this is commonly called *chatting*, and one of the first and most important application protocols designed to implement it in TCP/IP was the *Internet Relay Chat Protocol (IRC)*.

### **IRC History and Standards**

Prior to the widespread use of the Internet, people with computers would often communicate by dialing in to a *bulletin board system (BBS)* or other proprietary service. IRC was originally created by a gentleman from Finland named Jarkko Oikarinen, based on his experience with chat applications on BBSes. He wrote the first client and server software in 1988; the protocol was later formally defined in RFC 1459, [Internet Relay Chat Protocol](#), published May 1993. In April 2000, the IRC standard was revised and enhanced with several new extended capabilities, and published as a set of four smaller documents: RFCs 2810 through 2813. Each of these focuses on one particular area of IRC functionality.

**Note:** RFC 1459 has the [RFC status](#) “Experimental”, and the RFC 2810 to 2813 group is designated “Informational”. This makes IRC optional; it need not be implemented on TCP/IP devices.

---

### **IRC Communication Model and Client/Server Operation**

IRC is an interesting protocol in that it is not based strictly on [the standard client/server model of TCP/IP protocol operation](#). *IRC servers* are TCP/IP machines that run IRC server software. They are configured with information that allows them to establish TCP connec-

---

tions to each other; **TCP** is used because the connections are maintained over a long period of time and reliable transport of data is required. Server connections are used to exchange control information and user data, forming a logical *IRC network* at the application level, which allows any server to send to any other using intermediate servers as conduits. Servers are managed by *IRC operators (IRCops)* who have special privileges that allow them to ensure that everything runs smoothly on the network.

The IRC network forms the backbone of the IRC communication service. A user can access the network by running *IRC client* software on any TCP/IP-enabled device. The user enters the name of one of the servers on the network and establishes a TCP connection to that server. This causes the user to be connected directly to one server, and thus, indirectly to all of the others on the network. This allows that user to send and receive messages to and from all other users connected either to the user's server or other servers.

### ***Group Messaging and IRC Channels***

The most common type of communication in IRC is *group messaging*, which is accomplished using *IRC channels*. A channel is a virtual meeting place of sorts, and is also sometimes called a *chat room* (though IRC purists scoff at the use of that term.) Every IRC network has hundreds or even thousands of different channels, each of which is dedicated to a particular type of discussion, ranging from the serious to the silly. For example, a group of people interested in talking about meteorology could establish a channel called “#weather” where they would meet regularly to discuss various aspects of climatology and interesting weather events.

IRC is an inherently text-based protocol (though it is also possible to use IRC clients to transfer arbitrary files between users, including images and executable programs.) To communicate in a channel, all a user needs to do is enter text in the appropriate spot on the IRC client program; this text is automatically sent to every other member of the channel. The IRC network handles the relaying of these messages in real time from one user, to that user's connected server, to other servers in the network, and then to all user machines on those servers. When other users see the first user's message they can reply with messages of their own, which will in turn be propagated across the network. Each IRC user chooses a nickname (often abbreviated nick) that is like a “handle” used for communication while connected to the network.

### ***Individual Messaging***

IRC also supports one-to-one communication, which can be used for private conversation. To use this method, all a user needs is the nickname of another user to whom he or she wants to talk; he or she uses a special command to send messages directly to that user, who can respond in kind. This is not a secure form of communication, since the messages are not encrypted, and they pass through servers where they could be monitored. However, there is so much traffic on a typical IRC network that any given message is unlikely to be monitored, so there is not much concern (unless you work for the CIA or just developed a cure for the common cold or something. ☺)

---

The IRC protocol defines a rich command set that allows users to perform essential functions, such as joining or leaving a channel, changing nicknames, changing servers, setting operating modes for channels and so forth. The exact command set and features available depends both on the specific software used for the user's IRC client, and the features available on the IRC network itself, not all of which run the same version of the protocol.

IRC became very popular in the early 1990s because of the powerful way that it allows users from anywhere on the Internet to meet and share information dynamically. Not only does it act like a text-based “telephone”, it allows users across the globe to communicate without the expense of a long-distance call.

### ***IRC and the Modern Internet***

One of the most important characteristics of IRC is its open-ended nature: it gives every person the freedom to communicate in whatever way he or she considers best. For example, every IRC channel has an owner, who has certain rights related to how the channel is used, including the ability to decide who should be allowed in the channel and who not. This may seem autocratic, but IRC lets anyone start a new channel instantly and become that channel's owner, without the need for prior registration or authorization. This means that if you don't like how a particular channel is run, you can start your own with a minimum of fuss; you are not forced to adhere to anyone's rules, other than the rules set forth for the server (which are usually just intended to prevent abuse.)

This same principle extends to the IRC networks themselves as well—there isn't just one single IRC network, there are dozens of different ones. Some are large, well-established networks that may have over 100 servers and thousands of users, while others are smaller and devoted to specific areas of interest or geographical regions. Anyone can set up their own IRC network if they have the hardware and software, and some organizations have in fact set up private, dedicated IRC servers for their own use.

IRC is considered by many to be the most important “ancestor” of the related interactive applications collectively known as *instant messaging*. These services are offered by several organizations, including America Online (AOL), Yahoo! and Microsoft's MSN. The idea behind them is very similar to that of IRC; each allows a message sent by one user to be displayed immediately to another, though most are focused primarily on user-to-user messages rather than groups. Instant messaging has in fact surpassed IRC in overall use, perhaps due to the large subscriber base of services like AOL. However, IRC is still widely used by thousands of enthusiasts on a daily basis for both entertainment and business purposes.

---

## TCP/IP Administration and Troubleshooting Utilities and Protocols

The first two large subsections of [the large section devoted to TCP/IP applications and application protocols](#) discussed file and message transfer applications, and interactive and remote access applications, respectively. These are the classical applications that are most often employed by the users of TCP/IP internetworks. Since they are the means by which users communicate, they can be considered in some ways the “raison d’être” of TCP/IP and the Internet itself.

In contrast, this third subsection is a bit different. It doesn’t describe applications designed for end-users. Rather, it discusses a set of *TCP/IP troubleshooting utilities and protocols*, which are normally the province of internetwork administrators. Even though millions of people use TCP/IP every day without even knowing that these applications exist—much less how they work—they are critically important to those who maintain TCP/IP internetworks. Since many of you are studying TCP/IP so that you can implement and administer this technology, understanding how these applications work is well worth your time.

In this section I provide an overview description of a number of software utilities that are commonly employed to help set up, configure and maintain TCP/IP internetworks. These programs allow a network administrator to perform functions such as checking the identity of a host; verifying connectivity between two hosts; checking the path of routers between devices; examining the configuration of a computer; looking up a DNS domain name; and much more.

**Note:** The goal of this section is to provide explanations of the general purpose and function of troubleshooting utilities, so you will know how they can help you manage TCP/IP networks. As part of these descriptions, I demonstrate the typical syntax used to invoke each utility in both UNIX and Windows. While I have tried to be quite complete in these depictions, they are intended only to give you a better idea of what these programs can do—this section should not be considered a reference manual for these utilities. Due to variations in software implementations, please consult your operating system documentation for the details on exactly how each program should be used on your own network. On Windows systems, try “<program> /?” to see the syntax of the program; on UNIX/Linux try “man <program>”.

**Background Information:** Many of the software tools described in this section are designed to manage the operation of other TCP/IP protocols, such as the [Internet Protocol](#), [Domain Name System](#) or [Dynamic Host Configuration Protocol](#). To fully appreciate how these utilities work, you need to understand the basics of these and other key TCP/IP protocols. In particular, a number of the utilities discussed here communicate use ICMP messages, so I would recommend familiarity with [ICMP](#) before proceeding.

---

## TCP/IP Host Name Utility (*hostname*)

They say the best place to start is at the beginning. Therefore, in examining TCP/IP administration and troubleshooting utilities, why not begin with the basics? One of the most fundamental of tasks in diagnosing problems with a networked computer is identifying it. Just as the first thing we usually do when we meet someone is exchange names, one of the first actions an administrator takes when accessing a device is to determine its name, if it is not known. This is accomplished using the *hostname* utility.

You may recall from our [discussion of TCP/IP name systems](#) that there are two different ways that hosts can be named. The first way is to manually assign “flat” names to devices using [host tables](#) or equivalent means; this is most often used for devices that not going to be accessed on the public Internet. The second is to give a device a domain name within the [Domain Name System \(DNS\)](#). The *hostname* utility can be used for both types of named hosts, but it functions in a slightly different way for each.

On most systems, including Windows and many UNIX implementations, the *hostname* utility is very, very simple. When the command is entered by itself on a line with no arguments, it displays the full name of the host. If it is entered with the “-s” (“short”) parameter, then if the host name is a [fully qualified DNS domain name](#), only the local label of the node is shown and not the full domain name; if the host has a flat (non-DNS) name the parameter has no effect. A simple example is shown in [Table 284](#).

**Table 284: Using the *hostname* Utility To Check A Host Name**

```
% hostname
fearn.pair.com
% hostname -s
fearn
```

The *hostname* utility is also intended to allow an administrator to set the name of a host. The syntax for this is also simple; you just supply the name of the host as a parameter, as follows:

```
hostname <new_hostname>
```

However, in most implementations, the use of the *hostname* command for setting a device’s name is either disabled or restricted. In Windows systems, a special applet in the Control Panel is used to set the device’s name; attempting to set it using *hostname* will result in an error message. In UNIX, the super-user of the system can use *hostname* to set the device’s name, but it is more common for this to be done by other means, such as editing the configuration file */etc/hosts*. Obviously, if a simple flat name is being assigned to this host, the administrator has full control over it, while if DNS is used then the proper procedures for registering the name must be followed.

In most operating systems, the “-s” parameter is the only one that this command supports. The parameter is not supported on all implementations of the “hostname” command, however; on some of these, if you use “hostname -s”, the system may report its host name

---

as being “-s”. On certain Linux systems, a few additional parameters are included that allow different ways for the host name to be displayed, as well as some miscellaneous functions such as showing the version number of the program.

**Note:** One point worth mentioning is that the *hostname* utility is not, strictly speaking, tied into the operation of DNS or other formal mechanisms for identifying a host. It simply displays what the administrator has set it to show. Obviously it makes sense for this to be set to the host’s DNS name, but there may be exceptions.

**Key Concept:** The simplest and most basic of TCP/IP administrative utilities is *hostname*, which returns the name of the host upon which it is run.

---

## **TCP/IP Communication Verification Utility (ping/ping6)**

One of the most common classes of problems that network administrators are often called upon to solve is an inability of two hosts to communicate. For example, a user on a corporate network might not be able to retrieve one of his files from a local server, or another user might be having difficulty loading her favorite Web site. In these and many similar situations, one important step in diagnosing the problem is to verify that basic communication is possible between the TCP/IP software stacks on the two machines. This is most often done using the *ping* utility, or *ping6* in IPv6 implementations.

**Note:** Some people say that “ping” is an acronym for “Packet Internet Groper”, while others insist that it is actually based on the use of the term to refer to a sonar pulse sent by a submarine to check for nearby objects. I really don’t know which of these is true, but I prefer the second explanation. Consider that the utility works in a way similar to a sonar “ping”, and that it was originally written by a gent named Mike Muuss, who worked at the US Army Ballistics Research Laboratory. The first explanation is weaker; it’s possible, but the phrase “Packet Internet Groper” isn’t really grammatical, and I don’t even want to *think* about what it is this utility is supposed to be “groping”! ☺

The *ping* diagnostic utility is one of the most commonly used, and is present in just about every TCP/IP implementation. It is usually implemented and accessed as a command-line utility, though there are also now graphical and menu-based versions of the program on some operating systems.

---

## Operation of the *ping* Utility

The *ping* utility is implemented using ICMP *Echo (Request)* and *Echo Reply* messages. As explained in [the topic discussing these message types](#), they are designed specifically for these sorts of diagnostic purposes. When Device *A* sends an ICMP *Echo* message to device *B*, device *B* responds by sending an ICMP *Echo Reply* message back to device *A*. The same functionality exists in ICMPv6, the IPv6 version of ICMP; the [ICMPv6 Echo and Echo Reply messages](#) only differ from the IPv4 ones slightly in their field structure.

This would seem to indicate that *ping* would be an extremely simple utility that would send one *Echo* message and wait to see if an *Echo Reply* was received back; if so, then this would provide that the two devices were able to communicate, and if not, this would indicate a problem somewhere on the internetwork between the two. However, almost all *ping* implementations are much more complex than this. They use multiple sets of *Echo* and *Echo Reply* messages, along with considerable internal logic, to allow an administrator to determine all of the following, and more:

- ☛ Whether or not the two devices can communicate;
- ☛ Whether congestion or other problems exist that might allow communication to succeed sometimes but cause it to fail in others, seen as packet loss—if so, how bad the loss is;
- ☛ How much time it takes to send a simple ICMP message between devices, which gives an indication of the overall latency between the hosts, and also indicates if there are certain types of problems.

### Basic *ping* Use

The most basic use of the *ping* command is to enter it by itself with the IP address of a host. Virtually all implementations also allow a host name to be used, which will be [resolved to an IP address](#) automatically. When the utility is invoked with no additional options, default values are used for parameters such as what size message to send, how many messages to be sent, how long to wait for a reply, and so on. The utility will transmit a series of *Echo* messages to the host and report back whether or not a reply was received for each; if a reply is seen, it will also indicate how long it took for the response to be received. When the program is done, it will provide a statistical summary showing what percentage of the *Echo* messages received a reply, and the average amount of time for them to be received.

---

[Table 285](#) shows an example using the *ping* command on a Windows XP computer (mine!), which by default sends four 32-byte *Echo* messages and allows four seconds before considering an *Echo* message lost. I use a satellite Internet connection that has fairly high latency and also occasionally drops packets. This isn't great for me, but it is useful for illustrating how *ping* works.

**Table 285: Verifying Communication Using the *ping* Utility**

```
D:\aa>ping www.pcguide.com
Pinging pcguide.com [209.68.14.80] with 32 bytes of data:

Reply from 209.68.14.80: bytes=32 time=582ms TTL=56
Reply from 209.68.14.80: bytes=32 time=601ms TTL=56
Request timed out.
Reply from 209.68.14.80: bytes=32 time=583ms TTL=56

Ping statistics for 209.68.14.80:
    Packets: Sent = 4, Received = 3, Lost = 1 (25% loss),
    Approximate round trip times in milli-seconds:
        Minimum = 582ms, Maximum = 601ms, Average = 588ms
```

### **Methods of Diagnosing Connectivity Problems Using *ping***

Most people find that using *ping* with default settings is enough for their needs. In fact, the utility can be used in this simplest form to perform a surprising number of diagnostic checks. In many cases, the *ping* command can be used to diagnose connectivity problems by using it multiple times in sequence, often starting with checks at or close to the transmitting device and then proceeding outwards towards the other device with which the communication problem has been observed. Some examples of how *ping* can be used in this way:

- ④ **Internal Device TCP/IP Stack Operation:** By performing a *ping* on the device's own address, you can verify that its internal TCP/IP stack is working. This can also be done using the standard IP loopback address, 127.0.0.1.
- ④ **Local Network Connectivity:** If the internal test succeeds, it's a good idea to do a *ping* on another device on the local network, to verify that local communication is possible.
- ④ **Local Router Operation:** If there is no problem on the local network, it makes sense to *ping* whatever local router the device is using to make sure it is operating and reachable.
- ④ **Domain Name Resolution Functionality:** If a *ping* performed on a DNS domain name fails, you should try it with the device's IP address instead. If that works, this implies either a problem with domain name configuration or resolution.
- ④ **Remote Host Operation:** If all the preceding checks succeed, you can try *pinging* a remote host to see if it responds. If it does not, you can try a different remote host; if that one works, it is possible that the problem is actually with the first remote device itself and not with your local device.

**Note:** While the inability to get a response from a device to a *ping* has traditionally been interpreted as a problem in communication, this is not always necessarily the case. In the current era of increased security consciousness, some networks are set up to not respond to *Echo* messages, to protect against attacks that use floods of such messages. In this case a *ping* will fail, even though the host may be quite reachable.

**Key Concept:** The TCP/IP *ping* utility is used to verify the ability of two devices on a TCP/IP internetwork to communicate. It operates by having one device send ICMP *Echo (Request)* messages to another, which responds with *Echo Reply* messages. The program can be helpful in diagnosing a number of connectivity issues, especially if it is used to test the ability to communicate with other devices in different locations. It also allows the average round-trip delay to exchange messages with another device to be estimated.

### ***ping* Options and Parameters**

All *ping* implementations include a number of options and parameters that allow an administrator to fine-tune how it works. They allow *ping* to be used for more extensive or specific types of testing. For example, *ping* can be set in a mode where it sends *Echo* messages continually, to check for an intermittent problem over a long period of time. You can also increase the size of the messages sent or the frequency with which they are transmitted, to test the ability of the local network to handle large amounts of traffic.

As always, the exact features of the *ping* program are implementation-dependent; even though UNIX and Windows systems often include many of the same options, they usually use completely different option codes. [Table 286](#) shows some of the more important options that are often defined for the utility on many UNIX systems, and where appropriate, the parameters supplied with the option. [Table 287](#) shows a comparable table for a typical Windows system.

**Table 286: Common UNIX *ping* Utility Options and Parameters (Page 1 of 2)**

Option / Parameters	Description
<b>-c &lt;count&gt;</b>	Specifies the number of <i>Echo</i> messages that should be sent.
<b>-f</b>	Flood mode; sends <i>Echo</i> packets at high speed to stress-test a network. This can cause serious problems if not used carefully!
<b>-i &lt;wait-interval&gt;</b>	Tells the utility how long to wait between transmissions.
<b>-m &lt;ttl-value&gt;</b>	Overrides the default <a href="#">Time To Live (TTL)</a> value for outgoing <i>Echo</i> messages.
<b>-n</b>	Numeric output only; suppresses lookups of DNS host names to save time.

**Table 286: Common UNIX *ping* Utility Options and Parameters (Page 2 of 2)**

Option / Parameters	Description
<b>-p &lt;pattern&gt;</b>	Allows a byte pattern to be specified for inclusion in the transmitted <i>Echo</i> messages. This can be useful for diagnosing certain odd problems that may only occur with certain types of transmissions.
<b>-q</b>	Quiet output; only summary lines are displayed at the start and end of the program's execution, while the lines for each individual message are suppressed.
<b>-R</b>	Tells the utility to include the <i>Record Route</i> IP option, so the route taken by the ICMP <i>Echo</i> message can be displayed. This option is not supported by all implementations; the <i>traceroute</i> utility is usually a better idea.
<b>-s &lt;packet-size&gt;</b>	Specifies the size of outgoing message to use.
<b>-S &lt;src-addr&gt;</b>	On devices that have multiple IP interfaces (addresses), allows a ping sent from one interface to use an address from one of the others.
<b>-t &lt;timeout&gt;</b>	Specifies a timeout period, in seconds, after which the <i>ping</i> utility will terminate, regardless of how many requests or replies have been sent or received.

**Table 287: Common Windows *ping* Utility Options and Parameters**

Option / Parameters	Description
<b>-a</b>	If the target device is specified as an IP address, force the address to be resolved to a DNS host name and displayed.
<b>-f</b>	Sets the <i>Don't Fragment</i> bit in the outgoing datagram.
<b>-i &lt;ttl-value&gt;</b>	Specifies the <i>TTL value</i> to be used for outgoing <i>Echo</i> messages.
<b>-j &lt;host-list&gt;</b>	Sends the outgoing messages using the specified <i>loose source route</i> .
<b>-k &lt;host-list&gt;</b>	Sends the outgoing messages using the indicated <i>strict source route</i> .
<b>-l &lt;buffer-size&gt;</b>	Specifies the size of the data field in the transmitted <i>Echo</i> messages.
<b>-n &lt;count&gt;</b>	Tells the utility how many <i>Echo</i> messages to send.
<b>-r &lt;count&gt;</b>	Specifies the use of the <i>Record Route</i> IP option and the number of hops to be recorded. As with the corresponding UNIX "-R" option, the <i>traceroute</i> utility is usually preferable.
<b>-s &lt;count&gt;</b>	Specifies the use of the IP <i>Timestamp</i> option to record the arrival time of the <i>Echo</i> and <i>Echo Reply</i> messages.
<b>-t</b>	Sends <i>Echo</i> messages continuously until the program is interrupted.
<b>-w &lt;timeout&gt;</b>	Specifies how long the program should wait for each <i>Echo Reply</i> before giving up, in milliseconds (default is 4000, for 4 seconds).

## The *ping6* Utility

The IPv6 version of *ping*, sometimes called *ping6*, works in very much the same way as IPv4 *ping*. The main differences between the two utilities are that *ping6*'s options and parameters reflect the [changes made in addressing and routing in IPv6](#).

---

## **TCP/IP Route Tracing Utility (tracert/traceroute6)**

The *ping* utility described in [the preceding topic](#) is extremely helpful for checking whether or not two devices are able to talk to each other. However, it provides very little information regarding what is going on between those two devices. In the event that ping shows either a total inability to communicate or intermittent connectivity with high loss of transmitted data, we need to know more about what is happening to IP datagrams as they are carried across the internetwork. This is especially important when the two devices are far from each other, especially if we are trying to reach a server on the public Internet.

I described in my [overview of IP datagram delivery](#) that when two devices are not on the same network, data sent between them must be delivered from one network to the next until it reaches its destination. This means that any time data is sent from device *A* on one network to device *B* on another, it follows a *route*, which may not be the same for each transmission.

When communication problems arise, it is very useful to be able to check the specific route taken by data between two devices. A special route tracing utility is provided for this function, called *tracert* (abbreviated *tracert* in Windows systems, a legacy of the old eight-character limit for DOS program names). The IPv6 equivalent of this program is called *traceroute6*.

### ***Operation of the traceroute Utility***

Like the *ping* utility, *traceroute* is implemented using [ICMP messages](#). However, unlike *ping*, *traceroute* was originally not designed to use a special ICMP message type intended exclusively for route tracing. Instead, it makes clever use of the IP and ICMP features that are designed to prevent routing problems.

Recall that the [IP datagram format](#) includes a *Time To Live (TTL)* field. This field is set to the maximum number of times that a datagram may be forwarded before it must be discarded; it exists to prevent datagrams from circling an internetwork endlessly. If a datagram must be discarded due to expiration of the *TTL* field, the device that discards it is supposed to send back to the device that sent that datagram an ICMP *Time Exceeded* message. This is explained in much more detail in [the topic that describes that message](#).

Under normal circumstances, this only occurs when there is a problem, such as a router loop or other misconfiguration issue. What *traceroute* does is to force each router in a route to report back to it by intentionally setting the *TTL* value in test datagrams to a value too low to allow them to reach their destination.

Suppose we have device *A* and device *B*, which are separated by routers *R1* and *R2*—three hops total. If you do a *traceroute* from device *A* to device *B*, here's what happens:

1. The *traceroute* utility sends a dummy UDP message (sometimes called a *probe*) to a port number that is intentionally selected to be invalid. The *TTL* field of the IP datagram is set to 1. When *R1* receives the message, it decrements the field, which will make its value 0. That router discards the probe and sends an ICMP *Time Exceeded* message back to device *A*.

- 
2. Device A then sends a second UDP message with the *TTL* field set to 2. This time, *R1* reduces the *TTL* value to 1 and sends it to *R2*, which reduces the *TTL* field to 0 and sends a *Time Exceeded* message back to A.
  3. Device A sends a third UDP message, with the *TTL* field set to 3. This time, the message will pass through both routers and be received by device B. However, since the port number was invalid, the message is rejected by device B, which sends back a *Destination Unreachable* message to device A.

This process is illustrated in [Figure 321](#). Amusingly, we see that A sends out three messages to B, and gets back three error messages, and is happy about it! ☺ The route to device B is thus indicated by the identities of the devices sending back the error messages, in sequence. By keeping track of the time between when it sent each UDP message and received back the corresponding error message, the *traceroute* utility can also display how long it took to communicate with each device. In practice, usually three dummy messages are sent with each *TTL* value, so their transit times can be averaged by the user if desired.

**Key Concept:** The *traceroute* utility takes the idea behind *ping* one step further, allowing not only communication between two devices to be checked, but also letting an administrator see a list of all the intermediate devices between the pair. It works by having the initiating host send a series of test datagrams with *TTL* values that cause each to expire sequentially at each device on the route. The *traceroute* program also shows how much time it takes to communicate with each device between the sending host and a destination device.

---

### **Basic Use of the *traceroute* Utility**

[Table 288](#) shows an example of a *traceroute* sent between two of the UNIX computers I use on a regular basis. I added the “-q2” parameter to change the default of three dummy messages per hop to two, so the output would fit better in its display table. In this case, the servers are separated by 14 hops. Notice how the elapsed time generally increases as the distance from the transmitting device increases, but it is not consistent because of random elements in the delay between any two devices (see the incongruously-large value in hop #10, for example). Also notice the asterisk (“\*”) in the seventh hop, which means that no response was received before the timeout period for the second transmission with a *TTL* value of 7. Finally, there is no report at all for hop #13; this machine may have been configured not to send *Time Exceeded* messages..

**Figure 321: Operation of the traceroute/tracert Utility**

The traceroute utility identifies the devices in a route by forcing them to report back failures to route datagrams with parameters intentionally set to invalid values. The first message sent by device A here has a *Time To Live* (TTL) value of 1, which will cause R1 to drop it and send an *ICMP Time Exceeded* message back to A. The second one has a TTL value of 2, so it will be dropped and reported by R2. The third will pass both routers and get to the destination host, B, but since the message is deliberately chosen with a bogus port number, this will cause an *ICMP Destination Unreachable* to be returned. These error messages identify the sequence of devices in the route between devices A and B.

---

**Table 288: Route Tracing Using the *traceroute* Utility**

```
traceroute -q2 www.pcguide.com
traceroute to www.pcguide.com (209.68.14.80), 40 hops max, 40 byte packets
 1 cisco0fe0-0-1.bf.sover.net (209.198.87.10)  1.223 ms  1.143 ms
 2 cisco1fe0.bf.sover.net (209.198.87.12)  1.265 ms  1.117 ms
 3 cisco0a5-0-102.wnsvtao.sover.net (216.114.153.170)  8.004 ms  7.270 ms
 4 207.136.212.234 (207.136.212.234)  7.163 ms  7.601 ms
 5 sl-gw18-nyc-2-0.sprintlink.net (144.232.228.145)  15.948 ms  20.931 ms
 6 sl-bb21-nyc-12-1.sprintlink.net (144.232.13.162)  21.578 ms  16.324 ms
 7 sl-bb27-pen-12-0.sprintlink.net (144.232.20.97)  18.296 ms  *
 8 sl-bb24-pen-15-0.sprintlink.net (144.232.16.81)  18.041 ms  18.338 ms
 9 sl-bb26-rly-0-0.sprintlink.net (144.232.20.111)  20.259 ms  21.648 ms
10 sl-bb20-rly-12-0.sprintlink.net (144.232.7.249)  132.302 ms  37.825 ms
11 sl-gw9-rly-8-0.sprintlink.net (144.232.14.22)  23.085 ms  20.082 ms
12 sl-exped4-1-0.sprintlink.net (144.232.248.126)  43.374 ms  42.274 ms
13 * *
14 pcguide.com (209.68.14.80)  41.310 ms  49.455 ms
```

Additional “unusual” results may be displayed under certain circumstances. For example, the traceroute program may display a code such a “!H”, “!N” or “!P” to indicate receipt of an unexpected *Destination Unreachable* message for a host, network, or protocol, respectively. Other error messages may also exist, depending on the implementation.

**Note:** Not all *traceroute* utility implementations use the technique described above. Microsoft’s *tracert* works not by sending UDP packets but rather ICMP *Echo* messages with increasing TTL values. It knows it has reached the final host when it gets back an *Echo Reply* message. A [special ICMP Traceroute message](#) was also developed in 1993, which was intended to improve the efficiency of *traceroute* by eliminating the need to send many UDP messages for each route tracing. Despite its technical advantages, since it was introduced long after TCP/IP was widely deployed, it never became a formal Internet standard and is not seen as often as the traditional method.

---

### ***traceroute* Options and Parameters**

As is the case with *ping*, *traceroute* can be used with an IP address or host name. If no parameters are supplied, default values will be used for key parameters; on the system I used, the defaults are three “probes” for each *TTL* value, a maximum of 64 hops tested, and packets 40 bytes in size. However, a number of options and parameters are also supported

to give an administrator more control over how the utility functions (such as the “-q” parameter I used in [Table 288](#)). Some of the typical ones in UNIX systems are described in [Table 289](#), while a smaller number of options exist in Windows, shown in [Table 290](#).

**Table 289: Common UNIX *traceroute* Utility Options and Parameters**

Option / Parameters	Description
<b>-g &lt;host-list&gt;</b>	Specifies a source route to be used for the trace.
<b>-M &lt;initial-ttl-value&gt;</b>	Overrides the default value of 1 for the initial <i>TTL</i> value of the first outgoing probe message.
<b>-m &lt;max-ttl-value&gt;</b>	Sets the maximum <i>TTL</i> value to be used; this limits how long a route the utility will attempt to trace.
<b>-n</b>	Displays the route using numeric addresses only, rather than showing both IP addresses and host names. This speeds up the display by saving the utility from having to perform <a href="#">reverse DNS lookups</a> on all the devices in the route (ICMP messages use IP addresses, not domain names.)
<b>-p &lt;port-number&gt;</b>	Specifies the <a href="#">port number</a> to be used as the destination of the probe messages.
<b>-q &lt;queries&gt;</b>	Tells the utility how many probes to send to each device in the route (default is 3).
<b>-r</b>	Tells the program to bypass the normal routing tables and send directly to a host on an attached network.
<b>-s &lt;src-addr&gt;</b>	On devices that have multiple IP interfaces (addresses), allows the device to use an address from one interface on a traceroute using another interface.
<b>-S</b>	Instructs the program to display a summary of how many probes did not receive a reply.
<b>-v</b>	Sets verbose output mode, which informs the user of all ICMP messages received during the trace.
<b>-w &lt;wait-time&gt;</b>	Specifies how long the utility should wait for a reply to each probe, in seconds (typical default is 3 to 5).

**Table 290: Common Windows *tracert* Utility Options and Parameters**

Option / Parameters	Description
<b>-d</b>	Displays the route using numeric addresses only rather than showing both IP addresses and host names, for faster display. This is the same as the “-n” option on UNIX systems.
<b>-h &lt;maximum-hops&gt;</b>	Specifies the maximum number of hops to use for tracing; default is 30.
<b>-j &lt;host-list&gt;</b>	Sends the outgoing probes using the specified loose source route.
<b>-w &lt;wait-time&gt;</b>	Specifies how long to wait for a reply to each probe, in milliseconds (default is 4000, for 4 seconds).

---

## ***The traceroute6 Utility***

The *traceroute6* utility is the IPv6 version of *traceroute* and functions in a very similar manner to its IPv4 predecessor. It obviously uses [IPv6 datagrams](#) instead of IPv4 ones, and responses from traced devices are in the form of [ICMPv6 Time Exceeded](#) and [Destination Unreachable](#) messages rather than their ICMPv4 counterparts.

## **TCP/IP Address Resolution Protocol Utility (arp)**

TCP/IP allows us to create very large internetworks by connecting individual networks together. When we send data between devices on different networks, the data is routed between networks using the [Internet Protocol](#). This permits us to view even a huge inter-network such as the global Internet as if it were just a single large network. All devices on the internetwork are considered to be virtually connected at [layer three](#), since the process of routing lets any device talk to any other one.

However, there is no way for devices on distant networks to communicate directly. The internetwork communication at layer three really consists of a number of steps, called *hops*, that carry the data from its source to destination. Each hop in a route requires that data be sent between a pair of hardware devices, and each transmission must use layer two hardware addresses. Since TCP/IP uses layer three addresses, this means each hop requires that we translate the IP address of the target of the hop to a hardware address. This is called *address resolution*; the reasons why it is needed and the methods used for it are explained in detail in [the section on address resolution concepts](#).

In TCP/IP, address resolution functions are performed by the aptly-named [Address Resolution Protocol \(ARP\)](#). When a device needs to transmit to a device with a particular IP address, it can use [ARP's request/reply messaging protocol](#) to find out which hardware device corresponds to that IP address. However, each such message exchange takes time and network bandwidth, so for efficiency, every device maintains an [ARP cache](#), which is a table containing mappings between IP and hardware addresses. The ARP cache table can contain a combination of static cache entries that are manually inserted for frequently-accessed devices, and dynamic entries, which are entered automatically when a request/reply resolution is done, so the next time it is necessary to send to that device, the lookup process can be avoided.

### ***arp Utility Functions***

To allow administrators to manage this ARP cache table, TCP/IP devices include an *arp* utility. It has three basic functions, which are invoked using three different versions of the command (which, for once, are the same in UNIX and Windows!):

- 🔊 **ARP Cache Table Display (“arp -a”):** When the “-a” option is used with the utility, it displays the current contents of the ARP cache table. Each entry in the table shows the IP address and hardware address pair for one device (interface, actually); usually an indication is also given as to whether each entry is static or dynamic

---

The exact format of the display varies from one implementation to the next; some programs show IP addresses while others show host names, and still others may show both. Some systems default to displaying host names but allow the “-n” option to also be used to force only IP addresses to be displayed and not names.

- 🕒 **ARP Cache Table Entry Addition (“arp -s <host-name> <hw-addr>”)**: This syntax allows an administrator to make a new manual ARP cache table entry that maps the given host name to the specified hardware address.
- 🕒 **ARP Cache Table Entry Deletion (“arp -d <host-name>”)**: This command removes the specified cache entry from the table. Some implementations allow the addition of another parameter to specify that all entries should be removed from the cache.

### ***Additional arp Features***

Certain versions of the software may also supplement these basic commands with additional features. One common additional option on UNIX systems is the ability to specify a file from which cache table entries may be read, using “arp -f <file-name>”. This saves a considerable amount of time and effort compared to typing each entry manually using “arp -s”.

Note also that access to options that cause the ARP cache table to be changed may be restricted by the operating system to only authorized users. This is especially true of the delete function, and especially especially true of the function that allows the entire ARP table to be deleted. 😊

**Key Concept:** The TCP/IP *arp* utility is used by an administrator to inspect or modify a host’s ARP cache table, which contains mappings between TCP/IP host names and IP addresses.

---

## **TCP/IP DNS Name Resolution and Information Lookup Utilities (nslookup, host and dig)**

The [Domain Name System \(DNS\)](#) is a critically important part of TCP/IP internetworks, especially the modern Internet, because it allows hosts to be accessed using easily-remembered names rather than confusing numerical addresses. Two different primary types of devices are involved in the operation of DNS: [DNS name servers](#) that store information about domains, and [DNS resolvers](#) that query DNS servers to transform names into addresses, as well as performing other necessary functions.

DNS resolvers are employed by Internet users on a continual basis to translate DNS names into address, but under normal circumstances, they are always invoked indirectly. Each time a user types a DNS name into a program such as a [World Wide Web](#) browser or [FTP](#) client—or even uses it in one of the other utilities in this section, such as [ping](#) or [traceroute](#)—the resolver automatically performs the name resolution without the user having to ask. For this reason, there is no need for users to manually resolve DNS names into addresses.

---

However, administrators often **do** need to perform a DNS resolution manually. For example, when troubleshooting a problem, the administrator may know a host's name but not its address; in the case of a security problem, the address may show up in a log file but the host name may not be known. In addition, even though users do not need to know the specifics of the [resource records](#) that define a DNS domain, administrators often need to be able to check these details, to make sure a domain is set up properly. Finally, admins also need some way to be able to diagnose problems with DNS servers themselves.

### ***The nslookup Utility***

To support all of these needs, modern TCP/IP implementations come equipped with one or more DNS name resolution and information lookup utilities. One of the most common DNS diagnostic utilities is *nslookup* ("name server lookup"), which has been around for many years. The details of how the program is implemented of course depend on the operating system, though most of them are quite similar in operation and settings. The utility can normally be used in two modes: interactive or non-interactive.

#### **Non-Interactive Use of *nslookup***

The non-interactive version of *nslookup* is the simplest, and is most often used when an administrator wants to just quickly translate a name into an address or vice-versa. It is run by issuing the *nslookup* command using the following simple syntax:

```
nslookup <host> [<server>]
```

Here, "<host>" can be a DNS domain name, in which case a [normal resolution](#) will be performed, or it may be an IP address, which will cause *nslookup* to do a [reverse resolution](#) to return the associated DNS domain name. The "<server>" parameter is optional; if omitted, the program uses the default name server of the host where the command was issued. [Table 291](#) shows a simple example of non-interactive use of *nslookup*.

**Table 291: DNS Name Resolution Using the *nslookup* Utility**

```
D:\aa>nslookup www.pcguide.com
Server:  ns1-mar.starband.com
Address: 148.78.249.200

Non-authoritative answer:
Name:    pcguide.com
Address: 209.68.14.80
Aliases: www.pcguide.com
```

This example was done on my home PC that uses the Starband satellite Internet service; it is configured to use Starband's name server ("ns1-mar.starband.com"). The answer provided here is labelled "non-authoritative" because it came not from one of the DNS name servers that is a [DNS authority](#) for www.pcguide.com, but rather the Starband name server's [DNS cache](#).

**Note:** It is also possible to specify one or more options to modify the behavior of the lookup in non-interactive mode. These options are the same as the parameters controlled by the `nslookup set` command described in [Table 292](#); they are specified by preceding them with a dash. For example, “`nslookup -timeout=10 www.pcguides.com`” would perform the same lookup as in [Table 291](#) but with the timeout interval set to 10 seconds.

## Interactive Use of *nslookup*

The interactive mode of *nslookup* is selected by simply issuing the name of the command with no parameters. This will cause the program to display the current default name server’s DNS name and address, and then provide a prompt at which the administrator may enter commands. Interactive mode allows someone to perform multiple lookups easily without having to type “`nslookup`” each time. More importantly, it provides more convenient control over the types of information that can be requested and how the lookups are performed.

The exact command set available in an *nslookup* implementation can usually be determined by issuing the command “`help`” or “`?`” at the *nslookup* prompt. [Table 292](#) shows some of the commands that are usually found in most *nslookup* implementations.

**Table 292: Typical *nslookup* Utility Commands (Page 1 of 2)**

Command and Parameters	Description
<code>&lt;host&gt; [&lt;server&gt;]</code>	Look up the specified host, optionally using the specified DNS name server. Note that there is no actual command here, you just enter the name directly at the command prompt.
<code>server &lt;server&gt;</code>	Change the default server to <code>&lt;server&gt;</code> , using information obtained from the current default server.
<code>!server &lt;server&gt;</code>	Change the default server to <code>&lt;server&gt;</code> , using information obtained from the initial name server—that is, the system’s default server that was in place when the <i>nslookup</i> command was started (prior to any preceding changes of the current name server in this session).
<code>root</code>	Changes the default name server to one of the <a href="#">DNS root name servers</a> .
<code>ls [-t &lt;type&gt;] &lt;name&gt;</code>	<p>Requests a list of information available for the specified domain name, by conducting a <a href="#">zone transfer</a>. By default, the host names and addresses associated with the domain are listed; the “-t” option may be used to restrict the output to a particular record type. Other options may also be defined.</p> <p>Most servers restrict the use of zone transfers to designated slave servers, so this command may not work for ordinary clients.</p>
<code>help</code>	Displays help information (usually a list of valid commands and options).
<code>?</code>	Same as “ <code>help</code> ” (only on some systems).
<code>set all</code>	Displays the current value of all <i>nslookup</i> options

**Table 292: Typical *nslookup* Utility Commands (Page 2 of 2)**

Command and Parameters	Description
<b><i>set &lt;option&gt;[=&lt;value&gt;]</i></b>	Sets an option to control the behavior of the utility. Most implementations include quite a number of options, some of which are controlled by just specifying a keyword, while others require a value for the option. For example, “set recurse” tells the program to use <a href="#">recursive resolution</a> , while “set norecurse” turns it off; “set retry=3” sets the number of retries to 3.
<b><i>exit</i></b>	Quits the program.

### Problems With *nslookup*

The *nslookup* utility is widely deployed on both UNIX and Windows systems, but the program is not without its critics. The complaints about it mainly center around its use of non-standard methods of obtaining information, rather than standard resolution routines. I have also read reports that it can produce spurious results in some cases. One example of a significant problem with the command is that it will abort if it is unable to perform reverse lookup of its own IP address. This can cause confusion, because users mistake that error for an error trying to find the name they were looking up.

For this and other reasons, a number of people in UNIX circles consider *nslookup* to be a “hack” of sorts, and for this reason, in some newer UNIXes *nslookup* has been *deprecated*. This simply means that it is still included in the operating system for compatibility, but it is not recommended and may be removed in the future. Instead, a pair of newer utilities are provided: *host* and *dig*.

### The *host* Utility

The first alternative to *nslookup*, *host*, is most often used for simple queries such as would normally be performed using *nslookup*’s non-interactive mode. It is invoked in the same way as non-interactive *nslookup*:

```
host <host> [<server>]
```

The output is also similar to that of non-interactive *nslookup*, but less verbose. An example is shown in [Table 293](#).

**Table 293: DNS Name Resolution Using the *host* Utility**

```
%host www.pcguide.com
www.pcguide.com is an alias for pcguide.com.
pcguide.com has address 209.68.14.80
```

---

Even though *host* does not operate interactively, it includes a number of options that can allow an administrator to get the same information that would have been obtained using *nslookup*'s interactive mode. Some of the more common options are shown in [Table 294](#).

**Table 294: Typical *host* Utility Options and Parameters**

Option / Parameters	Description
<b>-d</b>	Turn on debug mode.
<b>-l</b>	Provides a complete list of information for a domain; this is similar to the “ls” command in interactive <i>nslookup</i> . This may be used with the “-t” option to select only a particular type of resource record for the domain.
<b>-r</b>	Disable recursion in the request. When this is specified, only the server directly queried will return any information; it will not query other servers.
<b>-t &lt;querytype&gt;</b>	Specifies a query for a particular resource record type, allowing any type of DNS information to be retrieved.
<b>-v</b>	Use verbose mode for output (additional details are provided).
<b>-w</b>	Wait as long as necessary for a response (no timeout).

### ***The dig Utility***

The second alternate to *nslookup* is *dig*, which stands for “Domain Information Groper” (likely a play on the supposed origin of the name “ping”). It differs from the *host* command in that it provides considerably more information about a domain, even when invoked in the simplest of ways. It is also quite a bit more complicated, with a large number of options, and features such as a batch mode for obtaining information about many domains.

The basic syntax for the *dig* command is different from *nslookup* or *host*, because if a non-default name server is specified, it is prepended with an at sign (“@”) and comes before the host to be looked up. A specific type of resource record can also be specified, like this:

```
dig [@<server>] <host> [<type>]
```

---

Table 295 shows the output from running *dig* on the same domain ([www.pcguide.com](http://www.pcguide.com)) that I used as an example for *nslookup* and *host*. You can see that it provides much more information about the domain.

**Table 295: DNS Name Resolution Using the *dig* Utility**

```
%dig www.pcguide.com

The *dig* command also allows specific types of resource records to be looked up, and includes dozens of options and settings. Since this topic is already getting very long and *dig* is by far the most advanced of the three utilities, I will stop here; consult your system's documentation for the full instructions on how *dig* works and a list of its parameters.

**Key Concept:** Most TCP/IP implementations provide one or more utilities that can be employed by an administrator to manually resolve DNS domain names to IP addresses or perform related searches for DNS information. One of the most common is *nslookup*, which allows a host name to be translated to an address or vice-versa; it has both interactive and non-interactive modes. On some operating systems, *nslookup* has been replaced by the *host* utility for simple DNS lookups, and the *dig* program for more detailed inspections of DNS resource information.

---

**On The Web:** The *dig* utility is very useful, but has still not been implemented on some systems. Fortunately, there is an online dig utility you can access using your browser on the Internet. Find it at <http://www.gont.com.ar/tools/dig>.

---

## **TCP/IP DNS Registry Database Lookup Utility (whois/nicname)**

Utilities such as *nslookup* and *host* allow an administrator to resolve a DNS domain name to an address and also view detailed information about a domain's resource records. There are cases, however, where we need to know not the technical information about a domain but rather its [DNS registration](#) information. This includes details such as what organization owns the domain, when its registration expires, and who are the [designated contacts](#) who manage it.

In the early days of DNS, all domain names were centrally registered by a single authority, called the *Internet Network Information Center* (*InterNIC* or just the *NIC*). To allow Internet users to look up information about domains and contacts, a special server at this center was set up. A protocol was created to allow users to retrieve information from this server, called both *nicname* and *whois*. It was initially described in RFC 812 (1982) and then later, RFC 943 (1985). Over time, the name “whois” has become the preferred of the two, and is the one used today for the utility program that allows an administrator to look up DNS registration data. (It can also be used to look up information about IP addresses, but is used for this purpose much less commonly.)

As the Internet grew and expanded, it of course moved away from having a single centralized authority. The modern Internet has a [hierarchical structure of authorities](#) that are responsible for registering domain names in different portions of the [DNS name space](#). In recent years, this has been further complicated by the deregulation process that allows multiple registries for the generic top-level domains such as .COM, .NET and .ORG. All of this means that more work is needed to look up domain registration information, since it is distributed across many databases on different servers.

### ***Syntax and Use of the whois Utility***

To make it easier for administrators to find information about domains in this large distributed database, modern TCP/IP implementations generally come with an intelligent version of the *whois* utility. It is able to accept as input the name of a domain and automatically locate the appropriate registry in which that domain's information is located. The utility is usually used as follows:

```
whois [-h <whois-host>] <domain>
```

In this syntax, “<domain>” represents the name about which registration information is requested. The administrator can use the “-h” parameter to force the program to query a particular *whois* server, but again, this is usually not required. Some implementations also include other options that can be used to direct queries to particular registries.

---

## Sample whois Output

Table 296 shows the sample output of the *whois* command on a FreeBSD UNIX machine (I have stripped out some of the preliminary general information and legal disclaimers to keep the table down to size).

**Table 296: DNS Domain Registry Lookup Using the *whois* Program**

```
%whois pcguide.com
Registrant:
  The PC Guide
  2080 Harwood Hill Road
  Bennington, VT 05201
  US

  ixl@fearn.pair.com
  +1.8025555555

Domain Name: PCGUIDE.COM

Administrative & Technical Contact:
  Charles Kozierok
  The PC Guide
  2080 Harwood Hill Road
  Bennington, VT 05201
  US

  ixl@fearn.pair.com
  +1.8025555555

Domain Name Servers:
  NS23.PAIR.COM
  NS0.NS0.COM

Modified:     July  7, 2003
Expires:      August 24, 2008

** Register Now at http://www.pairNIC.com/ **
```

In this case, the registrar of the domain “pcguide.com” is *pairNIC*, the DNS registry division of *pair Networks*, the company I have used for Web hosting for many years (since 1997, as you can see). This output is public information, and lets anyone who has an interest in pcguide.com, for whatever reason, determine that I own the domain and learn how to contact me. (That is obviously not my real phone number, of course.) It also tells them that pair Networks runs the name servers that contain domain information for my domain.

---

## Third-Party whois Tools

Many operating systems, including Windows, do not come with a *whois* command implementation, but there are third-party programs that will support the function. In recent years many different organizations have also set up Web sites that implement the *whois* function, which is much more convenient and user-friendly to those more accustomed to graphical operating systems like Windows. Many of these sites are provided as free services by DNS registrars, so customers can check if a name they are interested in is already taken, and if so, by whom.

One drawback of some of these systems is that they usually do not have the intelligence to check all the different registries where domain name records are stored. In most cases, a whois service provided by a registrar will only search for names in the particular [top-level domains \(TLDs\)](#) in which the registrar operates. So, if the registrar deals with .COM, .ORG and .NET, it may only support whois queries for those TLDs. To check the registration information for domains in more obscure TLDs, such as some of the less common [geopolitical \(country code\) domains](#), a considerable amount of searching may be required.

**Key Concept:** The TCP/IP *whois* utility allows registration information to be displayed for a DNS domain, such as its owner, contact information and the date that its registration expires. The program is most commonly found on UNIX operating systems, where it is given intelligence that allows it to automatically query the correct servers to find the information for most domains. Newer Web-based whois utilities also now exist, but are usually limited to displaying information about domains in only a specific subset of top-level domains.

---

## TCP/IP Network Status Utility (*netstat*)

TCP/IP is a very complex protocol suite, as I am sure you would agree after perusing the contents of this Guide. It is actually quite amazing that most of the time, all of the different protocols, services and programs perform their jobs both efficiently and silently. Most of us don't even realize just how much is going on in the background, and that's as it should be. ☺ On the other hand, when a problem does occur on a TCP/IP network, the administrator charged with fixing it needs to obtain as much information as possible about what all those bits and pieces of the suite are doing behind the scenes. The network status utility, *netstat*, is provided for this purpose.

The *netstat* program is very simple in concept, being designed for only one purpose: to show information about the operation of TCP/IP on a device. The aforementioned complexity of TCP/IP, however, leads to *netstat* being rather elaborate itself: the program can provide a large variety of information. As usual, the options and output of *netstat* depend on the particular operating system type and version. It is somewhat different on UNIX and Windows machines, so I will describe each platform separately.

## UNIX netstat

On most UNIX systems the *netstat* utility is very full-featured, with a typical implementation including dozens of options that can be used to control what information is displayed. These options may not all be used simultaneously; rather, they are arranged into *option groups*, each of which presents one class of information. Within each group, one option is mandatory; it identifies the group, and hence, the general kind of information that will be displayed. Other options are also possible in each group, which are optional and modify the command to provide better control on exactly what is output. In essence, then, *netstat* is really like many related utilities rolled into one.

### UNIX netstat Option Groups, Options and Parameters

Table 297 provides a simplified summary of the option groups for a typical UNIX *netstat* implementation, in this case FreeBSD.

Table 297: Typical UNIX *netstat* Option Groups, Options and Parameters (Page 1 of 2)

Option Group, Options and Parameters	Description
<b>netstat [-AaLSW] [-f &lt;family&gt;] [-p &lt;protocol&gt;] [-n]</b>	This is the default invocation of <i>netstat</i> , with no mandatory options. It prompts the utility to display a list of active <a href="#">sockets</a> on the host machine. The other options shown can be used to control what precisely is output; for example, “-a” causes server processes also to be shown.
<b>netstat -i</b> <b>[-abdt] [-f &lt;family&gt;] [-n]</b> <b>netstat -I &lt;interface&gt;</b> <b>[-abdt] [-f &lt;family&gt;] [-n]</b>	Tells <i>netstat</i> to provide information about all network interfaces (“-i”) or a particular network interface (“-I <interface>”). The “-a” option causes multicast addresses to be shown as well, “-b” displays bytes of data in and out on the interface, “-d” shows the number of dropped packets, and “-t” displays the value of watchdog timers.
<b>netstat -w &lt;interval&gt; -d</b> <b>[-I &lt;interface&gt;]</b>	Displays packet traffic information on all interfaces every “<interval>” seconds, or just on the specified interface if “-I <interface>” is included. If “-d” is included, also indicates the number of dropped packets.
<b>netstat -s [-s] [-z] [-f &lt;family&gt;] [-p &lt;protocol&gt;]</b>	Shows system-wide statistics for each of the protocols on the system (which may be modified to show information for only a particular address family or protocol). If the “-s” option is repeated, counters that have a value of zero are suppressed; the “-z” option resets the statistics after they are displayed.
<b>netstat -i -s</b> <b>[-f &lt;family&gt;] [-p &lt;protocol&gt;]</b> <b>netstat -I &lt;interface&gt; -s</b> <b>[-f &lt;family&gt;] [-p &lt;protocol&gt;]</b>	Displays statistics as for “netstat -s” just above, but on a per-interface basis rather than aggregated for the whole system.
<b>netstat -m</b>	Outputs memory management routine statistics.
<b>netstat -r [-Aa] [-f &lt;family&gt;] [-n] [-W]</b>	Displays the contents of the host’s <a href="#">routing tables</a> . The options “-A” and “-a” provide additional information about the routes.
<b>netstat -rs [-s]</b>	Displays routing statistics; “-s” suppresses counters with a zero value.

**Table 297: Typical UNIX *netstat* Option Groups, Options and Parameters (Page 2 of 2)**

Option Group, Options and Parameters	Description
<b>netstat -g [-W] [-f &lt;family&gt;]</b>	Shows multicast routing information.
<b>netstat -gs [-s] [-f &lt;family&gt;]</b>	Shows multicast routing statistics; “-s” suppresses counters with a zero value.

### UNIX *netstat* Universal Options and Parameters

Most of the options shown in these option groups are particular to those groups; for example, you cannot use “-s” when issuing the command “netstat -i”. However, there are also a number of *universal* options that can be used with more than one of these groups to modify the behavior of *netstat* variations in a consistent way. These options are described in [Table 298](#).

**Table 298: Typical UNIX *netstat* Universal Options and Parameters**

Option / Parameters	Description
<b>-f &lt;family&gt;</b>	Limits the output of the command to information on a particular protocol address family, for hosts running multiple protocol suites. For example, the address family for regular TCP/IP is “inet”, while for IPv6 it is “inet6”. Others may also be supported.
<b>-p &lt;protocol&gt;</b>	Restricts output to data related only to a particular protocol, such as IP, TCP, UDP, or ICMP.
<b>-n</b>	Shows network addresses in numeric form, instead of showing them as symbolic names. Also shows ports as numbers instead of converting <a href="#">well-known UDP and TCP port numbers</a> to the protocol names that use them (for example, “23” rather than “telnet”).
<b>-W</b>	Suppresses the automatic truncation of addresses (which is sometimes done for display formatting).

### Sample UNIX *netstat* Output

The *netstat* command can produce a startling amount of output, especially if you do not restrict it with some of the options in [Table 298](#). This is particularly true for *netstat* by itself and with the “-s” option. In [Table 299](#) I have shown sample output from running “plain” *netstat*, but I have truncated the list of connections so it would not be too long (I also reformatted the table so it would display better). Notice the last column, which shows the current state of the TCP connection (see, that [TCP finite state machine](#) stuff was useful after all! ☺)

[Table 300](#) shows an example of the output of “netstat -s”; here I have shortened the size of the output by using “-p ip” to tell the program to only show me the statistics for the Internet Protocol.

**Table 299: Sample Connections List From UNIX *netstat* Utility**

%netstat						
<i>Active Internet connections</i>						
<i>Prot</i>	<i>Rcv</i>	<i>Snd</i>	<i>Local Address</i>	<i>Foreign Address</i>	<i>(state)</i>	
<i>tcp4</i>	<i>0</i>	<i>0</i>	<i>pcguide.com.http</i>	<i>c-24-118-141-124.3384</i>	<i>ESTABLISHED</i>

<i>tcp4</i>	<i>0</i>	<i>0</i>	<i>qs36.smtp</i>	<i>MV1-24.171.17.64.1339</i>	<i>ESTABLISHED</i>	
<i>tcp4</i>	<i>0</i>	<i>0</i>	<i>pcguide.com.http</i>	<i>1Cust234.tnt1.le.1338</i>	<i>ESTABLISHED</i>	
<i>tcp4</i>	<i>0</i>	<i>0</i>	<i>pcguide.com.http</i>	<i>1Cust234.tnt1.le.1337</i>	<i>FIN_WAIT_1</i>	
<i>tcp4</i>	<i>0</i>	<i>84</i>	<i>pcguide.com.http</i>	<i>dial81-131-97-70.2902</i>	<i>FIN_WAIT_1</i>	
<i>tcp4</i>	<i>0</i>	<i>0</i>	<i>pcguide.com.http</i>	<i>216.76.14.221.9954</i>	<i>FIN_WAIT_2</i>	
<i>tcp4</i>	<i>0</i>	<i>0</i>	<i>pcguide.com.http</i>	<i>216.76.14.221.9945</i>	<i>FIN_WAIT_2</i>	
<i>tcp4</i>	<i>0</i>	<i>0</i>	<i>pcguide.com.http</i>	<i>1Cust234.tnt1.le.1326</i>	<i>TIME_WAIT</i>	

---

**Table 300: Sample IP Statistics From UNIX *netstat* Utility**

```
%netstat -s -p ip
ip:
    57156204 total packets received
    0 bad header checksums
    4 with size smaller than minimum
    0 with data size < data length
    0 with ip length > max ip packet size
    0 with header length < data size
    0 with data length < header length
    0 with bad options
    0 with incorrect version number
    138 fragments received
    6 fragments dropped (dup or out of space)
    128 fragments dropped after timeout
    2 packets reassembled ok
    57085912 packets for this host
    24736 packets for unknown/unsupported protocol
    0 packets forwarded (0 packets fast forwarded)
    44957 packets not forwardable
    4 packets received for unknown multicast group
    0 redirects sent
    66183465 packets sent from this host
    177 packets sent with fabricated ip header
    0 output packets dropped due to no bufs, etc.
    0 output packets discarded due to no route
    0 output datagrams fragmented
    0 fragments created
    0 datagrams that can't be fragmented
    0 tunneling packets that can't find gif
    22 datagrams with bad address in header
```

### **Windows *netstat***

The Windows *netstat* utility is quite a bit simpler than the UNIX one, because it has a lot fewer options. This is good for those of us learning about the program, but not so wonderful for those who want maximum power and flexibility in using it.

### **Windows *netstat* Option Groups, Options and Parameters**

Like the UNIX *netstat*, the Windows one has a set of options groups that dictate the general type of information shown, and a few universal options that can be used with multiple groups. The option groups and generic options are shown in [Table 301](#) and [Table 302](#).

**Table 301: Typical Windows *netstat* Option Groups, Options and Parameters**

Option Group, Options and Parameters	Description
<b><i>netstat [-n] [-o] [&lt;interval&gt;]</i></b>	When called with no mandatory options, netstat displays information about active TCP connections.
<b><i>netstat -a [-n] [-o] [-p &lt;protocol&gt; [&lt;interval&gt;]</i></b>	Displays all active TCP connections, as well as both TCP and UDP ports to which the host is listening.
<b><i>netstat -e [&lt;interval&gt;]</i></b>	Shows statistics for Ethernet interfaces.
<b><i>netstat -r [&lt;interval&gt;]</i></b>	Displays the current routing table for the device.
<b><i>netstat -s [-p &lt;protocol&gt; [&lt;interval&gt;]</i></b>	Displays TCP/IP statistics for the system by protocol.

**Table 302: Typical Windows *netstat* Universal Options and Parameters**

Option / Parameters	Description
<b><i>-n</i></b>	Displays network addresses in numeric form instead of symbolic name form. Also shows ports in numeric form instead of displaying standard process names associated with <a href="#">well-known UDP or TCP port numbers</a> .
<b><i>-o</i></b>	Displays the process ID associated with each connection.
<b><i>-p &lt;protocol&gt;</i></b>	Limits the display to only the information associated with the specified protocol.
<b><i>&lt;interval&gt;</i></b>	Causes the <i>netstat</i> command to be repeated every “<interval>” seconds, rather than just displaying its information once. This can be used with any of the <i>netstat</i> option groups.  For example, “netstat -s 5” would display TCP/IP statistics every five seconds.

### Sample Windows *netstat* Output

The output from the Windows *netstat* program is fairly similar to that of the UNIX utility when the same or similar options are given, but the UNIX version usually provides more details. I have shown in [Table 303](#) an example illustrating TCP/IP statistics on my home Windows XP machine, using “-p icmp” to restrict the output to ICMP stats only. [Table 304](#) shows the routing table display from netstat (which I modified slightly to fit the size limits of the table.) You would get similar output as these from the UNIX “netstat -s -p icmp” or “netstat -r” commands, but additional information would be provided.

**Table 303: Sample ICMP Statistics From Windows *netstat* Utility**

```
D:\aa>netstat -s -p icmp
ICMPv4 Statistics
```

	<i>Received</i>	<i>Sent</i>
<i>Messages</i>	243	248
<i>Errors</i>	0	0

**Key Concept:** TCP/IP implementations include the *netstat* utility to allow information about network status to be displayed. On UNIX systems, *netstat* is a full-featured program with many options arranged into option groups, each of which shows a particular type of information about the operation of TCP/IP protocols. On Windows systems, *netstat* is somewhat more limited in function but still allows a considerable amount of information to be displayed.

---

## **TCP/IP Configuration Utilities (ipconfig, winipcfg and ifconfig)**

A significant part of any network administrator's job is setting up and maintaining the devices that make a TCP/IP network function, a process generally called *configuration*. Networked hosts consist of both hardware and software that work together to implement all the layers and functions of the protocol stack. An administrator uses hardware tools to configure physical devices, performing tasks such as installing network interface cards, connecting cables, and manipulating switches and other hardware settings. Similarly, tools are required to configure the software that runs TCP/IP interfaces and controls the operation of higher-layer protocols on networked hosts.

### ***The ifconfig Utility***

On UNIX systems, the interface configuration utility, *ifconfig*, is used to view and modify the software settings that control how TCP/IP functions on a host. It is a very powerful program that allows an administrator to set up and manage a very wide array of network settings. The implementation of *ifconfig* varies greatly even between flavors of UNIX—while most are similar in general terms, they may have rather different options and syntaxes.

The *ifconfig* program can be used for a variety of purposes: to create or remove a network interface, change its settings, or simply examine the existing configuration. Thus, like the [netstat utility](#), *ifconfig* is really like several related programs combined into one, with the particular mode in which the program is used depending on the syntax used to invoke it. And also like *netstat*, *ifconfig* has a number of universal options that can be applied to many of its different uses.

### ***ifconfig* Syntaxes, Options and Parameters**

[Table 305](#) provides a simplified summary of the different functions that *ifconfig* can perform, and the syntaxes that are used to specify each in a typical UNIX implementation (NetBSD in this case). [Table 306](#) describes the common options and parameters that can be used for many of these different modes. When *ifconfig* is used to modify an interface's configuration,

this is done by setting any of several dozen configuration parameters, using the syntax shown in the last row of [Table 305](#); I have provided a brief description of some sample parameters in [Table 307](#) (see your *ifconfig* documentation for a complete list).

**Table 305: Typical UNIX *ifconfig* Syntaxes, Options and Parameters**

Syntax, Options and Parameters	Description
<b><i>ifconfig [-L] [-m] &lt;interface&gt;</i></b>	When <i>ifconfig</i> is called with just an interface specification and no other options (other than possibly “-L” and “-m”), it displays the configuration information for that network interface.  Note that entering “ifconfig” by itself with no interface just causes help information for the parameter to be displayed; to see all interfaces, the “-a” parameter should be used.
<b><i>ifconfig -a [-L] [-m] [-b] [-d] [-u] [-s] [&lt;family&gt;]</i></b>	Displays information about all the interfaces on the host. The output may be restricted using the universal parameters shown, or by specifying an address family (see <a href="#">Table 306</a> ).
<b><i>ifconfig -l [-b] [-d] [-u] [-s]</i></b>	Lists all available interfaces on the system.
<b><i>ifconfig &lt;interface&gt; create</i></b>	Creates the specified logical network interface on the host, which is then configured using the syntax shown in the last row of this table. Note that some variations of UNIX allow certain parameters to be set at the time of creation.
<b><i>ifconfig &lt;interface&gt; destroy</i></b>	Destroys the specified logical interface.
<b><i>ifconfig &lt;interface&gt; [&lt;family&gt;] [&lt;address&gt; [&lt;dest_address&gt;]] [&lt;parameters&gt;]</i></b>	Configures parameters for a particular interface on the host. If the address is being set, it is the first parameter specified, after the optional address family, if present. The “<dest_address>” is used to specify a destination address for a point-to-point link. After this, any of several dozen parameters may be specified for the interface, some of which are shown in <a href="#">Table 307</a> .

**Table 306: Typical UNIX *ifconfig* Universal Options and Parameters**

Option / Parameter	Description
<b>-L</b>	Displays the address lifetime for IPv6 addresses.
<b>-m</b>	Displays all supported media for the interface.
<b>-b</b>	Limits the display of interface information to broadcast interfaces.
<b>-d</b>	Shows only interfaces that are presently down (disabled).
<b>-u</b>	Shows only interfaces that are presently up (operational).
<b>-s</b>	Shows only interfaces that may be connected.
<b>&lt;family&gt;</b>	Specifies a particular address family, either to limit output or indicate what address type is being configured. The value “inet” is used for IPv4 and “inet6” for IPv6.

**Table 307: Typical UNIX *ifconfig* Interface Configuration Parameters**

Parameters	Description
<i>alias</i> / - <i>alias</i>	Establishes or removes a network address alias.
<i>arp</i> / - <i>arp</i>	Enables / disables the use of <a href="#">ARP</a> on this interface.
<i>delete</i>	Removes the specified network address.
<i>down</i>	Marks an interface as being “down”, disabling it.
<i>media</i> < <i>type</i> >	Sets the media type of the interface to a particular value.
<i>mtu</i> < <i>n</i> >	Sets the <a href="#">maximum transmission unit (MTU)</a> of the interface.
<i>netmask</i> < <i>mask</i> >	Sets the <a href="#">network or subnet mask</a> for the interface’s address.
<i>prefixlen</i> < <i>n</i> >	Same as “netmask” but allows the mask to be specified using a CIDR-style prefix length.
<i>up</i>	Sets an interface “up”, enabling it.

**Note:** Since creating, destroying or modifying interfaces can cause a host to stop working properly, administrative (super-user) rights are generally required on most systems in order to do anything with *ifconfig* other than examining the existing configuration.

### *ifconfig* Sample Output

In [Table 308](#), I have provided a sample output of the “*ifconfig -a*” command on one of the UNIX machines I use regularly, showing the settings for its interfaces.

**Table 308: Sample Routing Table Display From Windows *netstat* Utility**

<b>%ifconfig -a</b>	
<i>fxp0</i> :	<i>flags=8843&lt;UP,BROADCAST,RUNNING,SIMPLEX,MULTICAST&gt; mtu 1500</i>
<i>address</i> :	<i>00:a0:c9:8c:f4:a1</i>
<i>media</i> :	<i>Ethernet autoselect (100baseTX full-duplex)</i>
<i>status</i> :	<i>active</i>
<i>inet</i>	<i>166.84.1.3 netmask 0xffffffe0 broadcast 166.84.1.31</i>
<i>inet alias</i>	<i>166.84.1.13 netmask 0xffffffff broadcast 166.84.1.13</i>
<i>lo0</i> :	<i>flags=8009&lt;UP,LOOPBACK,MULTICAST&gt; mtu 33228</i>
<i>inet</i>	<i>127.0.0.1 netmask 0xff000000</i>

### *The ipconfig Utility*

Windows takes a somewhat different approach to network configuration than UNIX. As we have seen, the UNIX *ifconfig* program can be used both to view and modify a wide range of configuration parameters. In Windows, however, most setup and parameter modification is done using the Windows Control Panel. Windows does include a utility that is somewhat

---

similar to UNIX's *ifconfig*, but it has far less functionality, and is used mainly to inspect the existing configuration, not change it. It also allows an administrator to easily perform a few simple functions on a host.

### ***ipconfig* Options and Parameters**

On most newer versions of Windows, the equivalent of *ifconfig* is a command-line utility called *ipconfig*. Like *ifconfig*, the Windows utility is controlled using options that are supplied to the program. However, because it is so much simpler than *ifconfig*, there are only a few different options that can be used. These are summarized in [Table 309](#).

**Table 309: Typical Windows *ipconfig* Options and Parameters**

Option / Parameters	Description
<i>(none)</i>	When called with no options or parameters, <i>ipconfig</i> displays the IP address, subnet mask and default gateway for each interface on the host.
<i>/all</i>	Similar to calling <i>ipconfig</i> with no options, but displays more detailed configuration information about the host's interfaces.
<i>/release [&lt;adapter&gt;]</i>	<a href="#">Releases (terminates) the DHCP lease</a> on either the specified adapter (interface), or all interfaces if none is provided.
<i>/renew [&lt;adapter&gt;]</i>	Manually <a href="#">renews the DHCP lease</a> for either the specified adapter (interface), or all adapters if none is mentioned.
<i>/displaydns</i>	Displays the contents of the host's <a href="#">DNS resolver cache</a> .
<i>/flushdns</i>	Clears the host's DNS resolver cache.
<i>/registerdns</i>	Refreshes (renews) all DHCP leases and also re-registers any DNS names associated with the host.
<i>/showclassid &lt;adapter&gt;</i>	Displays DHCP class IDs associated with this adapter (these are used to arrange clients into groups that are given different treatment by DHCP servers.) The adapter must be specified, even if there is only one.
<i>/setclassid &lt;adapter&gt; [&lt;classid&gt;]</i>	Modifies the DHCP class ID for the specified adapter.

As mentioned earlier, *ipconfig* is most often used to just examine the existing configuration. When simplified information is needed it is called with no options; an example of the output from this use of the command is shown in [Table 310](#). For detailed information on interfaces, the “/all” option is used; an example is in [Table 311](#) (slightly modified so it is easier to read).

---

## ***ipconfig* Sample Output**

You can see from the list of options in [Table 309](#) that most of the non-viewing uses of *ipconfig* are actually related not to configuring a host but rather controlling the operation of protocols such as [DNS](#) and [DHCP](#). One common use of *ipconfig* is to force a host to seek out a new [DHCP lease](#), which can be done using “*ipconfig /release*” followed by “*ipconfig /renew*”.

**Table 310: Simplified Configuration Information From Windows *ipconfig* Utility**

```
D:\aa>ipconfig
Windows IP Configuration

Ethernet adapter Local Area Connection 2:

    Connection-specific DNS Suffix  . : 
    IP Address. . . . . : 148.64.133.73
    Subnet Mask . . . . . : 255.255.192.0
    Default Gateway . . . . . : 148.64.128.1
```

**Table 311: Detailed Configuration Information From Windows *ipconfig* Utility**

```
D:\aa>ipconfig /all
Windows IP Configuration

Host Name . . . . . : ixl
Primary Dns Suffix . . . . . : 
Node Type . . . . . : Hybrid
IP Routing Enabled. . . . . : No
WINS Proxy Enabled. . . . . : No

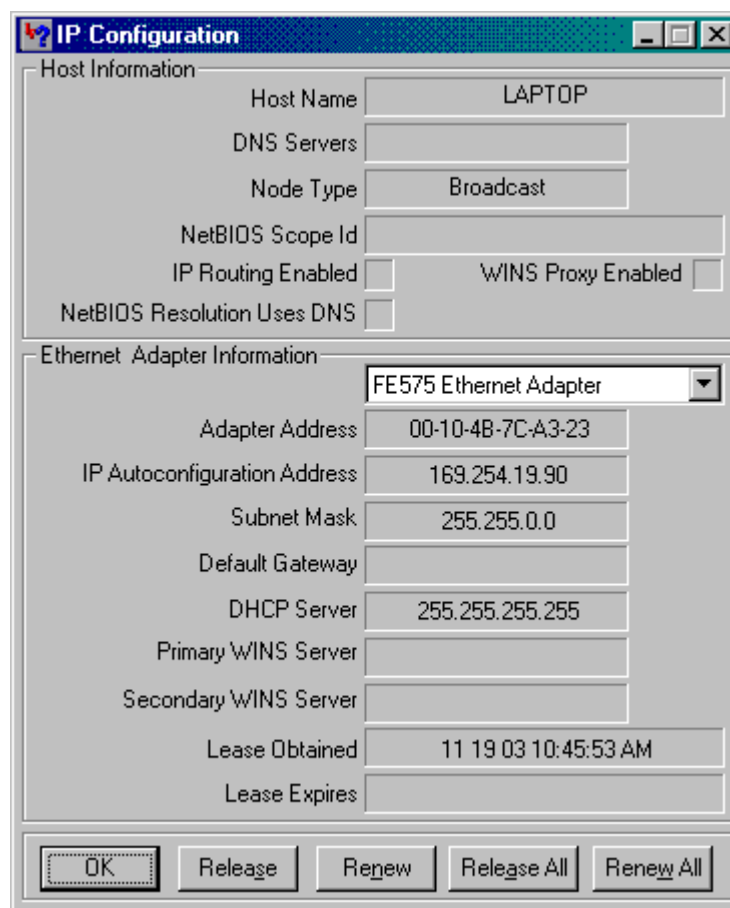

Ethernet adapter Local Area Connection 2:

    Connection-specific DNS Suffix  . : 
    Description . . . . . : 3Com PCI Ethernet Adapter
    Physical Address. . . . . : 00-04-76-4E-75-3F
    Dhcp Enabled. . . . . : Yes
    Autoconfiguration Enabled . . . . : Yes
    IP Address. . . . . : 148.64.133.73
    Subnet Mask . . . . . : 255.255.192.0
    Default Gateway . . . . . : 148.64.128.1
    DHCP Server . . . . . : 148.64.128.1
    DNS Servers . . . . . : 148.78.249.200
                             148.78.249.201
    Lease Obtained. . . . . : April 19, 2003 11:51:37 AM
    Lease Expires . . . . . : April 19, 2003 12:21:37 PM
```

## The *winipcfg* Utility

In earlier versions of Windows, a graphical tool called *winipcfg* is supplied (either instead of, or in addition to, the *ipconfig* command-line utility). This program allows configuration parameters to be examined in much the same way as *ipconfig*, and also allows DHCP leases to be released and renewed, but does not support the other options of *ipconfig* (such as displaying the host's DNS cache). An example of the main *winipcfg* screen is shown in Figure 322.

**Figure 322: Windows 95/98/ME *winipcfg* Utility**

The *winipcfg* utility can be used in older consumer-oriented versions of Windows to check the configuration of a host and release/renew DHCP leases.

**Key Concept:** On UNIX systems, the *ifconfig* utility can be used to display or modify a large number of TCP/IP configuration settings. Windows systems provide either the command-line utility *ipconfig* or the graphical tool *winipcfg*. Both let an administrator see basic TCP/IP configuration information for a host and allow tasks to be performed such as renewing a DHCP lease, but they are otherwise quite limited compared to the UNIX *ifconfig* program.

## **Miscellaneous TCP/IP Troubleshooting Protocols: Echo, Discard, Character Generator, Quote Of The Day, Active Users, Daytime, Time**

The old quip says that the only guarantees in life are death and taxes. When it comes to networking, you can add a few more, including this one: as soon as you set up a network, it will very quickly develop problems that you will need to address. Recognizing that the complexity of TCP/IP internetworks would make diagnosing certain problems difficult, the suite's architects defined a number of miscellaneous utility protocols that can be helpful in testing and troubleshooting networks. Despite having been around for over 20 years, these protocols are somewhat obscure and get little attention. I too will not devote much time to them (since they are no longer implemented on many systems) but I do feel they are worth a quick look.

These simple protocols are designed to be implemented as services that run on TCP/IP servers. Each listens for requests on a dedicated [well-known port number](#), and then responds with a particular type of information. These protocols can be used with both TCP and UDP, enabling each transport protocol to be tested. In the case of UDP, the server counts each UDP sent to it as a request, and sends a response to it. When used with TCP, a connection is of course first established by the client to the server. In some of the protocols, this connection is then used to send data continuously between the client and server; in others, the establishment of the connection is considered an implied request to the server, which will immediately send a response and then close the connection.

[Table 312](#) provides a brief description of each of these troubleshooting protocols/services under both UDP and TCP. I have shown for each the port number that the service uses, and also the RFC that defines it, if you want additional information.

**Table 312: Miscellaneous TCP/IP Troubleshooting Protocols (Page 1 of 2)**

Protocol	Well-Known Port Number	Defining RFC	Description
Echo Protocol	7	862	Echoes received data back to its originator. When used on UDP, the payload of each message is simply packaged into a return UDP datagram and sent back. For TCP, each byte sent by the client is echoed back by the server until the connection is closed.
Discard Protocol	9	863	Throws away all data that is sent to it. I think this should be called the "Black Hole Protocol". ☺

---

**Table 312: Miscellaneous TCP/IP Troubleshooting Protocols (Page 2 of 2)**

Protocol	Well-Known Port Number	Defining RFC	Description
Character Generator Protocol	19	864	Generates random characters of data and sends them to a device. When used with UDP, each UDP message sent to the server causes it to send back a UDP message containing a random number (0 to 512 bytes) of data. When used with TCP, the server just starts sending characters as soon as a client establishes a connection, and continues until the connection is terminated by the client.
Quote of the Day Protocol	17	865	Sends a short message (selected by the server's administrator) to a client device. For UDP, the message is sent for each incoming UDP message; for TCP, the message is sent by the server once when the connection is established, which is then closed.
Active Users	11	866	Sends a list of active users to a device. For UDP, the list is sent for each incoming UDP message; if it is longer than 512 bytes it will be sent in multiple messages. For TCP, the list is sent automatically when the connection is made to the server, and then the connection is terminated.
Daytime Protocol	13	867	Returns the current time on the server in human-readable form, in response to receipt of a UDP message or an incoming TCP connection.
Time Protocol	37	868	Returns the current time in machine-readable form—specifically, the number of seconds since midnight, January 1, 1900 GMT. The time is sent for each UDP message received by the server, or upon establishment of a TCP connection.  Note that this protocol cannot be used for time synchronization of servers, because it does not compensate for variability in the time required for the messages to be carried over the internetwork.
