## Dedication

This Guide is dedicated to my family: my wife Robyn and my three sons, Ryan, Matthew and Evan.

I suppose that it's a cliché to dedicate a book to your wife. If so, it's for a very good reason: who plays a more important role in the life of an author than his or her spouse? Robyn is my partner; the person who is always there; the one who shares my life in so many ways. The expression about a great woman being behind every good man is true, yet my wife is deserving of recognition for reasons that go far beyond the usual reasons such as being "supportive".

Financially, she agreed to take on a regular working position to make it possible for me to spend time on a very long project with an uncertain payoff. She took on most of the tasks of taking our children to school and dealing with their needs, to give me time to write. She also gracefully agreed to "do without" many things that many other wives would not have been too happy about.

But most of all, she deserves a world of credit for putting up with **me**. ☺ For constantly reassuring me that it was okay that I was spending years on a project that might not be successful. For listening to me talk for countless hours, and for giving her opinions on many portions of my writing, all on a subject that really doesn't interest her at all. And most importantly, for encouraging me when I felt this was a waste of time, and even kicking me in the butt when I felt like giving up. Without Robyn, this Guide simply would not exist. Thanks, R.

My three boys deserve credit for similar reasons, but to a lesser extent. They have had to put up with my constantly sitting at the computer trying to tune them out so I could concentrate; my too-frequent grouchy moods; and my reluctance to spend time with them when I had work on my plate. I am sure there were many times that they wished I just had a regular "day job".

Ryan, my big boy now at 10, has been very patient in waiting for me to finish this project so we can resume several activities that we used to engage in regularly. Matthew, my fun-loving and rambunctious 8-year-old, has also had to deal with my not having as much time as I would have liked to spend time with him. And little Evan, growing quickly at three, has had a father working on a long-term project for his entire life! All three of my boys have been very understanding, and provided me with much needed joy and laughter at times when I needed it most.

---

## Acknowledgments

I dedicated this Guide to my wife and children to reflect the important role they have played in life in general terms, and in accomplishing this Guide in particular. However, there are many others who also contributed to the completion of this document, and I'd like to take a moment to acknowledge them.

I want to thank my "original" family, my father Leon, and sisters Cari and Cindy, for being supportive and lending a helpful ear about various issues during the time that I've engaged in this project. Thanks also to my "adoptive" family, Eli, Marge, Larry and Steven. And I definitely want to thank the small group of close friends who have helped with ideas, advice and much needed laughs, especially Morley, Jeff, James and Jon, all of whom had to listen to far more of my blathering about this project over the last few years than any human being should have to tolerate. ☺

I would also like to specifically acknowledge the following individuals and organizations for their assistance:

- ☺ [Adobe Systems Incorporated](#), for providing this relatively unknown author with two important pieces of software that I used in creating this Guide. First, [Adobe Frame-maker](#), one of the best desktop publishing programs around, which was used to format and publish this document. Second, [Adobe Photoshop](#), the industry standard program for photo and graphics editing, which was used for some of the graphics in this Guide, and will play a more central role in subsequent Guides containing more photographs.
- ☺ [SmartDraw.com](#), for the excellent SmartDraw diagramming software that was used to create most of the over 300 illustrations that appear in this Guide.
- ☺ Harald Heim of [The Plugin Site](#), for graciously providing me with two excellent Photoshop plugins that any serious photographer should consider: the [FocalBlade](#) sharpening tool and [ColorWasher](#) color-correction plugin.
- ☺ Fernando Gont and Barry Margolin, for their excellent technical review of The TCP/IP Guide, and their corrections and suggestions for improvement to the document.
- ☺ Bill Pollock, president and publisher of [No Starch Press](#), for constantly expressing his faith in my abilities as an author, for answering questions about the business, for being a sounding board, and for agreeing to publish The TCP/IP Guide in book form.
- ☺ [Tcat Houser](#), author and instructor, whose generosity, positive attitude and enthusiasm for my writing helped boost my confidence as I worked to complete this project.
- ☺ All the regulars at [The PC Guide Discussion Forums](#), for creating a fun community, keeping the site active, and agreeing to provide opinions on my writing. Thanks especially to Paleo Pete and mjc for doing such a great job of moderating the forums.
- ☺ Christine Hylands of [Junefire DTP](#), for assistance with creating certain graphics in this Guide, as well as designing its Web site (on short notice).
- ☺ Everyone who has supported The PC Guide, financially and otherwise, which made it possible for me to spend time on this project.

I've probably missed a few people who should be on this list; I hope all who are deserving of my appreciation will forgive their omission and accept my thanks.

---

## About The Author

My name is Charles Kozierok, and I am the author of The TCP/IP Guide. For those who are interested in me, I'd like to take a few minutes to introduce myself. (I know, I am not supposed to write this in the first person. But then, I wasn't supposed to write the entire Guide in the first person and I did that, didn't I? ☺)

I was born in 1966, which makes me now... 38, that's right. ☺ I was born in Windsor, Ontario, Canada and raised in Toronto. I married my wife Robyn in 1990; we now live in rural southern Vermont with our three sons: Ryan (10), Matthew (8) and Evan (3).

I have had an interest in the field of computers ever since my early years. At the age of 14 I received my first computer, an Apple II that was a gift from my parents, and I was hooked; I have yet to recover. I taught myself programming and later took courses on the subject in high school. My first accomplishment was a program for drafting printed circuit board layouts, which I wrote in 1982. Since that time I have worked in various computer-related fields in hardware and software.

In 1984, I entered the University of Waterloo, in Waterloo, Ontario, Canada, and in 1989 graduated with a Bachelor of Applied Science. I entered the MIT Leaders for Manufacturing program in 1991, and completed my formal education in 1993 with two Master's degrees, in Management and in Electrical Engineering and Computer Science (EECS).

After leaving graduate school I initially embarked on a rather "conventional" technical career, working for two different manufacturing companies. However, my direction changed abruptly in 1997 when I first created and published The PC Guide, an extensive online reference work on personal computers. I was pleased to discover how many people enjoyed the quality and style of my writing. In 1998 I decided to devote myself to The PC Guide full time. In early 2001, I began work on the networking material that forms the content of this Guide. I plan to spend the next few years finishing and revising similar writing projects, including a complete rewrite of The PC Guide.

You may have noticed something missing here: no impressive listings of credentials. No, I'm not a New York Times best-selling author; I haven't been a professor at a prestigious Ivy League university for a quarter-century; neither am I a top executive at a Silicon Valley giant. In some ways, I am a student of technology, just like you are. And my experience over the years has shown me that many of the people who know the most about how technology works also have rather limited success in explaining what they know in a way that will allow me to understand it. My interests, and I believe my skills, lie not in being an expert, but an **educator**, in presenting complex information in a form that is sensible, digestible and fun to read. (Well, at least as much fun as this stuff can possibly be! ☺)

When I am not working—all too rare these days—I spend time with my family and enjoy the peaceful quiet and natural beauty of the state of Vermont. I enjoy listening to many types of music, walking in the woods, and hiking. I am an avid amateur photographer, with particular interests in nature, landscapes, macros and abstracts.

# The TCP/IP Guide: Introduction and "Guide To The Guide"

---

Chances are pretty good that even before you started reading this Guide, you had heard of "TCP/IP"—even if you didn't know exactly what it was or even what all those letters stood for. The reason for this is simple: TCP/IP is **everywhere**! It is today by far the most commonly-used internetworking protocol suite. It has gained prominence in large part due to its role in operating the global Internet, which has in a few short years transformed our society in so many ways. Millions of people use TCP/IP and the Internet without really knowing how they work. For those in the technology field, however, understanding TCP/IP is becoming more important with each passing year.

As we journey together through this TCP/IP Guide, we will explore many hundreds of pages of material that will explain both the generalities and specifics of TCP/IP in a way that I hope you will find educational and interesting. Before diving into the actual technology, however, I felt that I should provide you with some introductory material to help frame the discussions that follow. Thus, I have included this section, to serve as an introduction to this Guide and to provide some information that will help you use it to its full potential.

I begin with some material that will be of interest to those who want to know the background of The TCP/IP Guide. I provide a general introduction to the Guide, describing its history, and how it came about. I then describe the goals of this Guide and what I was trying to accomplish in writing it. I also discuss the scope of the Guide, so you know what it covers and what it does not.

The rest of the section contains more practical information to help you best utilize this rather large document. I explain how the Guide is structured and organized, and discuss its special features. I then provide some specific tips to help you navigate the Guide using the Adobe Acrobat Reader software you are likely using at this moment. ☺ I also explain how you can provide feedback on the Guide and suggestions for improving it, and I conclude with a summary of the Guide's version history.

**Note:** There is no actual technical content in this section. If you are the type who buys something and starts using it right away without cracking open the manual, you may want to skip this section. If so, you should start by looking at the high-level discussion of the [TCP/IP protocol suite](#); alternately, you may wish to begin at the [Networking Fundamentals](#) section or with a look at the [OSI Reference Model](#). However, I do recommend at least skimming the topics in this section before you move on, especially the topics discussing the structure and organization of the Guide and its features. This will make the rest of the Guide easier to understand and probably save you time in the long run.

---

---

## **Introduction To The TCP/IP Guide**

As I sit here writing this introductory material a few weeks before finishing off a multi-year project culminating in this TCP/IP Guide, I reflect on how funny life can be. Prior to a few years ago, I never really thought of myself as a writer. I have no training as an author, and my interests have always been in computers. I always assumed that I would end up in a technical job, such as computer programming or hardware design.

Perhaps ironically, then, it was my interest in personal computers that led to my writing The PC Guide in 1997. After I put the first version of that site online, I received many compliments on its usefulness. This didn't surprise me, since the material was of course designed to be useful. ☺ What shocked me were all the comments I received about how people appreciated my writing. They said they found my material easy to understand, and some said they had even read through textbooks but never understood the concepts they explained until they encountered my site. I discovered that I perhaps I had a talent I had never before considered; more, I realized that it felt good to dissect a difficult technical subject and help people understand it.

In early 2001 I decided that I wanted to embark on a new writing project to go along with the PC materials I had written in The PC Guide. I felt then, as I do now, that the future of information technology lies not so much in bigger and faster computers, but in better ways of exchanging information between them. I wanted to know more about networking and inter-networking. So, I decided to create a Networking Guide to complement my PC Guide. I thought that this would take about six months.

Remember what I said above about life being funny? ☺ Well, as soon as I embarked on my project to create a Networking Guide, I realized that I had opened a virtual Pandora's Box. I had never realized just how large a topic networking was; there were literally hundreds of different protocols, technologies, algorithms, concepts and devices to learn about. These were all interconnected in a myriad of ways, and it was hard to explain how one protocol or technology worked without first explaining another one. The amount of complexity was amazing.

To make matters worse, I found that it was very hard to find information about networks that really explained how everything worked. This seemed like an opportunity to me—I decided that since so many people felt I did a good job explaining PC technology, that I should take a crack at networking. Once I accepted that it would take more than six months, I figured I should plan on up to two years to get this writing project completed. Well... life is even funnier than I imagined. ☺ Fast forward from early 2001 to August 2003, and I find myself at my desk, looking over my writing project. I realize that I have been at this now for two-and-a-half years, yet due to my desire to cover as much as possible, I have at least a year's more work to go.

I began to feel burnt out from working on this new Networking Guide for such a long time, during which it has existed only in my mind and on my PC's hard disk drive. Even though part of me wanted to wait to finish the entire Networking Guide and publish it all at once, a larger part of me felt the need to publish at least some of what I had already written. I looked

---

over the material I had completed, and realized that most of the TCP/IP material was done. I felt TCP/IP was a topic that was particularly important in the Internet era, and one that I could cover as a standalone Guide. A few more months' work, and the TCP/IP Guide was born.

That's the story of the creation of an improbable TCP/IP Guide by an improbable author. ☺ You may look at the 1600-odd pages in this Guide and wonder at how this could be only a **part** of the document that I originally began. But that is in fact the case, and should give you an idea of just how large the complete project would have been had I waited to publish it in whole. Perfectionists should **never** start open-ended projects! ☺

So, after nearly three years in all, the TCP/IP Guide is complete, and I am pretty pleased with how it came out. I feel that the breadth and depth of the coverage is unparalleled in any other single TCP/IP resource, and I have worked very hard to make my descriptions understandable and enjoyable to read. I spent many weeks designing the layout of the Guide, and many more creating and fine-tuning hundreds of examples and diagrams to help illustrate most of the technologies and concepts that underlie TCP/IP. Add to this the many benefits of electronic publication, such as a clickable table of contents, hyperlinks and a real-time search index, and I think this Guide will be of value to both beginners and advanced users alike. I hope you find it useful.

## Goals of The TCP/IP Guide

Every author who sets out to write a book or other document has certain objectives that he or she hopes to accomplish when the work is completed. This is why you can go into a library or bookstore, pick up several books that cover the same subject, and discover that they are surprisingly different—not just in their content or scope, but in their entire approach to the material.

I too had a number of goals when I set out to write this Guide; you certainly don't need to know them in order to read and appreciate the material, but knowing what I had in mind while I was writing may help you while you are reading. ☺ And if you are reading this information prior to licensing The TCP/IP Guide, knowing what I strove for in writing the Guide may help you decide if this is the right resource for you.

My overall goal in writing this Guide was to create a resource that would allow anyone to obtain a deep understanding of how TCP/IP technologies really work. To accomplish this, I had a number of specific objectives that guided my writing efforts:

- ☉ **Comprehensiveness:** Like most authors writing a resource that covers a large subject, I wanted the TCP/IP Guide to be comprehensive. Of course no single document can cover everything, so I have had to limit [the scope of the material](#). However, I feel I cover more about TCP/IP as a whole than any other single book or other resource.

- 
- ☪ **Comprehensibility:** Creating a resource that is comprehensive is important, but I felt that it was even more important that the Guide be **comprehensive**. Over the past few years, I've had the opportunity to review many hundreds of books, guides, Web sites and papers related to networking. I have found that even though most of them are generally high in quality, too many use unexplained technical jargon or assume extensive prior knowledge of networking concepts and technologies on the part of the reader. I worked very hard to ensure that my descriptions, even of very complex concepts, can be understood by almost every student of networking.
  - ☪ **Rationale:** It's certainly important to know how every TCP/IP protocol functions. However, to gain a true understanding of complex material, one also needs to understand the reasons behind why things are what they are. In writing this material I have always tried to explain not just the *what* but also the **why** of TCP/IP. I have anticipated and answered questions that I believed would commonly arise in the mind of someone learning about this technology.
  - ☪ **Illustrations:** A picture is worth a thousand words, as they say. There are many concepts that no amount of verbiage will adequately explain, while a simple illustration will do the trick. For this reason, I spent many months creating over 300 full-color diagrams (some simple and some not so simple!) to complement the written material in The TCP/IP Guide.
  - ☪ **User-Friendliness:** I have intentionally broken many of the rules of conventional book authorship, in creating a document that uses a conversational, first-person style, and no small amount of humor where appropriate. My intention was to make you feel at home while you read material that can be quite technically difficult. I want you to think of me like a friend sitting next to you at your computer explaining how TCP/IP works, rather than a professor preaching at you from a pulpit.
  - ☪ **Organization:** Many networking books consist of dozens of subjects just listed one after the other, leaving the reader to wonder how everything fits together. When I first began this Guide, I spent weeks just organizing it, with the result being a [hierarchical structure](#) that indicates clearly how subjects are inter-related. I also carefully laid out each individual section to ensure that it covered its topic in a way that made sense.
  - ☪ **Multiple Levels of Detail:** I realized that some people reading a TCP/IP Guide might only want a quick summary of the operation of its constituent protocols, while others want to learn all the nuances of how everything works. I have provided the full details that most readers will want, while also providing overview topics in each section that summarize each technology for quick perusal. This gives you the option of either skimming the surface or "diving deep", as you choose.
  - ☪ **Platform Independence:** I have endeavored whenever possible to avoid describing TCP/IP in terms specific to any hardware or software platform. Even though I use a PC for most of my computing and UNIX for other aspects, most of the material is not particular to any type of device or operating system (though I do focus more on networks of smaller computers than larger ones).

How successful was I in achieving these goals? I'd like to think I did a pretty good job, but ultimately, you will be the judge!

---

## Scope of The TCP/IP Guide

The first step to dealing with a problem is recognizing that you have one. So, I have to come clean with you, my reader. I have a problem: an addiction to... detail. ☺ Every time I set out to write about a particular protocol, technology or concept, I start with a modest goal regarding how much I want to write. I always begin knowing that I really need to control myself, to prevent my project from going on forever. But as I explore each subject, I learn more and more, and I start to say to myself things like... “this is important, I simply **must** include coverage for it” and... “if I am going to cover subject #1, I also should cover subject #2, because they are related”. This is [how I turned a six-month project into a multi-year ordeal](#). ☺

However, even though self-control in this area is a weakness for me, even *I* realized I could not possibly cover **everything** related to TCP/IP in this Guide. Consider that the TCP/IP suite contains dozens of protocols and technologies that have each had thick books written about them. I was willing to spend years on this project but not decades. ☺ Thus, I had to limit the scope of this Guide somewhat, both to preserve what remains of my sanity and to spare you from having to wade through a ridiculously large document.

Here are a few different points that will help explain decisions that I made to limit the scope of The TCP/IP Guide:

- ☺ **Theory versus Practice:** This is primarily a *reference resource* on the TCP/IP protocol suite. The material here is designed to allow a student to learn the nuts and bolts of how TCP/IP works. I do discuss quite a number of “real-world” practical issues related to how TCP/IP internetworks operate, but this is not my primary focus here. If you want to really understand what TCP/IP is and what makes it work, you’ve come to the right place. If all you want is simple instructions on how to connect a few PCs together in your home using TCP/IP, this probably isn’t the Guide for you. ☺
- ☺ **Current versus Future Protocols:** Most of the emphasis in this Guide is on the present state of the art in TCP/IP. The suite is always changing, and there are constantly new protocols being written and revisions to existing protocols being published. I have not provided extensive coverage of technologies still in development, to try to keep the size of the Guide manageable, and to reduce the number of changes I will have to make to keep the material up-to-date.

The one exception to this general rule of thumb is version 6 of the Internet Protocol. IPv6 represents a significant change to the core of how most of TCP/IP operates. While not universally deployed yet, IPv6 is sufficiently far along in its development that I feel any student of TCP/IP needs to know what it is and how it works, and understand its significance. Thus, I have included a [detailed section describing it](#), and also mentioned how it impacts the operation of several other key protocols such as [ICMP](#), [DNS](#) and [DHCP](#).

- ☺ **Application Coverage:** There are many thousands of different applications that run on TCP/IP internetworks, and I could not possibly hope to describe all of them. The scope of this Guide is limited to the most important, [“classical” TCP/IP applications and application protocols](#), such as electronic mail, general file transfer and the World Wide Web.

- 
- ☉ **TCP/IP versus The Internet:** The TCP/IP protocol suite and the Internet are very closely related in many ways, as you will discover as you read this Guide. In fact, they are often tied together so much that it is hard to discuss one without the other. However, the Internet as a whole is an enormous subject, and trying to describe it in general terms would have substantially increased the size of this Guide. Thus, I describe Internet issues only within the context of explanations of TCP/IP technologies.

For example, while I cover the [World Wide Web](#) in this Guide, I discuss its generalities only briefly. I focus my technical discussions on how the [Hypertext Transfer Protocol \(HTTP\)](#) that implements it works. I don't talk all about how to set up a Web site, or how to choose a Web browser, or any of those sorts of details. These are covered in a dazzling array of different books, papers and of course, Web sites. ☺

- ☉ **Limited TCP/IP Security Coverage:** Security is a very important and very large topic, especially in modern networking. This Guide does include a fairly detailed section on the operation of the [IP Security protocols \(IPSec\)](#), and also touches upon security issues in describing several other protocols and technologies. However, it is not specifically geared towards detailed discussions of security considerations. It is possible that in the future I will add more security-related information, but for now, if your primary interest is TCP/IP security matters, you will want to supplement this Guide with other materials.
- ☉ **Small Computer Orientation:** In general terms, TCP/IP technologies can be used to connect together any types of devices that have the appropriate hardware and software. There are some issues, however, where explanations require me to focus on how specific types of underlying networks and devices work; this is especially true of some of my diagrams. In these cases, my preference has generally been to show how TCP/IP is used to connect together typical small computers such as PCs, Macintoshes and UNIX workstations, which are what most people use.

## Structure and Organization of The TCP/IP Guide

You may have already noticed that the TCP/IP Guide is organized in a way that is very different from most books. I believe this structure will help you not only find the information you need easily, it will even assist you in understanding the content. However, because it is unorthodox, I want to take a few moments to explain what I have done and why.

In reviewing other networking books and materials before I wrote this Guide, I was consistently disappointed—not in the descriptions of the various subjects, but in the way they were organized. Invariably, these resources would cover a lot of material, but it would be presented as a poorly-structured set of seemingly unrelated chapters—“subject salad” as I sometimes call it. A typical networking book would have dozens of little chapters cobbled together and presented almost as if they were independent of each other. The reader had to figure out how they all connected, and also had to wade through several repeated descriptions of similar concepts, due to aspects that were common between certain technologies. This was all exacerbated by the inability to hyperlink between related topics in a print book.

---

TCP/IP is a complex topic largely because so many of the concepts and technologies are closely related. TCP/IP as a whole consists of a number of defining concepts and a large number of individual protocols, many of which interact in a specific way. Many of those protocols in turn consist of either subprotocols or descriptive elements that are related to each other in a particular fashion. For example, you can't easily describe IP datagram formatting without making reference to IP addressing, which in turn is related to IP routing, which is of course related to IP routing protocols, and so forth.

For this reason, I didn't want to just make this book consist of several dozen chapters slapped together as peers and leave you to figure out how they fit together. So, I spent several weeks just trying to come up with a way to describe TCP/IP technologies in a coherent, organized way that made sense. My primary goal was to come up with a structure that would clearly show how all the various protocols, concepts and technologies were interrelated, to help you understand the subject as a whole, and not just as a collection of parts.

The result of this effort is that rather than using a set of dozens of chapters all at the same level, this Guide uses a *hierarchical* structure with many levels. The Guide contains several sections on various high-level subjects, which we will explore in a moment. Most of these contain subsections that describe components or more detailed elements within the higher-level subject. These in turn can contain their own subsections and so on, possibly going down several layers in detail.

The Guide is formatted so that each section header and section starts at the top of a page. This facilitates printing small sections of information (for use as handouts in a classroom setting, for example) and also helps make navigating using hyperlinks easier. A special horizontal divider graphic is used to clearly mark the end of each section.

Another organizational feature of this Guide is that I have made extensive use of *overview* topics. Most sections that include multiple individual topics begin with an overview topic that provides a high-level look at the contents of that section. These serve two purposes. First, they introduce the subject and provide a context for understanding the detailed discussions that follow it, for those who want to read about the protocol or technology in detail. Second, they serve as a "short cut" for those who do not wish to read an entire section. Some large sections containing subsections will have an overview for the section as a whole, and an overview for some of the subsections as well. This is by design, to provide you with flexibility in choosing what you want to read.

Some of you might find that this all of this takes a bit of getting used to, but it has advantages compared to a "flat" set of chapters. The hierarchical structure itself helps you understand how the many protocols, concepts and other bits and pieces of TCP/IP fit together. It shows you what aspects of TCP/IP are closely and more distantly related. The hierarchy and the use of overview topics allows you to explore a particular subject of interest in the manner you choose, by enabling you to easily choose some subsections to delve into while skipping others that you may already understand or simply not wish to know.

---

So, where to begin in exploring this large Guide? Well, you can just read the entire thing from cover to cover, but most people lack the time and patience to do that! The key to taking advantage of this Guide's hierarchical structure is to make use of the nested bookmarks that should appear on the left side of your Adobe PDF reader. These let you clearly see the structure of each part of the Guide and let you instantly jump to any topic of interest. The next two topics describe in more detail [features of the Guide](#) and how to [optimize your use of Adobe Acrobat Reader](#).

## **Chapters of The TCP/IP Guide**

Due to the hierarchical structure just described, there are only six “top-level” sections in this Guide, which I sometimes called *chapters*. You will probably find that it usually makes the most sense to begin with these higher-level sections and work your way down to the more detailed topics they contain. Here is a brief description of each, to get you started:

- ☉ [Introduction and “Guide To The Guide”](#): You’re reading it! ☺
- ☉ [Networking Fundamentals](#): This is a background chapter that provides lots of useful general information on networks for those who may be very new to the entire subject. It has subsections that explain what networking is, discuss key networking characteristics, describe networking standards, provide information on binary mathematics and much more. If you are experienced with networks and computers in general you may wish to skip this (or at least, skim it and only read the topics that interest you).
- ☉ [The Open System Interconnection \(OSI\) Reference Model](#): A description of the important OSI Reference Model, which is used extensively to explain networking architectures and protocol layering concepts. Unless you already know and understand the OSI model, this section is worth reading before getting into the “meat” of the Guide.
- ☉ [TCP/IP Protocol Suite and Architecture](#): This is the first section that is specifically about TCP/IP; it introduces the protocol suite and discusses it in general terms. This includes a look at its history, a description of the TCP/IP architectural model and an overview of key protocols. It should be the place to start reading about TCP/IP for virtually everyone using this Guide, as it provides necessary background information and a context for understanding the more detailed chapters below.
- ☉ [TCP/IP Lower-Layer \(Interface, Internet and Transport\) Protocols \(OSI Layers 2, 3 and 4\)](#): This large chapter describes all of the TCP/IP protocols that operate at layers 2 through 4 of the OSI model, and is organized by layer for easier reference by function. This chapter encompasses about half the entire Guide; it includes all of the most important “core” TCP/IP protocols, including IP, IPv6, ICMP, UDP, TCP and much more.
- ☉ [TCP/IP Application Layer Protocols, Services and Applications \(OSI Layers 5, 6 and 7\)](#): This chapter is also very large, as it covers all the TCP/IP application protocols and services that correspond to the upper three layers of the OSI Reference Model. This includes protocols such as DNS, DHCP, SNMP, FTP and HTTP, as well as applications such as electronic mail, the World Wide Web and diagnostic utilities.

As you can see, most of this Guide is actually contained in the last two chapters, since TCP/IP is primarily defined by the functions of its various protocols.

---

# **TCP/IP Guide Features, Inserts and Icons**

I created The TCP/IP Guide to provide you with an unparalleled breadth and depth of information on TCP/IP. This meant including a lot of content in this Guide—it has over 600 sections, subsections and individual topics, and is over 1,600 pages long. However, I recognized as I was writing this tome that the real goal is not just to provide a lot of detailed information, but also to present it in such a way that it can be easily understood by you, the reader. This requires more than just writing large amounts of text and putting it all into a large file.

For this reason, I have incorporated a number of special features into this Guide to help make it easier for you to “digest”. ☺ These include tools that will help you navigate through the information, others that let you quickly jump to related topics, and graphical elements that explain difficult topics or simply highlight important text elements. Most of these features are also designed to exploit the many advantages of electronic documents, such as hyperlinking and the ability to embed full-color graphics.

## ***Special Features***

Here is a description of some of these special features, in no particular order:

- ☛ **Hierarchical Table of Contents:** The TCP/IP Guide uses a hierarchical structure, which I described in detail in [the previous topic discussing the Guide’s organization](#). A complete [Table of Contents](#) has of course been included, which reflects this hierarchical structure. It is fully hyperlinked, so you can quickly jump to any topic of interest just by clicking your mouse on the topic’s title.

For your convenience, there is also a link to the Table of Contents in the footer of each page. Just click on the word “[Contents](#)” that appears after the name and version number of the Guide.

- ☛ **Hierarchical Bookmark List:** The Table of Contents mentioned just above is also implemented as a set of hierarchical bookmarks, which should automatically appear in a window pane on the left side of your screen when you open the Guide in Adobe Acrobat. These bookmarks are convenient, since they remain open while you read the Guide. You can use them to check your current location in the document, and to jump to any section or topic. [See the next topic for details on how to find these bookmarks](#) if they do not appear automatically when you open the Guide.
- ☛ **Figures:** The TCP/IP Guide contains over 300 full-color illustrations, which support the text descriptions of TCP/IP technologies and protocols, and help make sense of difficult concepts. Each figure is cross-referenced with a hyperlink from an appropriate place in the text. Most include brief descriptions that allow you to understand what the figure means without even having to read the full text of the topic where the figure is located.
- ☛ **Tables:** The Guide has over 300 tables, which present large amounts of information in an organized and readable manner, or highlight examples for your convenience. These tables use alternating white and colored rows for enhanced readability. Like the figures, these tables are cross-referenced from the text using hyperlinks.

- 
- ☉ **Lists of Figures and Tables:** I have provided a [List of Figures](#) and a [List of Tables](#) to allow you to easily find any figure or table using either its number or title. Like the Table of Contents, all entries on these lists are hyperlinked for your convenience.
  - ☉ **Hyperlinks:** In addition to the hyperlinks in the Table of Contents and lists mentioned above and the cross-references to figures and tables, there are over 3,000 additional hyperlinks within the actual text of the Guide. These links are shown in blue text; when you see one, clicking it will take you to the topic discussing whatever subject matter was highlighted by the link. This lets you quickly find information relevant to understanding the topic you are currently exploring.

Note that all hyperlinks that appear in the main part of this Guide are internal links that go to other places within the Guide; external links are shown separately (see below).

- ☉ **Highlighting:** I use a consistent highlighting mechanism to make the text easier to read. When new terms are introduced they are shown in *italics*; I also italicize the names of fields, messages, options and other protocol constructs to set them apart from regular text. Emphasized words are shown in ***bold italics***. Document titles are *italicized and underlined*. There are also a few places where colored text is used for emphasis.
- ☉ **Full Text Search:** The TCP/IP Guide does not have a conventional index of topics like most books because it has something better—the ability to search for any string and have the PDF file viewer software automatically take you to each place where it occurs in the document. This is described in detail in [the next topic](#).

## ***Inserts and Icons***

Most of the text discussions in The TCP/IP Guide are shown as free-form text as you would expect in any document. However, there are certain situations in which I want to provide you with a piece of information that is either not directly related to the subject of the main text, or is deserving of your special attention. For these purposes, the Guide uses a set of special *inserts*, each of which is clearly marked by a particular icon, and called out from the text using a pair of horizontal bars. There are five different inserts used in the Guide, which I have shown and described below.

**Note:** This insert used when I need to clarify or explain something that I feel you need to know, but which is either not directly related to the topic under discussion, or is sufficiently “tangential” that it needs to be separated from the main text to avoid disrupting its flow. Examples include terminology explanations, “sidebar” historical discussions, anecdotes, and clarifications relating to how I am describing particular concepts.

---

**Key Concept:** I tried very hard in crafting this Guide to provide a variety of ways to present information, to better suit the learning styles of different readers. To that end, I have created hundreds of these inserts, which summarize and highlight the most important concepts and essential pieces of knowledge in The TCP/IP Guide. They can be very useful for quickly distilling the essence of a topic without reading an entire explanation, or for refreshing your memory of a topic you have already read. Obviously, however, they contain few details, so you should not assume that you fully understand a topic or concept just by reading this sort of summary.

---

**Background Information:** When you see this insert near the front of a section or a particular description, it indicates that I am recommending that you read another part of the Guide before proceeding with that section. While I have attempted to make each section able to stand alone to a certain degree, some just make more sense if read in a particular order (usually the order in which the sections are listed within their parent section).

---

**Related Information:** This insert mentions another section or topic within The TCP/IP Guide that contains information related to the section where the insert is located, but which is not background material. It may help you understand the content you are reading, or put it into better context.

---

**On The Web:** This insert is used when I need to link to a relevant document or resource on the World Wide Web. The insert contains a brief description of the linked item and its URL, highlighted in blue italics.

---

Be sure to also read the next topic, which provides some very useful advice on how best to use the Adobe Acrobat (PDF) Reader software. This will help you get the most of the features I have just described.

## Tips For Using Adobe Acrobat Reader To View The TCP/IP Guide

The TCP/IP Guide is packaged as an Adobe Acrobat *portable document format (PDF)* file. PDF files are normally viewed using a software program called the *Adobe Acrobat Reader* (or just *Adobe Reader*). Since Acrobat has become the industry standard for distributing electronic documents, you have probably used it to view PDF files many times in the past.

---

Some of you, however, may be new to PDF files, and most others have probably never used it to view a document of this size. I felt it would be helpful to provide you with a few suggestions for how best to use the software to view this Guide.

Obviously, I cannot begin to explain all the features and options in the Adobe Acrobat software, nor would I wish to try. You should consult the built-in help features of the program for general assistance on how to use it. My interest here is only in highlighting some specific Acrobat tools that I think will help you in best navigating the Guide and benefitting from its features.

So, here are some specific tips to getting the most of The TCP/IP Guide using the Adobe Acrobat Reader. These are based on version 6 of the software, running on a Windows PC platform. Note that earlier versions of the software may not have all of the features I discuss below. Versions running on other operating systems likely have the same features, but may be accessed using different menu options or key sequences.

### ***Basic Navigation***

To move through the document:

- ☛ Use the “Up Arrow” and “Down Arrow” keys to go up or down one line.
- ☛ Use the “Page Up” and “Page Down” keys to go up or down one screenful of information.
- ☛ Use the “Left Arrow” and “Right Arrow” keys to go up or down one full page. (This may be the same as a full screen if you have the viewing mode set to display exactly one full page at a time on the screen.)
- ☛ Use the “Home” key to go to the first page, or “End” to go to the end of the Guide.

You can also use the scroll-wheel on most mice to navigate through the document, or the scroll bar on the right side of the document. There are also arrow buttons for navigation, at the bottom of the page on either side of the page number display, and the “View Menu” has a “Go To” submenu with navigation options as well.

### ***Hyperlinks***

Hyperlinks are shown in blue text; when you move the pointer over one, it will change from a hand to a pointing finger. Just click the link to go to its target.

To return to the place where the link was located, select the “View” menu, then “Go To” and “Previous View”, or more easily, press “Alt+Left Arrow”. The small green button pointing to the left at the bottom of the screen does the same thing. This is **very** useful when you want to follow a hyperlink quickly to check a related piece of information and then return back to the place where you were reading. You can do this multiple times as well—if you click three hyperlinks in sequence, you can go back three times to each hyperlink in sequence.

---

## ***Enabling Bookmarks***

When you open The TCP/IP Guide, a pane should automatically appear on the left side that shows the contents of the document in a hierarchical structure identical to [the structure of the Guide itself](#). Use these bookmarks to navigate the Guide and jump to topics of interest.

If for whatever reason the bookmarks are not displayed, click the vertical “Bookmarks” tab on the upper left of the document area to show them, or select the “View” menu, then “Navigation Tabs”, then “Bookmarks”.

## ***Wrapping Long Bookmarks***

Some of the section and topic titles in The TCP/IP Guide are quite long, and by default, you may only be able to see the first few words of each in the bookmarks area. To see the full title, click on the “Options” drop-down box in the bookmarks window, then select “Wrap Long Bookmarks”.

## ***Jumping To A Particular Page***

Most often, you will find that it is easiest to jump to a particular section or topic using the bookmarks, the [Table of Contents](#) or text hyperlinks. However, you can also go to a specific page number manually. Either click on the current page number near the bottom of the page and enter the number of the page you want, or press “Shift+Control+N” to bring up the “Go To Page” dialog box.

**Note:** I have intentionally numbered the entire Guide starting with page number 1—as opposed to restarting the page numbers after the Table of Contents and so forth—so that the Adobe Acrobat page numbers and document page numbers are identical.

---

## ***Zooming***

By default, The TCP/IP Guide opens up at 100% (actual size) magnification. This provides the best quality of text and graphics on most monitors, but may not be suitable for some displays, especially very small or large ones. You can change the displayed size in a variety of ways. Select a different magnification using the zoom factor drop-down box at the top of the program, or click one of the pictures of a piece of paper there. To bring up a dialog box with zoom options, select the “View” menu and then “Zoom To...”, or press “Ctrl+M”. If you are not sure what magnification to use, try making the Acrobat window full-screen and then selecting “Fit Width”.

## ***Page Layout***

By default, the Guide displays as a continuous scroll of pages, as I find this usually makes reading a long document easier. It also enables hyperlinks to properly position the document to the exact location of the target of the link. If you prefer, you can change to

---

single page layout by selecting the “View” menu, then “Page Layout”, then “Single Page”. If you do this, however, when you click a hyperlink, it will load the target page number without scrolling to the title of the hyperlink’s target.

## **Text Search**

To search for a term or phrase, select the “Edit” menu, then “Search”, or press “Ctrl+F”. This should cause a *pane* to appear on the right side that presents a few options for you to search the Guide. A few specific pointers here:

- ☛ To search for a word or phrase, simply enter it into the box at the top of the search pane. A results box will come up containing just the single TCP/IP Guide document; click the “+” next to it for a list of each location in the document where the word or phrase occurs. Select one and you will be taken directly to it.
- ☛ To instantly go to the next search result, press “Ctrl+G”; to go to the previous one, press “Shift+Ctrl+G”. Of course, you can also just select a different result from the box, rather than moving through each one in sequence.
- ☛ For more advanced searches, click “Use Advanced Search Options” near the bottom of the search window.
- ☛ Click “New Search” to look for a different word or phrase, or use the “Hide” button at the top right to close the search pane.
- ☛ The Guide comes with a precompiled index that makes searching through it very fast despite its size. This index should be automatically loaded when you open the Guide. Make sure it is selected by checking that under “Where would you like to search?” the button is next to “In the index named The TCP-IP Guide.pdx”. If you select instead “In the current PDF document”, the software will search through every page one by one which will take a long time.

If the index is not present as an option in the search box, try adding it manually. Click “Use Advanced Search Options” near the bottom of the search pane. Then click the “Look In:” drop-down box to see if the index is listed. If it is, select it, otherwise, click “Select Index...”. Then click “Add” and navigate to the location on your computer’s hard disk or CD-ROM drive where The TCP/IP Guide is located. Select “The TCP-IP Guide.pdx” and it should attach the index to the document. Then click “Use Basic Search Options” near the bottom of the window to return to the simpler search box.

**Note:** If you experience errors when attempting to use the index, this may be due to an issue with older versions of Adobe Acrobat Reader (even though the PDF was created to allow compatibility with older software!) Try upgrading to the latest version of the software; [you can download it free from Adobe’s Web site](#). Sorry for the inconvenience.

---

## Feedback and Suggestions

One of the ways that this Guide differs from the typical technical reference book is that it is a very *personal* work. When you read the material here, I want you to feel like I am explaining the many technologies and concepts to you personally, because that's how I feel when I am writing. A published Guide of this sort is by its nature a type of "one-way" communication, from me to you; however, I am also interested in what you have to say to me. For this reason I strongly encourage you to provide me with feedback on this Guide and suggestions that you may have for it.

**On The Web:** All technical documents have mistakes in them; this one is no exception, which is why the Guide is revised regularly. Before contacting me regarding an error or problem with this Guide, please check to see if you have the latest version, which may have addressed your concern; the list of versions and the major changes they contain is at <http://www.tcpipguide.com/versions.htm>. If you are reading the current version, please check the errata page, to see if what you found has already been reported. That page can be found here: <http://www.tcpipguide.com/errata.htm>

---

### ***Please Write Me About...***

Here, specifically are some of the areas where I would very much like your feedback:

- 🕒 **Error Reports:** Please don't be shy about reporting any errors you may find with this Guide, be they typos, mistakes in my reasoning, glitches in diagrams or anything else. Simply put, I'm not perfect, and I can't fix problems that I don't know exist.  
  
If you do decide to report an error, please check the errata page mentioned above before contacting me. If your problem is not mentioned there, please e-mail me (see below) and indicate clearly what version of the Guide you are using, and the topic name or page number where you found the problem.
- 🕒 **Constructive Criticisms and Suggestions for Improvement:** If there is something you don't like about the material, please tell me. Even better, make a suggestion for how to improve it.
- 🕒 **Requests For Additional Content:** Is there an area of the Guide where you wish I had gone into more detail, or a protocol you feel I should have covered but did not? Please feel free to let me know.
- 🕒 **Compliments:** If you like The TCP/IP Guide, then by all means please tell me, I won't mind at all! 😊
- 🕒 **Questions About The Guide:** Questions that pertain directly to the use of the Guide, its construction, or related matters are fine.

Obviously I cannot guarantee that I will implement every idea or suggestion, but I will certainly consider each one. I also try to always respond to my e-mail personally, since I think it is rude for me not to reply when someone takes the time to provide me with feedback. (I do not, however, usually bother to reply to "flaming" or rude e-mails.)

---

## ***Please Do Not Write Me About...***

The only request I would make is this: ***please do not contact me with technical questions or requests for assistance***. I'm a pretty busy guy and I get a lot of e-mail. I simply do not have the time to help people with specific problems. Since I initially wrote my first project (The PC Guide) in 1997, I have repeatedly asked people not to send me technical questions, but they keep doing it. I have now had to take the position of simply ignoring such messages. Specifically, I ***will not respond*** to the following:

- ☹ Requests for network or PC design, setup, configuration or troubleshooting assistance. There are a number of excellent resources for assistance with these types of issues on the Web, such as The PC Guide Discussion Forums (see below).
- ☹ Questions from exams, certification practice tests, and so forth. Please do your own homework, if you want to learn anything at all.
- ☹ Requests for me to write long treatises about TCP/IP protocols or technologies that go beyond what this Guide already contains. There's a lot of detail here, but I obviously couldn't include everything that everyone might have wanted to know about. If you don't find what you need here, try using another TCP/IP book, or searching the Internet for the information you need. I am happy to consider requests for enhancements to future versions of the Guide, but I do not have the time for personal instruction.

**On The Web:** If you do need help or advice with networking problems or issues, try The PC Guide Discussion Forums. While many of the discussions there are oriented specifically around PC hardware and operating system issues, there are also forums dedicated to networking concerns. You can find them here: <http://www.pcguides.com/forums>

---

## ***My Contact Address***

Now that you have read all that—you did read it, didn't you? ☺—you can reach me through e-mail at this address: [tcpipfb@tcpipguide.com](mailto:tcpipfb@tcpipguide.com)

## **Version History**

Like all technical documents, The TCP/IP Guide must be revised on a regular basis, to correct problems and make updates to reflect changing technology. The fact that the Guide is self-published in electronic form allows me to update it much more often than is possible with a printed book. To differentiate between successive revisions of the Guide, I use a version number system; you can find the version number of the document you are reading right now in the footer of each page. I also provide a history of the Guide's past versions in this topic, for your reference.

---

The version number takes the form “N.N”, where each “N” is an integer. The right-most digit is the minor version number; it is incremented whenever a new version of the Guide is published that contains only relatively minor fixes and improvements. The left-most digit is the major version number, and is changed only when significant changes are made to the Guide, such as a large number of fixes and enhancements, or the addition of substantial new content.

**On The Web:** The version history in this topic is obviously only current as of the date that this particular version of the Guide was published. The most recent list of versions can be found at <http://www.tcpipguide.com/versions.htm>. Also, even though this is an electronic document, a fair bit of work is still required to publish each new version. Therefore, I do not put out a new version each time a problem is reported to me or I make a minor enhancement. To see a list of problems or issues that are due to be corrected in the next version, please check The TCP/IP Guide errata page: <http://www.tcpipguide.com/errata.htm>

---

The version history of The TCP/IP Guide can be found in [Table 1](#).

**Table 1: Version History**

Version Number	Version Date	Description
1.0	January 1, 2004	Initial release of The TCP/IP Guide.
2.0	June 7, 2004	Extensive rewrite of version 1.0 of The TCP/IP Guide. The Guide was thoroughly reviewed by two TCP/IP experts and numerous technical errors and clarity problems were addressed. Most of the larger topics have had subheaders added to make them more readable. Hundreds of other minor glitches, typos and problems have also been corrected.

---

# Networking Fundamentals

---

In order to get the most of The TCP/IP Guide, a certain level of knowledge regarding the basics of networking is very helpful. Unlike many other resources, however, I did not want to start with the assumption that my reader knew what networking was all about. After all, that's why you are reading this Guide!

So, I decided to include this section, which provides an overview of some of the basic issues related to networking. This area is where I place discussions of some of the most fundamental networking concepts and ideas. It serves not only to provide you, the reader, with useful background material, but also as a repository for “general” information so that I don't need to repeat it in many different places elsewhere in the Guide. This in turn allows those who already know about these basics to avoid having to skip over them in many other locations.

In this section I have provided several subsections that introduce networking and talk about some of its most important fundamental concepts. First, I introduce networking in very broad terms, discussing what it is and why it is important. Then, I describe several fundamental characteristics of networks that you will need to understand the various networking technologies. I discuss the different general types and sizes of networks and how they are differentiated. I then talk about many different matters related to network performance. I explain the importance of networking standards and standards organizations. Finally, I provide a background section that describes the fundamentals of how data is stored and manipulated in computers; if you are new to computing you may find that information useful when reading some parts of this Guide.

**Note:** If you are experienced in networking and related technologies, you may wish to skip this chapter. Hyperlinks in other areas of the Guide refer back here as appropriate, so if you need to “fill in” your knowledge of a particular fundamental “on the fly” you can do so rather easily.

---

**Note:** This section discusses fundamental networking issues that may be of use in understanding certain TCP/IP concepts. However, some of the material is very broadly oriented towards discussions of networking as a whole and is not specific to TCP/IP internetworking.

---

---

# Introduction to Networking

In this day and age, networks are everywhere. The Internet has also revolutionized not only the computer world, but the lives of millions in a variety of ways even in the “real world”. We tend to take for granted that computers should be connected together. In fact, these days, whenever I have two computers in the same room, I have a difficult time **not** connecting them together!

Given the ubiquitousness of networking, it's hard to believe that the field is still a relatively young one, especially when it comes to hooking up small computers like PCs. In approaching any discussion of networking, it is very useful to take a step back and look at networking from a high level. What is it, exactly, and why is it now considered so important that it is assumed that most PCs and other devices should be networked?

In this section, I provide a quick introduction to networking, discussing what it is all about in general terms. I begin by defining networking in the most general terms. I then place networking in an overall context by describing some of its advantages and benefits, as well as some of its disadvantages and costs.

## What Is Networking?

For such an extensive and involved subject, which includes so many different technologies, hardware devices and protocols, the definition of networking is actually quite simple. A network is simply a collection of computers or other hardware devices that are connected together, either physically or logically, using special hardware and software, to allow them to exchange information and cooperate. Networking is the term that describes the processes involved in designing, implementing, upgrading, managing and otherwise working with networks and network technologies.

**Key Concept:** A network is a set of hardware devices connected together, either physically or logically to allow them to exchange information.

---

Networks are used for an incredible array of different purposes. In fact, the definitions above are so simple for the specific reason that networks can be used so broadly, and can allow such a wide variety of tasks to be accomplished. While most people learning about networking focus on the interconnection of PCs and other “true” computers, you use various types of networks every day. Each time you pick up a phone, use a credit card at a store, get cash from an ATM machine, or even plug in an electrical appliance, you are using some type of network.

---

In fact, the definition can even be expanded beyond the world of technology altogether: I'm sure you've heard the term "networking" used to describe the process of finding an employer or employee by talking to friends and associates. In this case too, the idea is that independent units are connected together to share information and cooperate.

The widespread networking of personal computers is a relatively new phenomenon. For the first decade or so of their existence, PCs were very much "islands unto themselves", and were rarely connected together. In the early 1990s, PC networking began to grow in popularity as businesses realized the advantages that networking could provide. By the late 1990s, networking in homes with two or more PCs started to really take off as well.

This interconnection of small devices represents, in a way, a return to the "good old days" of mainframe computers. Before computers were small and personal, they were large and centralized machines that were shared by many users operating remote terminals. While having all of the computer power in one place had many disadvantages, one benefit was that all users were connected because they shared the central computer.

Individualized PCs took away that advantage, in favor of the benefits of independence. Networking attempts to move computing into the middle ground, providing PC users with the best of both worlds: the independence and flexibility of personal computers, and the connectivity and resource sharing of mainframes. In fact, networking is today considered so vital that it's hard to conceive of an organization with two or more computers that would not want to connect them together!

## **The Advantages (Benefits) of Networking**

You have undoubtedly heard the "the whole is greater than the sum of its parts". This phrase describes networking very well, and explains why it has become so popular. A network isn't just a bunch of computers with wires running between them. Properly implemented, a network is a system that provides its users with unique capabilities, above and beyond what the individual machines and their software applications can provide.

Most of the benefits of networking can be divided into two generic categories: *connectivity* and *sharing*. Networks allow computers, and hence their users, to be connected together. They also allow for the easy sharing of information and resources, and cooperation between the devices in other ways. Since modern business depends so much on the intelligent flow and management of information, this tells you a lot about why networking is so valuable.

Here, in no particular order, are some of the specific advantages generally associated with networking:

- 
- ② **Connectivity and Communication:** Networks connect computers and the users of those computers. Individuals within a building or work group can be connected into *local area networks (LANs)*; LANs in distant locations can be interconnected into larger *wide area networks (WANs)*. Once connected, it is possible for network users to communicate with each other using technologies such as electronic mail. This makes the transmission of business (or non-business) information easier, more efficient and less expensive than it would be without the network.
  - ② **Data Sharing:** One of the most important uses of networking is to allow the sharing of data. Before networking was common, an accounting employee who wanted to prepare a report for her manager would have to produce it on his PC, put it on a floppy disk, and then walk it over to the manager, who would transfer the data to her PC's hard disk. (This sort of “shoe-based network” was sometimes sarcastically called a “sneakernet”.)

True networking allows thousands of employees to share data much more easily and quickly than this. More so, it makes possible applications that rely on the ability of many people to access and share the same data, such as databases, group software development, and much more. [Intranets and extranets](#) can be used to distribute corporate information between sites and to business partners.

- ② **Hardware Sharing:** Networks facilitate the sharing of hardware devices. For example, instead of giving each of 10 employees in a department an expensive color printer (or resorting to the “sneakernet” again), one printer can be placed on the network for everyone to share.
- ② **Internet Access:** The Internet is itself an enormous network, so whenever you access the Internet, you are using a network. The significance of the Internet on modern society is hard to exaggerate, especially for those of us in technical fields.
- ② **Internet Access Sharing:** Small computer networks allow multiple users to share a single Internet connection. Special hardware devices allow the bandwidth of the connection to be easily allocated to various individuals as they need it, and permit an organization to purchase one high-speed connection instead of many slower ones.
- ② **Data Security and Management:** In a business environment, a network allows the administrators to much better manage the company's critical data. Instead of having this data spread over dozens or even hundreds of small computers in a haphazard fashion as their users create it, data can be centralized on shared servers. This makes it easy for everyone to find the data, makes it possible for the administrators to ensure that the data is regularly backed up, and also allows for the implementation of security measures to control who can read or change various pieces of critical information.
- ② **Performance Enhancement and Balancing:** Under some circumstances, a network can be used to enhance the overall performance of some applications by distributing the computation tasks to various computers on the network.
- ② **Entertainment:** Networks facilitate many types of games and entertainment. The Internet itself offers many sources of entertainment, of course. In addition, many multi-player games exist that operate over a local area network. Many home networks are set up for this reason, and gaming across wide area networks (including the Internet) has also become quite popular. Of course, if you are running a business and have easily-amused employees, you might insist that this is really a **disadvantage** of networking and not an advantage!

**Key Concept:** At a high level, networks are advantageous because they allow computers and people to be connected together, so they can share resources. Some of the specific benefits of networking include communication, data sharing, Internet access, data security and management, application performance enhancement, and entertainment.

---

Well, if that list isn't enough to convince you that networking is worthwhile, then... I have **no** idea what it is you do with your computers! ☺ At any rate, it's quite possible that only some of the above items will match your particular circumstances, but at least one will definitely apply to almost every situation, assuming you own or manage more than one computer.

## The Disadvantages (Costs) of Networking

Now that I have portrayed the [great value and many useful benefits of networking](#), I must bring you crashing back to earth with that old nemesis of the realistic: TANSTAAFL. For those who are not Heinlein fans, this acronym stands for “There Ain’t No Such Thing As A Free Lunch”. Even though networking really does represent a “whole that is greater than the sum of its parts”, it does have some real and significant costs and drawbacks associated with it.

Here are a few of the items that balance against the advantages of networking.

- ☉ **Network Hardware, Software and Setup Costs:** Computers don't just magically network themselves, of course. Setting up a network requires an investment in hardware and software, as well as funds for planning, designing and implementing the network. For a home with a small network of two or three PCs, this is relatively inexpensive, possibly amounting to less than a hundred dollars with today's low prices for network hardware, and operating systems already designed for networks. For a large company, cost can easily run into tens of thousands of dollars—or more.
- ☉ **Hardware and Software Management and Administration Costs:** In all but the smallest of implementations, ongoing maintenance and management of the network requires the care and attention of an IT professional. In a smaller organization that already has a system administrator, a network may fall within this person's job responsibilities, but it will take time away from other tasks. In more substantial organizations, a network administrator may need to be hired, and in large companies an entire department may be necessary.
- ☉ **Undesirable Sharing:** With the good comes the bad; while networking allows the easy sharing of useful information, it also allows the sharing of undesirable data. One significant “sharing problem” in this regard has to do with viruses, which are easily spread over networks and the Internet. Mitigating these effects costs more time, money and administrative effort.

- 
- ☹ **Illegal or Undesirable Behavior:** Similar to the point above, networking facilitates useful connectivity and communication, but also brings difficulties with it. Typical problems include abuse of company resources, distractions that reduce productivity, downloading of illegal or illicit materials, and even software piracy. In larger organizations, these issues must be managed through explicit policies and monitoring, which again, further increases management costs.
  - ☹ **Data Security Concerns:** If a network is implemented properly, it is possible to greatly improve the security of important data. In contrast, a poorly-secured network puts critical data at risk, exposing it to the potential problems associated with hackers, unauthorized access and even sabotage.

Most of these costs and potential problems can be managed; that's a big part of the job of those who set up and run networks. In the end, as with any other decision, whether to network or not is a matter of weighing the advantages against the disadvantages. Of course today, nearly everyone decides that networking *is* worthwhile.

**Key Concept:** Networking has a few drawbacks that balance against its many positive aspects. Setting up a network has costs in hardware, software, maintenance and administration. It is also necessary to manage a network to keep it running smoothly, and to address possible misuse or abuse. Data security also becomes a much bigger concern when computers are connected together.

---

---

# Fundamental Network Characteristics

There are many different kinds of networks, and network technologies used to create them. The proliferation of networking methods has generally occurred for a very good reason: different needs require different solutions. The drawback of this is that there are so many different types of protocols and technologies for the networking student to understand! Before you can really compare these approaches, you need to understand some of the basic characteristics that make networks what they are. While network types may be quite dissimilar, they are often described and even contrasted on the basis of a number of common attributes.

In this section, I introduce and discuss a number of key networking concepts that describe and differentiate different types of networks and networking technologies. I also introduce and define a number of terms and “buzzwords” that you cannot avoid if you are going to learn about networks. The topics here include explanations of protocols, switching methods, types of network messages, message formatting, and ways of addressing messages. I also discuss the differences between client-server and peer-to-peer networking.

**Note:** If you have considerable experience in networking, you may not need to read everything in this section. I'd suggest scanning the headings of the various topics here; if you understand the terminology mentioned in a topic's title, you can probably feel pretty safe in skipping it.

---

## Networking Layers, Models and Architectures

One of the reasons why many people find networking difficult to learn is that it can be a very complicated subject. One of the chief reasons for this complexity is that networks consist of so many hardware and software elements. While a network user may only perceive that he or she is using one computer program (like a Web browser) and one piece of hardware (like a PC), these are only parts of a much larger puzzle. In order for even the simplest task to be accomplished on a network, dozens of different components must cooperate, passing control information and data to accomplish the overall goal of network communication.

The best way to understand any complex system is to break it down into pieces and then analyze what they do and how they interact. The most logical approach for this is to divide the overall set of functions into modular components, each of which is responsible for a particular function. At the same time, we also need to define interfaces between these components, which describe how they fit together. This enables us to simplify the complexity of networking by approaching it in digestible chunks.

---

## Networking Layers

Networking technologies are most often compartmentalized in this manner by dividing their functions into *layers*, each of which contains hardware and/or software elements. Each layer is responsible for performing a particular type of task, as well as interacting with the layers above it and below it. Layers are conceptually arranged into a vertical stack. Lower layers are charged with more concrete tasks such as hardware signaling and low-level communication; they provide services to the higher layers. The higher layers in turn use these services to implement more abstract functions such as implementing user applications.

Dividing networks into layers this way is somewhat like the division of labor in a manufacturing facility, and yields similar benefits. Each hardware device or software program can be specialized to perform the function needed by that layer, like a well-trained specialist on an assembly line. The different modules can be combined in different ways as needed. Understanding how a network functions overall is also made much easier this way.

## Networking Models

One other important benefit of layering is that makes it possible for technologies defined by different groups to interoperate. For this to be possible, it is necessary for everyone to agree on how layers will be defined and used. The most common tool for this purpose is a *networking model*. The model describes what the different layers are in the network, what each is responsible for doing, and how they interact. A universally-accepted model ensures that everyone is on the same page when creating hardware and software.

The most common general model in use today is the *Open Systems Interconnection (OSI) Reference Model*, which concepts of seven stacked layers. These range from the Physical Layer (layer one) at the bottom, which is responsible for low-level signaling, to the Application Layer (layer seven) at the top, where application software is implemented. Understanding the OSI model is essential to understanding networking as a whole. I explain models and layers in more detail, as well as providing a complete description of the OSI Reference Model, in [its own dedicated section](#).

## Networking Architectures

Closely related to the concept of a model is that of an *architecture*. An architecture is essentially a set of rules that describes the function of some portion of the hardware and software that constitute a stack of layers. Such a ruleset usually takes the form of a specification or standard that describes how equipment and programs using the technology must behave. A networking architecture is designed to implement the functions associated with a particular contiguous set of layers of the OSI Reference Model, either formally or informally.

In this Guide we are, of course, interested in the TCP/IP protocol suite, which runs the Internet, and a complex set of technologies that spans many layers of the OSI model. It is by examining the various components of TCP/IP and how they implement different OSI model layers that we will really learn how TCP/IP works. For starters, the name of the suite, TCP/IP, comes from the Transmission Control Protocol (TCP), which operates at layer four

---

of the OSI model, and the Internet Protocol (IP) that runs at OSI model layer three. IP provides services to layer four and uses services of layer two below it. TCP uses IP's functions and provides functions to the layers above it. The complete examination of TCP/IP starts by looking at [its architecture and a second, special model](#) that was developed specifically to make sense of TCP/IP.

## **Protocols: What Are They, Anyway?**

If there's one word you will get used to seeing a lot as you go through this Guide, it is this one: *protocol*. You will see reference to networking protocols, internetworking protocols, high-level protocols, low-level protocols, protocol stacks, protocol suites, sub-protocols, and so on. Clearly protocols are important, yet many reference works and standards use the term over and over again without ever explaining it. One reason for this may be because the term is somewhat vague and can have many meanings, which can make it difficult to grasp.

### ***The Meaning of the Word "Protocol"***

In some cases, understanding a technical term is easier if we go back to look at how the term is used in plain English. In the real world, a protocol often refers to a code of conduct, or a form of etiquette observed by diplomats. These people must follow certain rules of ceremony and form to ensure that they communicate effectively, and without coming into conflict. They also must understand what is expected of them when they interact with representatives from other nations, to make sure that, for example, they do not offend due to unfamiliarity with local customs. Even we "normal people" follow protocols of various sorts, which are sort of the "unwritten rules of society".

This may seem to have little to do with networking, but in fact, this is a pretty good high-level description of what networking protocols are about. They define a language and a set of rules and procedures that enable devices and systems to communicate. Obviously, computers do not have "local customs", and they hardly have to worry about committing a "faux pas" that might cause another computer to take offense. What networking protocols concern themselves with is ensuring that all the devices on a network or internetwork are in agreement about how various actions must be performed in the total communication process.

So, a protocol is basically a way of ensuring that devices are able to talk to each other effectively. In most cases, an individual protocol describes how communication is accomplished between one particular software or hardware element in two or more devices. In the context of the [OSI Reference Model](#), a protocol is formally defined as a set of rules governing communication between entities at the same Reference Model layer. For example, the [Transmission Control Protocol \(TCP\)](#) is responsible for a specific set of functions on TCP/IP networks. Each host on a TCP/IP network has a TCP implementation, and they all communicate with each other logically at [layer four of the OSI model](#).

---

While OSI Reference Model definitions are sometimes overly theoretical in nature, this particular one is rather accurate in assessing protocols in real-world networking. If something doesn't specify a means of communication, it arguably isn't a protocol.

**Key Concept:** A *networking protocol* defines a set of rules, algorithms, messages and other mechanisms that enable software and hardware in networked devices to communicate effectively. A protocol usually describes a means for communication between corresponding entities at the same OSI Reference Model layer in two or more devices.

**Related Information:** The formalized OSI Reference Model meaning of the word “protocol” is covered in the [OSI model topic on horizontal layer communication](#).

### ***Different Uses of the Word “Protocol”***

Despite the strict OSI definition, the term “protocol” is often used colloquially to refer to many different concepts in networking. Some of the more common “alternative” uses of the word include the following:

- 🕒 **Protocol Suites:** It is very common to hear the word “protocol” used to refer to sets of protocols that are more properly called *protocol suites* (or *stacks*, in reference to a stack of layers). For example, TCP/IP is often called just a “protocol” when it is really a (large) set of protocols.

Sometimes, the name of the technology itself leads to this confusion. The [Point-to-Point Protocol \(PPP\)](#), for example, is not one protocol; it contains many individual protocols that serve different functions and even have distinct message formats. Thus, PPP is really a protocol suite, or alternately, can be considered a protocol with “sub-protocols”.

- 🕒 **Microsoft Windows Protocols:** One important example of the issue of referring to protocol suites as single protocols is the networking software in Microsoft Windows. It usually calls a full networking stack like [TCP/IP](#) or [IPX/SPX](#) just a “protocol”. When you install one of these “protocols”, however, you actually get a software module that supports a full protocol suite.
- 🕒 **Other Technologies:** Sometimes technologies that are not protocols at all are called protocols, either out of convention or perhaps because people think it sounds good. For example, [TCP/IP Remote Network Monitoring \(RMON\)](#) is often called a protocol when it is really just an enhancement to the [Simple Network Management Protocol \(SNMP\)](#)—which is a protocol!

---

So, does it really matter whether a protocol is a “true” protocol or not? Well, the networking hardware devices and software programs sure don’t care. ☺ But hopefully having read about the term and what it means, you will be able to better understand the word when you encounter it in your studies—especially in the places where it may not always be used in a way entirely consistent with its formal definition.

## **Circuit Switching and Packet Switching Networks**

In my “[grand overview](#)” of [networking](#), I describe networks as devices that are connected together using special hardware and software, to allow them to exchange information. The most important word in that sentence is the final one: *information*. As you will see in your exploration of this Guide, there are many methods for exchanging information between networked devices. There are also a number of ways of categorizing and describing these methods and the types of networks that use them.

One fundamental way of differentiating networking technologies is on the basis of the method they use to determine the path between devices over which information will flow. In highly simplified terms, there are two approaches: either a path can be set up between the devices in advance, or the data can be sent as individual data elements over a variable path.

### ***Circuit Switching***

In this networking method, a connection called a *circuit* is set up between two devices, which is used for the whole communication. Information about the nature of the circuit is maintained by the network. The circuit may either be a fixed one that is always present, or it may be a circuit that is created on an as-needed basis. Even if many potential paths through intermediate devices may exist between the two devices communicating, only one will be used for any given dialog. This is illustrated in [Figure 1](#).

The classic example of a circuit-switched network is the telephone system. When you call someone and they answer, you establish a circuit connection and can pass data between you, in a steady stream if desired. That circuit functions the same way regardless of how many intermediate devices are used to carry your voice. You use it for as long as you need it, and then terminate the circuit. The next time you call, you get a new circuit, which may (probably will) use different hardware than the first circuit did, depending on what's available at that time in the network.

### ***Packet Switching***

In this network type, no specific path is used for data transfer. Instead, the data is chopped up into small pieces called *packets* and sent over the network. The packets can be routed, combined or fragmented, as required to get them to their eventual destination. On the receiving end, the process is reversed—the data is read from the packets and re-

**Figure 1: Circuit Switching**

In a circuit-switched network, before communication can occur between two devices, a circuit is established between them. This is shown as a thick blue line for the conduit of data from Device A to Device B, and a matching purple line from B back to A. Once set up, all communication between these devices takes place over this circuit, even though there are other possible ways that data could conceivably be passed over the network of devices between them. Contrast this diagram to [Figure 2](#).

assembled into the form of the original data. A packet-switched network is more analogous to the postal system than it is to the telephone system (though the comparison isn't perfect.) An example is shown in [Figure 2](#).

**Figure 2: Packet Switching**

In a packet-switched network, no circuit is set up prior to sending data between devices. Blocks of data, even from the same file or communication, may take any number of paths as it journeys from one device to another. Compare this to [Figure 1](#)

**Key Concept:** One way that networking technologies are categorized is based on the path used to carry data between devices. In *circuit switching*, a circuit is first established and then used to carry all data between devices. In *packet switching* no fixed path is created between devices that communicate; it is broken into packets, each of which may take a separate path from sender to recipient.

---

### ***Comparing Circuit Switching and Packet Switching***

A common temptation when considering alternatives such as these is to ask which is “better”—and as usually is the case, the answer is “neither”. There are places where one is more suited than the other, but if one were clearly superior, both methods wouldn't be used.

One important issue in selecting a switching method is whether the network medium is *shared* or *dedicated*. Your phone line can be used for establishing a circuit because you are the only one who can use it—assuming you can keep that pesky wife/husband/child/sister/brother/father/mother off the phone.

However, this doesn't work well in LANs, which typically use a single shared medium and baseband signaling. If two devices were to establish a connection, they would “lock out” all the other devices for a long period of time. It makes more sense to chop the data into small pieces and send them one at a time. Then, if two other devices want to communicate, *their* packets can be interspersed and everyone can share the network.

The ability to have many devices communicate simultaneously without dedicated data paths is one reason why packet switching is becoming predominant today. However, there are some disadvantages of packet switching compared to circuit switching. One is that since all data does not take the same, predictable path between devices, it is possible that some pieces of data may get lost in transit, or show up in the incorrect order. In some situations this does not matter, while in others it is very important indeed.

While the theoretical difference between circuit and packet switching is pretty clear-cut, understanding how they are used is a bit more complicated. One of the major issues is that in modern networks, they are often combined. For example, suppose you connect to the Internet using a dial-up modem. You will be using IP datagrams (packets) to carry higher-layer data, but it will be over the circuit-switched telephone network. Yet the data may be sent over the telephone system in digital packetized form. So in some ways, both circuit switching and packet switching are being used concurrently.

Another issue is the relationship between circuit and packet switching, and whether a technology is connection-oriented or connectionless. The two concepts are related but not the same; [the next topic](#) discusses this in much more detail.

**Note:** Note that the word “packet” is only one of several terms that are used to refer to messages that are sent over a network. Other terms you will encounter include [frame](#), [datagram](#), [cell](#) and [segment](#).

---

## Connection-Oriented and Connectionless Protocols

In [the previous topic](#) I described and contrasted networking technologies based on whether or not they use a dedicated path, or *circuit*, over which to send data. Another way in which technologies and protocols are differentiated has to do with whether or not they use *connections* between devices. This issue is closely related to the matter of packet versus circuit switching.

### ***Division of Protocols into Connection-Related Categories***

Protocols are divided into two categories based on their use of connections:

- ☉ **Connection-Oriented Protocols:** These protocols require that a logical connection be established between two devices before transferring data. This is generally accomplished by following a specific set of rules that specify how a connection should be initiated, negotiated, managed and eventually terminated. Usually one device begins by sending a request to open a connection, and the other responds. They pass control information to determine if and how the connection should be set up. If this is successful, data is sent between the devices. When they are finished, the connection is broken.
- ☉ **Connectionless Protocols:** These protocols do not establish a connection between devices. As soon as a device has data to send to another, it just sends it.

**Key Concept:** A *connection-oriented* protocol is one where a logical connection is first established between devices prior to data being sent. In a *connectionless* protocol, data is just sent without a connection being created.

---

### ***The Relationship Between Connection Orientation and Circuits***

You can probably immediately see the relationship between the concepts of circuits and connections. Obviously, in order to establish a circuit between two devices, they must also be connected. For this reason, circuit-switched networks are inherently based on connections. This has led to the terms “circuit-switched” and “connection-oriented” being used interchangeably.

---

However, this is an oversimplification that results due to a common logical fallacy—people make the mistake of thinking that if A implies B, then B implies A, which is like saying that since all apples are fruit, then all fruit are apples. A connection is needed for a circuit, but a circuit is **not** a prerequisite for a connection. There are, therefore, protocols that are connection-oriented, while not being predicated on the use of circuit-based networks at all.

These connection-oriented protocols are important because they enable the implementation of applications that require connections, over packet-switched networks that have no inherent sense of a connection. For example, to use the TCP/IP [File Transfer Protocol](#), you want to be able to connect to a server, enter a login and password, and then execute commands to change directories, send or retrieve files, and so on. This requires the establishment of a connection over which commands, replies and data can be passed. Similarly, the [Telnet Protocol](#) obviously involves establishing a connection—it lets you remotely use another machine. Yet, both of these work (indirectly) over the IP protocol, which is based on the use of packets, through the principle of [layering](#).

To comprehend the way this works, one must have a basic understanding of the layered nature of modern networking architecture (as I discuss in some detail in [the chapter that talks about the OSI Reference Model](#)). Even though packets may be used at lower layers for the mechanics of sending data, a higher-layer protocol can create logical connections through the use of messages sent in those packets.

**Key Concept:** Circuit-switched networking technologies are inherently connection-oriented, but not all connection-oriented technologies use circuit switching. Logical connection-oriented protocols can in fact be implemented on top of packet switching networks to provide higher-layer services to applications that require connections.

---

### ***Connection-Oriented and Connectionless Protocols in TCP/IP***

Looking again at TCP/IP, it has two main protocols that operate at the [transport layer of the OSI Reference Model](#). One is the [Transmission Control Protocol \(TCP\)](#), which is connection-oriented; the other, the [User Datagram Protocol \(UDP\)](#), is connectionless. TCP is used for applications that require the establishment of connections (as well as TCP's other service features), such as FTP; it works using a set of rules, as described earlier, by which a logical connection is negotiated prior to sending data. UDP is used by other applications that don't need connections or other features, but do need the faster performance that UDP can offer by not needing to make such connections before sending data.

Some people consider this to be like a “simulation” of circuit-switching at higher network layers; this is perhaps a bit of a dubious analogy. Even though a TCP connection can be used to send data back and forth between devices, all that data is indeed still being sent as packets; there is no real circuit between the devices. This means that TCP must deal with all the potential pitfalls of packet-switched communication, such as the potential for data

---

loss or receipt of data pieces in the incorrect order. Certainly, the existence of connection-oriented protocols like TCP doesn't obviate the need for circuit switching technologies, though you will get some arguments about that one too. ☺

The principle of layering also means that there are other ways that connection-oriented and connectionless protocols can be combined at different levels of an internetwork. Just as a connection-oriented protocol can be implemented over an inherently connectionless protocol, the reverse is also true: a connectionless protocol can be implemented over a connection-oriented protocol at a lower level. In a preceding example, I talked about Telnet (which requires a connection) running over IP (which is connectionless). In turn, IP can run over a connection-oriented protocol like ATM.

## **Messages: Packets, Frames, Datagrams and Cells**

Many networking technologies are based on [packet switching](#), which involves the creation of small chunks of data to be sent over a network. Even though the word “packet” appears in the name of this method, the data items sent between networked devices are most generically called *messages*. “Packet” is one of a variety of similar words that are used in different contexts to refer to messages sent from one device to another.

In some cases these different terms can be very useful; simply the type of name used for the message can tell you something about what the message contains. In particular, different message names are usually associated with protocols and technologies operating at specific layers of the [OSI Reference Model](#). Thus, the use of these different names can help clarify discussions that involve multiple protocols operating at different layers.

Unfortunately, these terms can also cause confusion, because they are not always applied in a universal or even consistent manner. Some people are strict about applying particular message designations only to the appropriate technologies where they are normally used, while others use the different terms completely interchangeably. This means that you should be familiar with the different message types and how they are normally used, but be prepared for the unexpected.

### ***Common Names For Messages***

The most common terms that are used for messages are the following:

- ☉ **Packet:** This term is considered by many to most correctly refer to a message sent by protocols operating at the [network layer](#) of the OSI Reference Model. So, you will commonly see people refer to “IP packets”. However, this term is commonly also used to refer generically to any type of message, as I mentioned at the start of this topic.
- ☉ **Datagram:** This term is basically synonymous with “packet” and is also used to refer to network layer technologies. It is also often used to refer to a message that is sent at a higher level of the OSI Reference Model (more often than “packet” is).

- 
- ☞ **Frame:** This term is most commonly associated with messages that travel at low levels of the OSI Reference Model. In particular, it is most commonly seen used in reference to [data link layer](#) messages. It is occasionally also used to refer to [physical layer](#) messages, when message formatting is performed by a layer one technology. A frame gets its name from the fact that it is created by taking higher-level packets or datagrams and “framing” them with additional header information needed at the lower level.
  - ☞ **Cell:** Frames and packets, in general, can be of variable length, depending on their contents; in contrast, a *cell* is most often a message that is fixed in size. For example, the fixed-length, 53-byte messages sent in Asynchronous Transfer Mode (ATM) are called cells. Like frames, cells usually are used by technologies operating at the lower layers of the OSI model.
  - ☞ **Protocol Data Unit (PDU) and Service Data Unit (SDU):** These are the formal terms used in the OSI Reference to describe protocol messages. A PDU at layer N is a message sent between protocols at layer N. It consists of layer N header information and an encapsulated message from layer N+1, which is called both the *layer N SDU* and the *layer N+1 PDU*. After you stop scratching your head, see [the topic on OSI model data encapsulation](#) for a discussion of this that may actually make sense. ☺

I should also point out that there are certain protocols that use unusual names to refer to their messages, which aren’t used elsewhere in the world of networking. One prominent example is the [Transmission Control Protocol \(TCP\)](#), which calls its messages *segments*.

**Key Concept:** Communication between devices on packet-switched networks is based on items most generically called *messages*. These pieces of information also go by other names such as *packets*, *datagrams*, *frames* and *cells*, which often correspond to protocols at particular layers of the OSI Reference Model. The formal OSI terms for messages are *protocol data unit (PDU)* and *service data unit (SDU)*.

---

### **Message Terminology in this Guide**

As for this Guide and its use of these terms, I have made a specific effort not to imply anything about the nature of a message solely based on the name it uses, but I do to follow the most common name used for a particular technology. For example, messages sent over Ethernet are almost always called Ethernet frames—they are not generally called Ethernet datagrams, for example. However, I do not structure discussions so that the type of name used for a message is the only way to determine what sort of message it is.

---

## Message Formatting: Headers, Payloads and Footers

*Messages* are the structures used to send information over networks. They vary greatly from one protocol or technology to the next in how they are used, and as I described in [the previous topic](#), they are also called by many different names. Shakespeare had the right idea about names, however. The most important way that messages differ is not in what they are called but in terms of their *content*.

Every protocol uses a special *formatting method* that determines the structure of the messages it employs. Obviously, a message that is intended to connect a Web server and a Web browser is going to be quite different from one that connects two Ethernet cards at a low level. This is why I separately describe the formats of dozens of different protocol messages in various parts of this Guide.

### ***Fundamental Message Elements***

While the format of a particular message type depends entirely on the nature of the technology that uses it, messages on the whole tend to follow a fairly uniform overall structure. In generic terms, each message contains the following three basic elements (see [Figure 3](#)):

- **Header:** Information that is placed before the actual data. The header normally contains a small number of bytes of control information, which is used to communicate important facts about the data that the message contains and how it is to be interpreted and used. It serves as the communication and control link between protocol elements on different devices.
- **Data:** The actual data to be transmitted, often called the *payload* of the message (metaphorically borrowing a term from the space industry!) Most messages contain some data of one form or another, but some actually contain none: they are used only for control and communication purposes. For example, these may be used to set up or terminate a logical connection before data is sent.
- **Footer:** Information that is placed after the data. There is no real difference between the header and the footer, as both generally contain control fields. The term *trailer* is also sometimes used.

Since the header and footer can both contain control and information fields, you might rightly wonder what the point is of having a separate footer anyway. One reason is that some types of control information are calculated using the values of the data itself. In some cases, it is more efficient to perform this computation as the data payload is being sent, and then transmit the result after the payload in a footer. A good example of a field often found in a footer is redundancy data, such as a CRC code, that can be used for error detection by the receiving device. Footers are most often associated with lower-layer protocols, especially at the [data link layer](#) of the OSI Reference Model.

**Figure 3: Network Message Formatting**

In the most general of terms, a message consists of a *data payload* to be communicated, bracketed by a set of *header* and *footer* fields. The data of any particular message sent in a networking protocol will itself contain an encapsulated higher-layer message containing a header, data, and footer. This “nesting” can occur many times as data is passed down a protocol stack. The header is found in most protocol messages; the footer only in some.

**Key Concept:** The general format of a networking message consists of a *header*, followed by the *data* or *payload* of the message, followed optionally by a *footer*. Header and footer information is functionally the same except for position in the message; footer fields are only sometimes used, especially in cases where the data in the field is calculated based on the values of the data being transmitted.

### ***Interpretation of Message Elements***

Generally speaking, any particular protocol is only concerned with its *own* header (and footer, if present). It doesn't care much about what is in the data portion of the message, just as a delivery person only worries about driving the truck and not so much on what it contains. At the beginning of that data will normally be the headers of other protocols that were used higher up in the protocol stack; this too is shown in [Figure 3](#). In the OSI Reference Model, a message handled by a particular protocol is said to be its *protocol data unit* or *PDU*; the data it carries in its payload is its *service data unit* or *SDU*. The SDU of a lower-layer protocol is usually a PDU of a higher-layer protocol. [The discussion of data encapsulation](#) contains a full explanation of this important concept.

## **Message Addressing and Transmission Methods: Unicast, Broadcast and Multicast Messages**

In a networking technology that uses messages to send data, there are a number of tasks that must be undertaken in order to successfully transmit the data from one place to another. One is simply the *addressing* of the message—putting an address on it so that the system knows where it is supposed to go. Another is *transmitting* the message, which is of course sending it to its intended recipient.

---

There are several different ways of addressing and transmitting a message over a network. One way in which messages are differentiated is in how they are addressed, and to how many recipients. Which method is used depends on what the function of the message is, and also on whether or not the sender knows specifically whom they are trying to contact, or only generally.

### ***Message Transmission Methods***

To help explain these different methods, I will use a real-world analogy. Consider a social function with 300 people that is being held in a large hall. These people are mingling and are having different conversations. There are different kinds of messages that may need to be sent in this setting, much as is the case with networks.

Bearing this analogy in mind, consider these three kinds of message transmissions, which are illustrated in [Figure 4](#):

- 🕒 **Unicast Messages:** These are messages that are sent from one device to another device; they are not intended for others. If you have a friend at this social event, this is the equivalent of pulling him or her aside for a private conversation. Of course, there is still the possibility of someone else at the event overhearing your conversation—or even eavesdropping on it. The same is true in networking as well—addressing a message to a particular computer doesn't guarantee that others won't also read it, just that they normally will not do so.
- 🕒 **Broadcast Messages:** As the name suggests, these messages are sent to every device on a network. They are used when a piece of information actually needs communicating to everyone on the network, or used when the sending station needs to send to just one recipient, but doesn't know its address.

For example, suppose a new arrival at the social gathering saw a blue sedan with New Hampshire plates in the parking lot that had its lights left on. He of course does not know whose car this is. The best way to communicate this information is to broadcast it by having the host make an announcement that will be heard by all, including the vehicle's owner. In networks, broadcast messages are used for a variety of purposes, including finding the locations of particular stations or the devices that manage different services.

- 🕒 **Multicast Messages:** These are a compromise between the previous two types: they are sent to a group of stations that meet a particular set of criteria. These stations are usually related to each other in some way, such as serving a common function, or being set up into a particular *multicast group*. (Note that one can also consider broadcast messages to be a special case of multicast, where the group is “everyone”.)

Back to our analogy: this would be somewhat like a group of friends who go to this large social hall and then stay together in a small discussion group—or perhaps use radios to talk to each other from a distance. Multicasting requires special techniques that make clear who is in the intended group of recipients.

**Figure 4: Unicast, Multicast and Broadcast Message Addressing and Transmission**

The three basic type of addressing and message delivery in networking are illustrated in this simplified local area network. Device #6 is sending a *unicast* message to #2 shown in purple. Device #4 is sending a *multicast* message to multicast group "X". In this case, that group includes devices #1 and #3, shown in green. Finally, Device #5 is sending a *broadcast* message, which goes to all other devices on the LAN.

### **Message Addressing Methods**

Since the transmission methods above differ based on how many and which devices receive the transmission, they are tied directly to the methods used for addressing:

- 🕒 **Unicast Addressing:** Unicast delivery requires that a message be addressed to a specific recipient. This is the most common type of messaging, so this addressing capability is present in almost all protocols.
- 🕒 **Broadcast Addressing:** Broadcasts are normally implemented via a special address that is reserved for that function. Whenever devices see a message sent to that address, they all interpret it as meaning "this message goes to everyone".

- 
- ☛ **Multicast Addressing:** Multicasts are the most complex type of message because they require a means of identifying a set of specific devices to receive a message. It is often necessary to create several such groups, which may or may not partially overlap in their membership. Some mechanism is needed to manage which devices are in which groups.

---

**Key Concept:** Three basic methods are used to address and transmit data between networked devices. A *unicast* transmission goes from one device to exactly one other; this is the “normal” method used for most message transactions. A *broadcast* transmission is sent from one device to all connected devices on a network. A *multicast* transmission is addressed and sent to a select group of devices.

---

---

**Note:** A new type of message addressing method was defined as part of [IP version 6](#): the *anycast* message. This term identifies a message that should be sent to the closest member of a group of devices. [The topic on IPv6 multicast and anycast addressing](#) describes this type of addressing and transmission.

---

Finally, one special case in the field of addressing is worth mentioning. In some networks or links, only two devices are connected together, forming what is often called a *point-to-point network*. In this situation, everything sent by one device is implicitly intended for the other, and vice-versa. Thus, no addressing of messages on a point-to-point link is strictly necessary.

## Network Structural Models and Client/Server and Peer-to-Peer Networking

I mentioned in [my discussion of the advantages of networking](#) that networks are normally set up for two primary purposes: *connectivity* and *sharing*. If you have a network with a number of different machines on it, each computer can interact with the hardware and software of the others, to enable a variety of tasks to be performed. How precisely this is done depends to a large degree on the overall design of the network.

### ***Resource Sharing Roles and Structural Models***

One very important issue in network design is how to configure the network for the sharing of resources. Specifically, the network designer must decide whether or not to dedicate resource management functions to the devices that constitute it. In some networks, all devices are treated equal in this regard, while in others, each computer is responsible for a particular job in the overall function of providing services. In this latter arrangement, the devices are sometimes said to have *roles*, somewhat like actors in a play.

---

Two common terms are used to describe these different approaches to setting up a network, sometimes called choosing a *structural model*.

### Peer-to-Peer Networking

In a strict peer-to-peer networking setup, every computer is an equal, a *peer* in the network. Each machine can have resources that are shared with any other machine. There is no assigned role for any particular device, and each of the devices usually runs similar software. Any device can and will send requests to any other, as illustrated in [Figure 5](#).

**Figure 5: Peer-to-Peer Networking**

In this model, each device on the network is treated as a peer, or equal. Each device can send requests and responses, and none are specifically designated as performing a particular role. This model is more often used in very small networks. Contrast to [Figure 6](#).

---

## Client/Server Networking

In this design, a small number of computers are designated as centralized *servers* and given the task of providing services to a larger number of user machines called *clients*. The servers are usually powerful computers with a lot of memory and storage space, and fast network connections. The clients are typically smaller, “regular” computers like PCs, optimized for human use.

The term “client/server” also frequently refers to protocols and software, which are designed with matching, complementary components. Usually, server software runs on server hardware, and client software is used on client computers that connect to those servers. Most of the interaction on the network is between client and server, and not between clients, as shown in [Figure 6](#). Server software is designed to efficiently respond to requests, while client software provides the interface to the human users of the network.

**Figure 6: Client/Server Networking**

In the client/server model, a small number of devices are designated as servers and equipped with special hardware and software that allows them to more efficiently interact simultaneously with multiple client machines. While the clients can still interact with each other, most of the time they send requests of various sorts to the server, and the server sends back responses to them. Contrast this to the peer-to-peer networking example in [Figure 5](#).

**Key Concept:** Networks are usually configured to share resources using one of two basic *structural models*. In a *peer-to-peer network*, each device is an equal and none are assigned particular jobs. In a *client/server network*, however, devices are assigned particular roles—a small number of powerful computers are set up as *servers* and respond to requests from the other devices, which are *clients*. Client/server computing also refers to the interaction between complementary protocol elements and software programs, and is rising in popularity due to its prevalence in TCP/IP and Internet applications.

---

### ***Comparing Client/Server and Peer-to-Peer Networking***

The choice of client/server or peer-to-peer is another where there is no “right answer” in this regard. Which should be used depends entirely on the needs of the particular network.

Peer-to-peer networking has primary advantages of simplicity and low cost, which means it has traditionally been used on small networks. Client/server networking provides advantages in the areas of performance, scalability, security and reliability, but is more complicated and expensive to set it up. This makes it better-suited to larger networks. Over time, however, there has been a steady evolution towards client/server networking, even on smaller networks. Many years ago it was common to see even networks with 20 to 50 machines using the peer-to-peer model; today, even networks with only a half-dozen machines sometimes are set up in a client/server mode because of the advantages of centralized resource serving.

The rise in popularity of client/server networking is ironic because in some ways, it is actually a throwback to the days of large mainframes decades ago. A mainframe with attached terminals can be thought of as a client/server network with the mainframe itself being the server and the terminals being clients. This analogy is not perfect, of course, because modern client computers do a lot more work than dumb terminals do on mainframes.

One of the reasons why the client/server structural model is becoming dominant is that it is the primary model used by the world’s largest network: the Internet. Client/server architecture is the basis for most TCP/IP protocols and services. For example, the term “Web browser” is really another name for a “Web client”, and a “Web site” is really a “Web server”.

**Related Information:** For more information on client/server computing, I recommend you read [the topic devoted to TCP/IP client/server operation](#). That topic also contains a very relevant exposition on the different meanings of the terms “client” and “server” in hardware, software and transactional contexts.

---

---

## Types and Sizes of Networks

One of the reasons that understanding networks can be difficult at times is that there are so many different types! When someone talks about a “network”, this can mean anything from two computers hooked together in an apartment to a globe-spanning entity with millions of nodes. Every network is unique, and each one has an important role to play in filling the communication and data-sharing needs of different individuals and organizations. In fact, the great diversity and flexibility of networking is one of its most important strengths.

In this section I describe the major types of networks that exist by drawing distinctions between them based on their size and scope, and show how each type and size is used. I begin with a discussion of LANs, WLANs and WANs, and a few variations on these three main categories. I explore the many terms that are related to the various sizes of networks and how they are used, including segments, subnetworks, internetworks, intranets and extranets

**Note:** As with other networking fundamentals discussions, if you have some background or experience in networking, you may not need to read everything in this section. I'd suggest scanning the headings of the various topics here to get a handle for what you feel you need to read.

---

## Local Area Networks (LANs), Wireless LANs (WLANs) and Wide Area Networks (WANs) and Variants (CANs, MANs and PANs)

Two of the most basic ways that networks are differentiated and contrasted are the relative distances between the devices that they connect, and the general mechanisms used to communicate between them. The reason for making these distinctions is that the technological needs of a network differ greatly depending on the amount of ground you are trying to cover, and also on the overall way that you want to transmit and receive information.

### ***Fundamental Network Classifications***

Many people, including me, like to divide the many kinds of networks in existence into three general classes:

- ① **Local Area Networks (LANs):** Networks that connect together computers that are relatively close to each other—generally, within the same room or building. When most people think about networking PCs and other small computers, this is what they usually have in mind. The vast majority of regular LANs connect using cables, so the term “LAN” by itself usually implies a wired LAN, but not always.

- 
- ☉ **Wireless Local Area Networks (Wireless LANs or WLANs):** Local area networks that connect devices without wires, using radio frequencies or light. WLANs can be entirely wireless, but most are not: they usually connect wireless devices to each other and also to the wired portion of the network. Due to the limits of most wireless technologies, wireless LANs usually connect devices that are very close to each other, generally within a few hundred feet at most.
  - ☉ **Wide Area Networks (WANs):** Networks that connect together devices or other networks over a greater distance than is practical for local area networking. If the distance between devices can be measured in miles, you will generally use WAN and not LAN technology to link them.

More often than not, WANs are used to link together physically distant LANs. For example, a company with locations in two different cities would normally set up a LAN in each building and then connect them together in a WAN. I also consider most Internet access technologies to be a form of wide area networking, though some might not agree with that. There is also the term *wireless WAN* (*WWAN*), which just refers to a WAN that uses wireless technology.

### ***Difficulties in Categorizing Network Classes***

As with most other distinctions and categorizations in the world of networking, the lines between these various definitions are not very concrete. As I mentioned already, wireless LANs are usually not entirely wireless, because they contained wired elements. Similarly, trying to say absolutely when a network is “local” and when it is “wide” is difficult.

It's also somewhat pointless to spend too much energy on differentiating these network classes precisely. In some cases it's not the definitions that decide what technology to use, but rather the technology that indicates what kind of network you have! Since some protocols are designed for wide area networking, if you are using them, many would say you have a WAN, even if all the devices in that technology are near each other. On the other hand, some LAN technologies allow the use of cables that can run for many miles; most would still consider a mile-long Ethernet fiber link to be a LAN connection, even though it may span WAN distances.

There are many dimensions in which local and wide area networking technologies differ; two of the most important are *cost* and *performance*. It's easy to establish a high-speed conduit for data between two systems that are in the same room; much more difficult if the two are in different states. This means that in the world of WAN, one either pays a lot more or gets a lot less throughput—and often both.

### ***“Intermediate” Network Types***

The blurry line between LAN and WAN is becoming more muddled every years. One reason is the emergence of “intermediate” network types that straddle the line between these more familiar terms.

- 
- ② **Campus Area Networks (CANs):** A *campus area network (CAN)* is one created to span multiple buildings in the same location, such as the campus of a university. Campus area networking is a “gray area”, since neither LANs nor WANs alone are always well-suited for this type of application. Often, a mix of LAN and WAN techniques are used for campus networking, depending on the characteristics of the campus and the needs of the organization.
  - ② **Metropolitan Area Networks (MANs):** Another “intermediate” term that you may see sometimes is the *metropolitan area network* or *MAN*. As the name implies, this refers to a network that spans a particular small region or a city. Metropolitan area networks can be considered either as “small WANs” that cover a limited geographical area, or as “large LANs” that cover an area greater than that normally associated with a local network. Wireless metropolitan area networks are of course sometimes called *WMANs*; IEEE 802.16 is an example of a WMAN standard.

### ***Personal Area Networks (PANs)***

Finally, there is one other term occasionally used that should be mentioned: the *personal area network (PAN)*. This type of network generally means a very small LAN with a range of only a few feet, intended mostly to connect together devices used by a single person (or very small group). The term is most commonly used in reference to Bluetooth / IEEE 802.15 wireless technology, so you will sometimes see the terms *wireless personal area network (WPAN)* and just *PAN* used interchangeably.

**Key Concept:** Networks are often divided by size and general communication method into three classes. *Local area networks (LANs)* generally connect together proximate devices, usually using cables. *Wireless LANs (WLANs)* are like cabled LANs but use radio frequency or light technology to connect devices without wires. *Wide area networks (WANs)* connect distant devices or LANs to each other. *Campus area networks (CANs)* and *metropolitan area networks (MANs)* fall between *LANs* and *WANs* in terms of overall size; *personal area networks (PANs)* are like very small LANs and often appear as *wireless PANs (WPANs)*.

---

## **Segments, Networks, Subnetworks and Internetworks**

One of the reasons that networks are so powerful is that they can not only be used to connect computers together, but to connect groups of computers together. Thus, network connections can exist at multiple levels; one network can be attached to another network, and that entire whole can be attached to another set of networks, and so on. The ultimate example of this is, of course, the Internet, a huge collection of networks that have been interconnected into... dare I say a “Web”? ☺

This means a larger network can be described as consisting of several smaller networks or even parts of networks that are linked together. Conversely, we can talk about taking individual networks or network portions and assembling them into larger structures. The

---

reason why this concept is important is that certain technologies are best explained when looking at an entire large network at a high level, while others really require that we drill down to the detailed level of how constituent network pieces work.

### ***Common Terms Describing the Size of Networks***

Over time, a collection of terms has evolved in the networking world to describe the relative sizes of larger and smaller networks. Understanding these different terms is important not only for helping you comprehend what you read about networks, but also because they are important concepts in network design. This is particularly true for local area networking, where decisions regarding how to set up segments and how to connect them to each other have an important impact on the overall performance and usability of the network. Here are some of the most common ones.

#### **Network**

This is the least specific of the terms mentioned here. Basically, a network can be of pretty much any size, from two devices to thousands. When networks get very large, however, and are clearly comprised of smaller networks connected together, they are often no longer called networks but internetworks, as we will see momentarily. Despite this, it is fairly common to hear someone refer to something like “Microsoft’s corporate network”, which obviously contains thousands or even tens of thousands of machines.

#### **Subnetwork (Subnet)**

A subnetwork is a portion of a network, or a network that is part of a larger internetwork. This term is also a rather subjective one; subnetworks can in fact be rather large when they are part of a network that is very large.

The abbreviated term “subnet” can refer generically to a subnetwork, but also has a [specific meaning in the context of TCP/IP addressing](#).

#### **Segment (Network Segment)**

A segment is a small section of a network. In some contexts, a segment is the same as a subnetwork and the terms are used interchangeably. More often, however, the term “segment” implies something smaller than a subnetwork. Networks are often designed so that, for the sake of efficiency, with computers that are related to each other or that are used by the same groups of people put on the same network segment.

This term is notably problematic because it is routinely used in two different ways, especially in discussions related to Ethernet. The earliest forms of Ethernet used coaxial cables, and the coax cable itself was called a “segment”. The segment was shared by all devices connected to it, and became the *collision domain* for the network (a phrase referring generally to a collection of hardware devices where only one can transmit at a time.)

---

Each Ethernet physical layer had specific rules about how many devices could be on a segment, how many segments could be connected together, and so on, depending on what sort of network interconnection devices were being used. Devices such as hubs and repeaters were used to extend collision domains by connecting together these segments of cable into wider networks. Over time, the terms “collision domain” and “segment” started to be used interchangeably. Thus today a “segment” can refer either to a specific piece of cable, or to a collection of cables connected electrically that represent a single collision domain.

---

**Note:** As if that potential ambiguity in the use of the word “segment” isn’t bad enough, it also has another, totally unrelated meaning: it is the name of [the messages sent in the Transmission Control Protocol](#)!

---

### Internetwork (or Internet)

Most often, this refers to a larger networking structure that is formed by connecting together smaller ones. Again, the term can have either a generic or a specific meaning, depending on context. In some technologies, an internetwork is just a very large network that has networks as components. In others, a network is differentiated from an internetwork based on how the devices are connected together.

An important example of the latter definition is TCP/IP, where a network usually refers to a collection of machines that are linked at [layer two of the OSI Reference Model](#), using technologies like Ethernet or Token Ring and interconnection devices such as hubs and switches. An internetwork is formed when these networks are linked together at [layer three](#), using routers that pass Internet Protocol datagrams between networks. Naturally, this is highly simplified, but in studying TCP/IP you should keep this in mind when you encounter the terms “network” and “internetwork”.

---

**Note:** The shorter form of the word internetwork (“internet”) is often avoided by people who wish to avoid confusion with the proper noun form (“The Internet”). The latter of course refers only to the [well-known global internetwork of computers](#) and all the services it provides. I personally try to use the word “internetwork” most of the time in this Guide instead of “internet”, for this very reason.

---

**Key Concept:** Several terms are often used to describe the relative sizes of networks and parts of networks. The most basic term is *network* itself, which can refer to most anything, but often means a set of devices connected using an OSI layer two technology. A *subnetwork* is a part of a network (or internetwork), as is a *segment*, though the latter often has a more specific meaning in certain technologies. An *internetwork* refers either generically to a very large network, or specifically to a set of layer-two networks connected using routers at layer three.

---

## The Internet, Intranets and Extranets

I mentioned in [the topic discussing segments, networks, subnetworks and internetworks](#) that the Internet is really the king of internetworks. After all, you don't get to be called "the" something unless you pretty much define it.

In fact, the Internet is not just a large internetwork, but substantially more. The Internet is defined not just as the computers that are connected to each other around the world, but as the set of services and features that it offers. More than that, the Internet defines a specific way of doing things, of sharing information and resources between people and companies. And though it might be a bit melodramatic to say so, to many people the Internet is a way of life. As Internet use and popularity exploded in the 1990s, many people realized that the techniques and technologies used on the Internet would be useful if applied to internal company networks as well. The term *intranet* was coined to refer to an internal network that functioned like a "private Internet". It comes from the prefix "intra", which means "within". Of course, "inter" is the opposite of "intra", so this makes some people think that an "intranet" is the opposite of an "internet". In fact, most intranets **are** internetworks as well!

As if that weren't bad enough from a jargon standpoint, the buzzword buzzards then decided to take matters a step further. If an intranet is "extended" to allow access to it not only strictly from within the organization, but also by people or groups outside the main company, this is sometimes called an *extranet*. "Extra" of course, is a prefix that means "outside" or "beyond".

So, an extranet is a type of internal, private Internet that, uh, well, isn't entirely internal. An extranet is an extended intranet, which is really a type of internet that works like the Internet. (You can start to see why I am not a big fan of these fancy terms. But then, I don't get to choose them; I just have to help you understand them!) An extranet isn't public and open to all—it is controlled by a private organization. At the same time, it isn't entirely private either.

As you can see, the lines between the Internet, intranets and extranets were pretty blurry from the start, and the concepts are rapidly blending into a diffuse mass of gray, as the whole computing world becomes more tightly integrated. For example, even if you have an entirely private intranet, you will want to connect it to the Internet to communicate with the

---

“outside world” and to allow access to Internet resources. And an extranet may be implemented, in part, through the public Internet infrastructure, using technologies such as virtual private networking (VPN). I think you get the picture.

The key that binds all of these concepts together is that they all use “Internet technologies”, a term that is itself somewhat vague. This usually refers to the use of the [TCP/IP protocol suite](#), which is the defining technology of the Internet, as well as the set of services that are available on the Internet.

The bottom line is that being told that a company has an “intranet” or an “extranet”—as opposed to a plain old boring “network”—doesn’t tell you much at all. It is best not to rely on the slogans and instead look at the underlying characteristics of the network or internetwork itself. Furthermore, when designing such a network, focus on using the technologies and protocols that make sense—let the marketing people decide what to call it later. 😊

**Key Concept:** The generic noun *internet* is a short form for the word *internetwork*, while the proper noun *Internet* refers to the global internetwork of TCP/IP networks we all know and use. The term *intranet* refers to an internal network that uses TCP/IP technologies like the Internet does. An *extranet* is like an intranet that is extended to individuals or organizations outside the company. All these terms can be used ambiguously, so care must be taken in determining exactly what they mean in any given context.

---

---

## **Network Performance Issues and Concepts**

Networking is largely about connecting together devices so that information can be shared between them. Since the idea is to send data from one place to another, a very important characteristic of any network is its *speed*: how fast can data be transmitted and received? This matter of speed turns out to be only one of several issues that determine the overall *performance* of a network. The issue is complex enough that I decided a section was warranted to introduce the various related topics and help you understand how to look at network performance in a balanced way. When it comes to network performance, there's a *lot* of hype out there!

In the computing world, performance is, in general, one of the most often discussed but least well-understood characteristics of any system or hardware device. This is true of networking as well. For example, most people know the raw throughput rating of their network hardware, and may even start to draw conclusions about its capabilities based on those numbers. Many, however, don't realize that they will never actually achieve that "rated" amount of performance in the real world.

Most of the other "subtle" issues related to performance are also typically ignored or misunderstood, such as the impact of software drivers on hardware performance, and the fact that certain applications need more than just raw bit speed—they need **reliable** delivery of data. But even beyond all of this, one of the most important issues related to network performance is understanding what your needs are, to make sure you don't spend too much money for performance you don't need—or worse, create a network that can't meet your requirements.

In this section, I discuss various performance issues and concepts that are related to networking in one way or another. First and foremost, I try to put performance in context, and also contrast it with non-performance issues. Then, I talk about several key performance terms and metrics: speed, bandwidth, throughput and latency. I also talk about some of the units used to measure network performance. I then explain how the real-world performance of a network differs from its theoretical performance, and talk about factors that have an impact on network performance. I conclude by contrasting full-duplex and half-duplex network operation, and talking about quality of service, a concept that is especially important in the use of networks for real-time applications such as streaming multimedia.

## **Putting Network Performance In Perspective**

*Performance* is probably the "mother of all buzzwords" in the computer industry. There are many people who consider it the ultimate goal of any computer or computer system, and by extension, any network. A lot of people spend many dollars and hours of time trying to maximize it. There's good reason for this: performance *is* very important. A network that does not offer adequate performance simply will not get the job done for those that rely on

---

it. However, it is very important to keep performance in perspective. Successfully maximizing performance requires that you first take a step back and look at the issue in a big picture way.

The first question you must ask yourself is also the most essential one: how important is performance to you? Before you answer this question, recall the old auto racing adage: “speed costs money—how fast do you want to go?” While there are some situations where you can get much better performance in a network by spending just a little more money, in general, you don't get more performance without paying for it in some way. That may mean more dollar cost for the network, or it may mean a trade-off of some non-performance characteristic.

If you are designing or specifying a network, it's very important to keep in mind that your goal is to come up with a system that will meet the needs that were determined for it during requirements analysis. This means coming up with a network that has a level of performance that matches the requirements, and of course leaves some room for expansion. Unless you have an unlimited budget—and who does?—your objective is not “performance at any cost”. It is to create a network that meets **all** of your users' needs, including [balancing performance and non-performance characteristics](#).

A primary reason why I make a point of trying to keep performance in perspective is that so many others do not—especially those who are trying to sell you things. Companies are constantly coming out with the “latest and greatest” high-performance networking technologies. The usual way that they try to sell them is by attempting to convince everyone that they just cannot live without this latest advance; that they “need” to upgrade—immediately, if not sooner! Well, it's simply not the case. As just one example, even though Ethernet hardware now exists that runs with a theoretical throughput of 10,000 megabits per second, there are many older networks that continue to work just fine at a hundredth that speed—or even a thousandth!

Finally, remember that designing a network is usually not an “irreversible”, permanent decision. Networks can be upgraded and expanded. While it is prudent to build some “slack” into any network to allow for growth, it is not wise to spend too much on planning for the future when changes can be made later. This is especially true given that network hardware prices drop over time. Again here, this is a matter of drawing an appropriate balance between future performance planning and budget.

## **Balancing Network Performance with Key Non-Performance Characteristics**

We all know that performance is very important to any network. However, anyone putting together a network must also be concerned with many different non-performance characteristics as well. Depending on the network, these can be just as essential to the users of the network as performance, and possibly even more critical. More than this, non-performance issues often **trade off** against performance, and in fact, often more than not one has to be reduced to get performance to increase.

---

So, if you want to create a very-high-performance network, you need to understand the key non-performance network characteristics where you may need to compromise. Here are a few of these issues, and specifically how they relate to performance concerns:

- ☉ **Design and Implementation Cost:** Unless you have bottomless pockets, you need to be concerned with the network's costs. As mentioned in [the prior topic](#), cost is the main trade-off with performance. Going faster costs more money—not always, but usually.
- ☉ **Quality:** The quality of the network is a function of the quality of the components used and how they are installed. Quality is important because of its impact on all of the factors described here, such as reliability and ease of administration, as well as performance. Quality doesn't trade off **directly** with performance—you can design high-quality, high-performance networks—but it does **compete** with performance for resources such as budget. All else being equal, it costs a great deal more to implement a high-quality, high-performance network than a high-quality, low-speed one.
- ☉ **Standardization:** Network protocols and hardware can either be designed to meet universally-accepted standards, or non-standard, proprietary ones. Standard designs are almost always preferable, as they make interoperability, upgrading, support and training easier. Proprietary standards may include enhancements that improve performance, but may increase cost and/or make management more difficult.
- ☉ **Reliability:** This is related to several other issues, especially quality and performance. Faster networks aren't necessarily less reliable, but it's more difficult and expensive to run them as reliably as slower ones.
- ☉ **Expandability and Upgradability:** It's very important to always plan for the future when creating a network. Higher-performance networks can be more difficult to expand; they are certainly more expensive to expand. Once again, the matter of implementing a network with capacity for future needs now, as opposed to upgrading later if it becomes necessary, is an important network design decision.
- ☉ **Ease of Administration and Maintenance:** Higher-performance networks require more work and resources to administer and maintain, and are more likely to require troubleshooting, than slower ones.
- ☉ **Premises and Utility Issues:** Implementation of high-speed networks may be limited by the physical premises, or may have an impact on how they are laid out. Choosing a higher-speed option may require more infrastructure to be put in place, increasing cost. The classic example of this is seen in choosing between wired and wireless options for a home or small office network: with wires you can go much faster, but do you really want to run the wires?

Anyway, now you have a flavor of how performance balances against some of the other key issues in networking. The idea of this topic wasn't to convince you not to build a high-performance network, just to let you know part of the price you will pay.

**Key Concept:** While performance is one of the most important characteristics of any network, there are others that are equally important. In many cases, the cost, quality, reliability, expandability, maintainability and other attributes of a network may in fact trade off against overall performance. The faster you want your network to go, the more difficult it is to ensure these other attributes are kept at sufficiently high levels.

---

## Performance Measurements: Speed, Bandwidth, Throughput and Latency

There are a number of terms that are commonly used to refer to various aspects of network performance. Some of them are quite similar to each other, and you will often see them used—and in many cases, misused or even **abused**. ☺ It's a good idea for us to take a look at each of them, therefore, discuss how they are commonly used and what they really mean.

More than just the issue of different terms related to performance, however, is the more important reality that there are multiple **facets** to performance. Depending on the application, the manner in which data is sent across the network may be more important than the raw speed at which it is transported. In particular, many multimedia applications require real-time performance; they need data sent in such a manner that it will be delivered steadily. For these purposes, raw speed isn't as important as **consistent** speed, and this is an issue that is often not properly recognized.

### **Performance Measurement Terms**

Let's take a look at the most common performance measurement terms and see what they are all about.

#### **Speed**

This is the most generic performance term used in networking. As such, it can mean just about **anything**. Most commonly, however, it refers to the *rated* or *nominal* speed of a particular networking technology. For example, Fast Ethernet has a nominal speed of 100 megabits per second; it is for that reason often called 100 Mbit Ethernet, or given a designation such as “100BASE-TX”.

Rated speed is the biggest “performance magic number” in networking—you see it used to label hardware devices, and many people bandy the numbers about as if they actually were the real “speed of the network”. The problem with using nominal speed ratings is that they are *theoretical* only, and as such, tell an incomplete story. No networking technology can run at its full rated speed, and many run **substantially** below it, due to [real-world performance factors](#).

---

Speed ratings such as “100 Mbps Ethernet” are also often referred to as the “throughput” of a technology, even though the maximum theoretical speed of a technology is more analogous to bandwidth than throughput, and the two are not identical. More on this in the next two bullet points.

## Bandwidth

Bandwidth is a widely-used term that usually refers to the data-carrying capacity of a network or data transmission medium. It indicates the maximum amount of data that can pass from one point to another in a unit of time. The term comes from the study of electromagnetic radiation, where it refers to the width of a band of frequencies used to carry data. It is usually given in a theoretical context, though not always.

Bandwidth is still used in these two senses: “frequency band width” and data capacity. For example, radio frequencies are used for wireless technologies, and the bandwidth of such technologies can refer to how wide the RF band is. More commonly, though, it refers to how much data can be sent down a network, and is often used in relative terms. For example, for Internet access, a cable or xDSL is considered “high bandwidth” access; using a regular analog modem is “low bandwidth”.

## Throughput

Throughput is a measure of how much actual data can be sent per unit of time across a network, channel or interface. While throughput can be a theoretical term like bandwidth, it is more often used in a practical sense, for example, to measure the amount of data actually sent across a network in the “real world”. Throughput is limited by bandwidth, or by rated speed: if an Ethernet network is rated at 100 megabits per second, that's the absolute upper limit on throughput, even though you will normally get quite a bit less. So, you may see someone say that they are using 100 Mbps Ethernet but getting throughput of say, 71.9 Mbps on their network.

The terms bandwidth and throughput are often used interchangeably, even though they are really not exactly the same, as I just discussed.

**Key Concept:** The three terms used most often to refer to the overall performance of a network are *speed*, *bandwidth*, and *throughput*. These are related and often used interchangeably, but are not identical. The term *speed* is the most generic and often refers to the rated or nominal speed of a networking technology. *Bandwidth* can mean either the width of a frequency band used by a technology or more generally to data capacity, where it is more of a theoretical measure. *Throughput* is a specific measure of how much data flows over a channel in a given period of time. It is usually a practical measurement.

---

---

## Latency

This very important, often overlooked term, refers to the *timing* of data transfers on a communications channel or network. One important aspect of latency is how long it takes from the time a request for data is made until it starts to arrive. Another aspect is how much control a device has over the timing of the data that is sent, and whether the network can be arranged to allow for the consistent delivery of data over a period of time. Low latency is considered better than high latency.

### ***Applying Performance Measurement Terms***

As with all networking terms, there are no hard and fast rules; many people are rather loose with their use of the terms above. You will even see terms such as “throughput bandwidth”, “bandwidth throughput” and other charming inventions from the department of redundancy department. ☺ More often, you will just see a lot of mish-mashed term usage, and especially, spurious conclusions being drawn about what data streams a network can handle based on its rated speed. Making matters worse is that speed ratings are usually specified in bits per second, but throughput may be given in bits or bytes per second.

In general, “speed”, bandwidth and throughput get a lot of attention, while latency gets little. Yet latency considerations are very important for many real-time applications such as streaming audio and video and interactive gaming. In fact, they are often more important than raw bandwidth.

For example, suppose you move to a rural home and your choices for Internet access are a regular 28.8 kbps modem connection or fancy satellite Internet. The companies selling satellite connectivity call it “broadband” and advertise very high rated speeds—400 kbps or more. They make a big deal about it being “over 10 times as fast as dialup” and they certainly charge a lot for this very high-tech service. This is a slam dunk, right?

Wrong. The satellite connection has high bandwidth, but very poor (high) latency due to the time it takes for the signals to travel to and from the satellite. It is definitely much better than the modem for downloading that nice little 150 MB patch from Microsoft. However, it is much **worse** than the modem for playing the latest online video game with your buddy over the Internet, because of the latency, or *lag*, in transmissions. Every move you make in your game will be delayed for over half a second as the signal bounces around between the satellite and the earth, making online gaming nearly impossible. Thus, whether satellite Internet is worth the extra money depends entirely on what you plan to use it for.

**Related Information:** An important issue closely related to latency is quality of service, a general term that refers (among other things) to the ability of networks to deliver necessary bandwidth and reliable data transfer for applications that need it. [See the topic devoted to this subject later in this section.](#)

---

**Key Concept:** Where bandwidth and throughput indicate how fast data moves across a network, *latency* describes the nature of how it is conveyed. It is most often used to describe the delay between the time that data is requested and the time when it arrives. A networking technology with very high throughput and bad (high) latency can be worse for some applications than one with relatively low throughput but good (low) latency.

---

## Understanding Performance Measurement Units

People who make networking hardware, or write materials that try to tell you how to operate it, make use of many terms to describe performance, such as [throughput and bandwidth](#). In addition, they also use several different *units* to measure performance. Unfortunately—and I'm sure you knew this was coming—these units are often used incorrectly, and they are also very similar to each other in name. Worse, they also have overlapping abbreviations, and lots of people use these abbreviations without making clear what the heck they are talking about. Isn't that great?

### ***“Bits and Bytes”***

The first issue is “the infamous letter B”. Or rather, I should say, the matter of the “big B” and the “little b”. By popular convention, the capitalized “B” is supposed to be used for “byte”, and the lower-case “b” for bit—this is the way these abbreviations are always used in this Guide. (A byte is normally eight bits; sometimes the term *octet* is used instead. If you aren't familiar with these terms, refer to [the primer on binary basics](#), where you will also find a discussion of the small “controversy” related to bytes and octets.)

Unfortunately, this convention is not followed strictly by everyone. As a result, you may on occasion see “b” being used to refer to bytes, and “B” used for bits. This “b” and “B” business causes a tremendous amount of confusion sometimes, with people mistaking bits for bytes and accidentally thinking that networks are running eight times faster or slower than they really are.

Bear in mind when looking at speed ratings that they are almost always given in terms of bits, not bytes. The “56k” in a “56k modem” means 56,000 bits, not 56,000 bytes, of theoretical transfer speed. (This is true even if someone calls it a “56K” modem.) Similarly, Fast Ethernet operates at 100 megabits per second, not megabytes, and a 1.544 Mbps T-1 link sends a theoretical maximum of 1,544,000 bits each second. This, at least, is usually pretty consistent.

When it comes to throughput measurements, however, both bits and bytes are used, so you have to be careful. Raw throughput values are normally given in bits per second, but many software applications report transfer rates in bytes per second, including many Web browsers and FTP client programs. This often leads to users wondering why they are only getting one eighth of their expected download or transfer speeds.

**Key Concept:** In most cases in discussions of networking performance, the lower-case letter “b” refers to “bits” and the upper-case “B” to “bytes”. However, these conventions are not always universally followed, so context must be used to interpret a particular measurement.

---

### ***Throughput Measurement Units and the Kilo, Mega and Giga Multipliers***

The standard unit for bit throughput is the “bit per second”, commonly abbreviated “bit/s”, “bps” or “b/s”. The byte unit is “byte per second”, abbreviated “bytes/s”, “Bps” or “B/s”—unless some cruel author decides to use a lower-case “b” just to confuse you. This means that the maximum theoretical throughput of 100BASE-TX (100 Mbps) Ethernet is about 12 MB/s. Where the context is unclear, it is better to spell out the unit as “100 Mbits/s” or “12 Mbytes/s”, which of course, I try to do in this Guide.

You will also occasionally, especially when dealing in the realm of communications, see throughput measured in characters per second, or “cps”. In most computer systems (including PCs) each character takes up one byte, so “cps” is equivalent to “bytes/s”, “B/s” or “Bps”.

Of course, most networking technologies don’t move just a few bits and bytes around every second; they move, thousands, millions, or even billions. Thus, most speed ratings are not in bits per second, but rather *kilobits* (kb), *megabits* (Mb), or *gigabits* (Gb) per second, and the same thing can be done for bytes. Thus, we find terms such as “100 Mbps Ethernet” or “700 kb/s ADSL”.

Here we run into another problem: the existence of both decimal and binary versions of the terms “kilo”, “mega” and “giga”. For example, the decimal form of the prefix for a million (“mega”) is  $10^6$  or 1,000,000, while the binary form is  $2^{20}$  or 1,048,576. This differential of about 5% leads to all sorts of confusion. When you see these abbreviations, bear in mind that in networking, they almost always refer to the decimal form. Thus, 100 Mbps Ethernet is rated at 100,000,000 bits per second, not 104,857,600 bits per second.

**Key Concept:** The unit most often used to express networking throughput is *bits per second* or *bps*. This term is often expressed in thousands, millions or billions as *kbps*, *Mbps* or *Gbps*. It almost always uses the decimal, not binary, versions of the kilo, mega or giga multipliers.

---

### ***Signaling Rate and the Baud***

Finally, there’s another term that you will encounter frequently in discussions of modems and some other technologies: the *baud*. Named for telegraphy pioneer Jean Maurice Emile Baudot (1845-1903), this is a unit that measures the number of changes, or transitions, that occur in a signal in each second. So, if the signal changes from a “one” value to a “zero” value (or vice-versa) one hundred times per second, that is a rate of 100 baud.

---

In the early days of very slow modems, each bit transition encoded a single bit of data. Thus, 300 baud modems sent a theoretical maximum of 300 bits per second of data. This led to people confusing the terms “baud” and “bits per second”—and the terms are still used interchangeably *far* too often. You'll commonly hear people refer to a 28.8kbps modem, for example, as running at “28,800 baud”.

But the two units are in fact not the same; one measures data (the throughput of a channel) and the other transitions (called the *signaling rate*). Modern modems use advanced modulation techniques that encode more than one bit of data into each transition. A 28,800 bps modem typically encodes nine bits into each transition; it runs at 3,200 baud, not 28,800 baud (the latter number being the product of 3,200 and 9). In fact, there's no way to operate a modem on a conventional phone line at 28,800 baud—it exceeds the frequency bandwidth of the phone line. That's the reason why advanced modulation is used to encode more data into each transition.

**Key Concept:** The units *baud* and *bps* are often treated equivalently, but are not the same. *Baud* measures not the throughput of a network but its signaling rate, meaning the number of times that the signal changes value in each second. Since modern encoding and modulation techniques often encode either greater or fewer than one bit value into each such transition, the throughput and baud rate of network technologies are usually different.

---

Wow, when I started writing this topic, I never envisioned that I would have to write so much just to explain something that *should* be fairly simple. Leave it to computer people to complicate the simple, but well, there you have it. At least you should now be able to figure out what all those terms are about, and can impress your friends and relatives with explanations of why their 56k modem doesn't actually run at 56,000 baud. ☺

## Theoretical and Real-World Throughput, and Factors Affecting Network Performance

When assessing the performance of networks, keep in mind that there is always a difference between theoretical speed ratings, and “real-world” throughput. If you are lucky—rather, if your network is set up well—then this difference is relatively small but still significant. Otherwise, the difference can be extremely large. Notice that there is no option for the difference between theoretical and practical performance being “negligible”!

### ***Major Categories of Real-World Performance Impact Factors***

The reasons for the difference between what a network or communications method is supposed to be able to do and what it can actually do are many. I consider them as generally falling into three categories: normal network overhead, external performance limiters, and network configuration problems.

---

## Normal Network Overhead

Every network has some degree of normal network overhead, which guarantees that you will never be able to use all of the bandwidth of any connection for data. Take as an example 10 Mbit/s Ethernet. Sure, the line may be able to transmit 10,000,000 bits every second, but not all of those bits are data! Some are used to package and address the data—data can't just be thrown onto the network in raw form. Also, many of those bits are used for general overhead activities, dealing with collisions on transmissions, and so on. There are natural inefficiencies in any networking technology.

Even beyond this, there are other overhead issues. Any network transaction involves a number of different [hardware and software layers](#), and overhead exists at each of them, from the application and operating system down to the hardware. These overheads mean that you generally lose at least 20% of the “rated” speed of a LAN technology “off the top”, and sometimes even more. For example, 7 Mbits/s user data throughput on a regular 10 Mbit/s Ethernet network is actually very good.

## External Performance Limiters

There are external factors that limit the performance of a network. Important issues here include the ability of the hardware to process the data, and also any bandwidth limitations that exist in the chain of data transmission between two nodes. Hardware issues most often show up with very fast networking technologies. Consider a Gigabit (1000 Mbps) Ethernet connection between two regular PCs. In “theory”, this connection should allow the transmission of 1 gigabit of data every second. Well, even beyond the matter of overhead mentioned above, no regular PC is capable of pumping this much data per second if its life depended on it. Only high-end servers have this capacity—and even they would have problems sustaining this unless they were doing nothing else. An older PC's hard disk probably can't even stream data fast enough to keep a 100 Mbit/s Ethernet connection busy. Thus, upgrading a 100 Mbps Ethernet card in an older machine to Gigabit is not likely to help as much as you might expect.

Bandwidth limitations cause network throughput issues because the entire network can only run as fast as its slowest link. These bottlenecks create reduced performance. As a common example, suppose you have a cable modem connection to the Internet that is rated at 1 Mbps for downloads. It may be very fast most of the time, but if the Web site you are accessing is totally bogged down, or it is having connectivity problems itself, you are not going to download from that site at 1Mbps. In fact, probably not even close.

Finally, it's also important to remember that there are many technologies that simply do not always operate at a constant fixed speed; they may change speeds based on physical network characteristics. A good example is an analog modem, which can vary greatly in performance depending on the quality of the line over which it operates.

---

## Network Configuration Problems

The issues I mentioned above are usually ones that you cannot do anything about; they are just the nature of the networking beast. The third category of performance limiters, *misconfiguration*, is different. This refers to network slowdowns that occur because hardware or software have not been set up correctly. Poor cabling, misconfigured interface cards, or bad drivers can **seriously** reduce the performance of a network—by 90% or even more.

These problems can usually be corrected, but only if you are looking for them. Driver problems are particularly insidious because the natural tendency is for people to blame hardware when slowdowns occur. However, you cannot get the most of your hardware devices without proper software to run it. These issues are much more significant with “bleeding edge” hardware than with established products, incidentally.

Also included in this category of issues are problems that occur due to poor design. For example, putting 30 busy workstations on a shared 10 Mbit/s Ethernet segment is likely to result in poor performance—using a network switch would be much better, since this would create multiple, independent segments for higher performance. Another common mistake is not providing a “fatter pipe” (higher bandwidth connection) to servers in a client/server setup. These issues can be avoided or ameliorated by reconfiguring the network—or even better, designing it properly in the first place, right?

**Key Concept:** The theoretical rated speed of a network is never achieved in practice, for a number of reasons. *Overhead* issues mean that not all of the possible capacity of a network can be used for data. *External factors* such as hardware bandwidth limitations restrict data input and output. *Configuration problems* can also greatly reduce real-world performance. Finally, it is important to remember that many technologies are asymmetric, offering higher speed in one direction than the other, and the larger number is often the one that is advertised.

---

### *The Effect of Assymetry*

In addition to the above, bear in mind that many networking technologies, especially ones used for Internet access, are *asymmetric*, meaning that they offer much higher bandwidth in one direction than the other. Usually, this is arranged so that more bandwidth goes down to the user than from the user to the network, since most Internet users download far more than they upload. However, it's always important to find out if a speed rating is for both directions, or for only one direction, and if so, what the other direction's speed is. Common technologies with asymmetric performance include 56k modems, ADSL, cable modems, and satellite Internet access. Beware, because the marketing droids who sell these technologies will often try to hide the asymmetry of their services, usually highlighting only the bigger download figure and avoiding mention of the slower uploads.

Asymmetry can also have unexpected effects on network performance, because most communications, even if they seem unidirectional, are not. The most common case is when an Internet access technology has much higher download bandwidth than upload

---

bandwidth. When using TCP/IP to download data, acknowledgments must be sent regularly. If the upstream bandwidth is too low, this may make it impossible to fully exploit the download bandwidth of the link.

### ***Performance Metric Issues***

Finally, take into account that there are many different ways of measuring and assessing performance. Synthetic benchmark programs are often used to measure throughput, and can produce impressive performance scores—which usually have little to do with how a network will actually operate. Such metrics are best used for comparison purposes, by showing that one network or system is faster than another, rather than paying too much attention to the actual number they produce. Even when doing comparisons, however, caution is wise.

## **Simplex, Full-Duplex and Half-Duplex Operation**

Another aspect of performance that is worthy of some attention is the mode of operation of the network or connection. Obviously, whenever we connect together device *A* and device *B*, there must be some way for *A* to send to *B* and *B* to send to *A*. Many people don't realize, however, that networking technologies can differ in terms of how these two directions of communication are handled. Depending on how the network is set up, and the characteristics of the technologies used, performance may be improved through the selection of performance-enhancing modes.

### ***Basic Communication Modes of Operation***

Let's begin with a look at the three basic modes of operation that can exist for any network connection, communications channel, or interface.

#### **Simplex Operation**

In simplex operation, a network cable or communications channel can only send information in one direction; it's a "one-way street". This may seem counter-intuitive: what's the point of communications that only travel in one direction? In fact, there are at least two different places where simplex operation is encountered in modern networking.

The first is when two distinct channels are used for communication: one transmits from *A* to *B* and the other from *B* to *A*. This is surprisingly common, even though not always obvious. For example, most if not all fiber optic communication is simplex, using one strand to send data in each direction. But this may not be obvious if the pair of fiber strands are combined into one cable.

---

Simplex operation is also used in special types of technologies, especially ones that are asymmetric. For example, one type of satellite Internet access sends data over the satellite only for downloads, while a regular dial-up modem is used for upload to the service provider. In this case, both the satellite link and the dial-up connection are operating in a simplex mode.

### **Half-Duplex Operation**

Technologies that employ half-duplex operation are capable of sending information in both directions between two nodes, but only one direction or the other can be utilized at a time. This is a fairly common mode of operation when there is only a single network medium (cable, radio frequency and so forth) between devices.

While this term is often used to describe the behavior of a pair of devices, it can more generally refer to any number of connected devices that take turns transmitting. For example, in conventional Ethernet networks, any device can transmit, but only one may do so at a time. For this reason, regular (unswitched) Ethernet networks are often said to be “half-duplex”, even though it may seem strange to describe a LAN that way.

### **Full-Duplex Operation**

In full-duplex operation, a connection between two devices is capable of sending data in both directions simultaneously. Full-duplex channels can be constructed either as a pair of simplex links (as described above) or using one channel designed to permit bidirectional simultaneous transmissions. A full-duplex link can only connect two devices, so many such links are required if multiple devices are to be connected together.

Note that the term “full-duplex” is somewhat redundant; “duplex” would suffice, but everyone still says “full-duplex” (likely, to differentiate this mode from half-duplex).

### ***Comparing Half-Duplex and Full-Duplex Operation***

Of these three options, full-duplex is obviously the one that yields the highest performance. Full-duplex operation doubles the theoretical bandwidth of the connection. If a link normally runs at 1 Mbps but can work in full-duplex mode, it really has 2 Mbps of bandwidth (1 Mbps in each direction). Remember the key word “theoretical” however—you do not really get double the performance in real life, because communications usually do not involve sending lots of data in both directions at once. However, you certainly get better throughput than in a half-duplex mode.

In some cases, the mode of operation is a function of the technology and cannot be changed. In others, however, full-duplex mode is a matter of the correct hardware settings, and also whether the software supports full-duplex operation or not. Thus, getting higher performance in this area is sometimes simply a matter of ensuring proper configuration.

Full-duplex operation has been pretty much taken for granted in communications for years. The more interesting development has been the rise in significance of full-duplex operation for local area networking. Traditionally, LANs have always used half-duplex operation on a

---

shared access medium. As the use of switches has increased, allowing dedicated bandwidth to each computer, full-duplex operation has become very popular. Full-duplex operation in Ethernet not only allows the simultaneous transmission of data in both directions, it also eliminates contention for the formerly shared access medium—no more collisions. The combination of these two effects improves performance, sometimes substantially.

**Key Concept:** There are three basic operating modes that describe how data is sent between connected devices on a network. In *simplex* operation, data can flow in only one direction between two devices. *Half-duplex* networks allow any device to transmit, but only one may do so at a time. *Full-duplex* operation means two attached devices can each transmit and receive simultaneously—this offers the greatest potential performance, since throughput is not decreased by forcing one device to wait for another before sending data.

---

## Quality of Service (QoS)

I mentioned in my [discussion of common network performance measurements](#) that there were many different aspects to network performance. I also introduced the concept of *latency*, which measures how long it takes for data to travel across a network. Latency is one important part of a larger issue in networking that is sometimes called *quality of service* or QoS.

The inherent nature of most networking technologies is that they are more concerned with pumping data from one place to another as fast as possible than they are with how the data is sent. For example, the Internet is designed on top of the [Internet Protocol](#), a [packet-switching technology](#) that is designed to get packets from point “A” to point “B” in whatever way is most effective, without the user necessarily having any ability to know what route will be taken. In fact, some packets in the same data stream may be sent along different routes. Packets may be stored for a while before being forwarded to their destination, or even dropped and retransmitted.

For most applications, such as simple file or message transfers, this is perfectly fine. However, there are applications where this sort of service is simply of “too low quality”. In these cases, the nature of how the data is delivered is more important than merely how fast it is, and there is a need for technologies or protocols that offer “quality of service”. This general term can encompass a number of related features; common ones include the following:

- ☉ **Bandwidth Reservation:** The ability to reserve a portion of bandwidth in a network or interface for a period of time, so that two devices can count on having that bandwidth for a particular operation. This is used for multimedia applications where data must be streamed in real-time and packet rerouting and retransmission would result in problems. This is also called *resource reservation*.

- 
- ☛ **Latency Management:** A feature that limits the latency in any data transfer between two devices to a known value.
  - ☛ **Traffic Prioritization:** In conventional networks, “all packets are created equal”. A useful QoS feature is the ability to handle packets so that more important connections receive priority over less important one.
  - ☛ **Traffic Shaping:** This refers to the use of buffers and limits that restrict traffic across a connection to be within a pre-determined maximum.
  - ☛ **Network Congestion Avoidance:** This QoS feature refers to monitoring particular connections in a network, and rerouting data when a particular part of the network is becoming congested.

So, in essence, quality of service in the networking context is analogous to quality of service in the “real world”. It is the difference between getting take-out and sit-down service at a nice French restaurant—both cure the hunger pangs, but they meet very different needs. Some applications, especially multimedia one such as voice, music and video, are time-dependent and require a constant flow of information more than raw bandwidth; for these uses, a burger and fries in a paper bag just won’t cut the mustard. 😊

**Key Concept:** The generic term *quality of service* describe the characteristics of how data is transmitted between devices, rather than just how quickly it is sent. Quality of service features seek to provide more predictable streams of data rather than simply faster ones. Examples of such features include bandwidth reservation, latency minimums, traffic prioritization and shaping, and congestion limitation. Quality of service is more important for specialty applications such as multimedia than for routine applications such as those that transfer files or messages.

---

To support quality of service requirements, many newer technologies have been developed or enhanced to add quality of service features to them. This includes the ability to support *isochronous transmissions*, where devices can reserve a specific amount of bandwidth over time to support applications that must send data in real time. One technology that has received a lot of attention for its quality of service features is Asynchronous Transfer Mode (ATM). ATM is designed to support traffic management features that are not generally available on networks not created to provide quality of service features (such as Ethernet)

**Note:** “Quality of service” has become a big buzzword, lately. By itself, this term conveys about as much useful information about what the technology offers as being told that it is “high performance”. You have to dig past the marketingspeak and find out exactly what QoS features are being offered.

---

---

## Network Standards and Standards Organizations

You can't study networking and its related technologies without very quickly encountering a whole host of standards that are related to the subject—and organizations that create these standards. Network standards facilitate the interoperability of network technologies and are extremely important. It may be an exaggeration to say that networking wouldn't exist without standards, but it isn't to say that networking **as we know it** would not exist without them. Networks are literally everywhere, and every hardware device or protocol is governed by at least one standard, and usually many.

In this section I provide a brief examination of the often-overlooked subject of network standards and standards organizations. I begin with a background discussion of why standards are important, highlighting the differences between proprietary, de facto and open standards. I give an overview of networking standards in general terms, and then describe the most important international standards organizations and industry groups related to networking. I then describe the structure of the organizations responsible for Internet standards, including the registration authorities and registries that manage resources such as addresses, domain names and protocol values. I conclude with a discussion of the Request For Comment (RFC) process used for creating Internet standards.

### Proprietary, Open and De Facto Standards

Why are standards important? Well, because I said so. They are. Alright, fine, I'll try to do a bit better than that; even my young kids won't take that for an answer any more. But I have to warn you that the proper answer is a lot longer than the cute answer. ☺

An old saw in the computer world says that “the beauty of standards is that there are so many to choose from”. This little joke reflects the frustration that technicians often feel at the sheer number of standards that are found in the industry: thousands. Aside from differing in terms of content—what technologies and protocols they describe—standards also often differ in terms of the type of standards they are, and how they came about. In fact, part of the reason why there are sometimes “so many to choose from” in a particular area is **because** of how they come about.

#### ***Proprietary Standards***

In the early days of computing, many people didn't quite understand just how important universal standards were. Most companies were run by skilled inventors, who came up with great ideas for new technologies and weren't particularly interested in sharing them. It wasn't considered a “smart business move” to share information about new inventions with other companies—the competition! Oh sure, every company believed that standards were important, but they thought it was even more important that **they** be the ones to control those standards.

---

I'll give you an example of what I mean. Let's imagine that it's 1985, and I have just come up with a great networking technology, which I have incorporated into a fancy new local area networking product called "SooperDoooperNet". (Catchy, eh?) SooperDoooperNet is *my* product. I have patents on the technology, I control its design and manufacture, and I sure as heck don't tell anyone else how it works—if I did, they would copy me, right?

Now, I could sell interface cards, cables and accessories for SooperDoooperNet, and a company that wanted to use it could install the cards in all of their PCs and be assured that they would be able to talk to each other. This solves the interoperability problem for this company by creating a "SooperDoooperNet standard". This would be an example of a *proprietary* standard—it's owned by one company or person.

The problem with proprietary standards is that other companies are excluded from the standard development process, and therefore have little incentive to cooperate with the standard owner. In fact, just the opposite: they have a strong motivation to develop a competing proprietary standard, even if it doesn't improve on the existing one.

So when my competition sees what I am doing, he is not going to also create network interface cards that can work with SooperDoooperNet, which would require paying me a royalty. Instead, he's going to develop a new line of networking hardware called MegaAwesomeNet, which is very similar to SooperDoooperNet in operation but uses different connectors and cable and logic. He too will try to sell bunches of cards and cables—to my customers, if possible!

You can see what the problem is here: the market ends up with different companies using different products that can't interoperate. If you install SooperDoooperNet, you *have* to come to me for any upgrades or changes—you have no choices. Worse, what happens if Acme Manufacturing, which has 50 PCs running SooperDoooperNet, merges with Emca Manufacturing, which has 40 PCs running MegaAwesomeNet? Well, the IT people have a problem, that's what. Sure, there would be ways to solve it, but wouldn't everyone be better off to just avoid these difficulties in the first place? And how could you create something like the Internet if everyone's networks used different "standards"?

## ***Open Standards***

Eventually, companies learned that they would be better off to have standards that everyone agreed with, instead of constantly fighting with each other. This is particularly true of networking, where devices need to talk to each other. If many companies get together and agree to cooperate, they can create an *open standard* instead of a bunch of proprietary ones. The name is rather self-explanatory; rather than being the closely-guarded secret of one organization, an open standard is available to any who are interested in using it.

One key to the success of an open standard is a steering organization to promote it. Usually, a neutral, non-profit trade association or working group is established to develop and promote the standard, and the various for-profit hardware and software companies join this group and support it financially. These groups also work with [standards approval bodies](#) like the ITU and ISO to gain acceptance for their standards.

---

Of course, the companies aren't doing this just to be nice to their customers. In creating open standards, they split the “market share pie” between them, but they make the pie grow much larger by attracting more customers. Customers like open standards more than proprietary ones, because they give them more choices, and increase their ability to interact with other companies, troubleshoot problems, hire skilled workers, and expand in the future. As for the companies, they still compete in their specific offerings, so it's not like they all end up making the same products. For all of these reasons, open standards are now far more common than proprietary ones.

However, the process involved in creating these standards is often a difficult one. In some cases the standards organization will draft the standard from the ground up, but in others it may select one technology as the basis for the standard from several that are submitted in what is commonly called a “technology bake-off”. Thus, many different companies may come to the table with different approaches, each of them vying for selection as the standard for use by the group. Politics can cause groups to get bogged down for years fighting over various options, or even to split into multiple groups. Good examples are what occurred in the conflict between supporters of 100VG-AnyLAN and Fast Ethernet, and the problems with standards politics that have plagued the world of powerline networking.

Furthermore, there are still some companies that believe strongly in proprietary standards, because they really want to control and direct the market. One of the most famous/infamous in this regard is Sony, a company that makes excellent hardware but frequently refuses to accept established standards. For this reason, some people avoid their products, even though they are good; because they want to stick to industry standards.

### ***De Facto Standards***

This brings me to the third type of standard that is often seen in the computer world: the *de facto* standard. “De facto” is Latin for “in fact”, so a de facto standard is one that is used as a universal standard just because over time it became widely used, and not because the standard was developed and approved by a standards committee. A good example of a de facto standard is the “AT” command set used by modems; virtually all modems use it, but this resulted not from an industry group agreeing to adopt and deploy it. Rather, it was developed unilaterally by Hayes, the pioneering modem company, and then adopted by virtually every other modem maker until it became a standard.

One reason why proprietary standards are still sometimes seen is that some companies want to produce a standard that will become so universally used that it becomes the de facto standard, thus giving them a leadership position in that market. Again, in my estimation Sony falls into this category—they often want to do things “their way” and create proprietary standards that they try to promote using their powerful market presence.

Sometimes this succeeds but often it does not, resulting a fragmented market of incompatible products. An excellent example is when Sony created a new format for digital camera flash memory (the “memory stick”) rather than using the CompactFlash format used by other camera manufacturers. The result of this was not everyone using memory sticks as Sony had hoped, but two incompatible standards that increase confusion and yield no real benefit to the customer.

**Key Concept:** Networking standards can be classified as *proprietary*, *open* or *de facto*. *Proprietary* standards are owned by one particular organization. If that organization has sufficient market clout and the industry lacks alternatives to its standard, it may be adopted by the whole industry, becoming a *de facto* standard. Usually, however, differing proprietary standards compete with each other, resulting in a fragmented market. In contrast, *open* standards are not owned by anyone—they are created by neutral organizations to ensure that compatible products can be designed and developed by many different companies. This makes life easier for the customer as well as promoting the market as a whole.

---

## Networking Standards

All networking technologies have standards associated with them. These are usually highly technical documents, and often presume that the reader has a fair bit of knowledge about networking. If you aren't an expert, you will probably have some difficulty understanding networking standards. (Some people seem to think *I* am an expert, but I too have trouble with most of the details in a typical networking standard.)

In fact, many technologies have quite a number of standards associated with them. A networking technology may have more than one standard for any or all of the following reasons:

- ☉ The original standard has been revised or updated;
- ☉ The technology is sufficiently complex that it needs to be described in more than one document;
- ☉ The technology borrows from or builds on documents used in related technologies;
- ☉ More than one organization has been involved in developing the technology.

Standards documents created in the United States are usually developed in English, but are also routinely translated into other languages. European standards are often published simultaneously in English, French and German, and perhaps other languages as well.

Today, virtually all networking standards are “open” standards, administered by a standards organization or industry group. As I explained in the [previous topic](#), open standards are more popular than proprietary ones in the computer industry, and that's particularly so when it comes to networking. In fact, the few technologies where there is no universally-accepted open standard have been losing ground to those with open standards, particularly in the areas of wireless LANs and home networking—pretty much proving how important an open process really is.

I considered having a separate section where I listed all of the various standards used for networking within the Guide. However, this would be a very large section indeed, and the discussions of the various standards would be somewhat “detached” from the places where I describe the technologies they define. Instead, I have many different smaller discussions

---

of standards, within the sections where I describe each networking method or protocol. These can usually be found in an overview topic introducing each technology type, though for more complex protocols I have a dedicated topic just discussing relevant standards and where they are documented.

## International Networking Standards Organizations

The rise of [open standards](#) not owned by any one company has been a great boon to customers of computer and networking products, as well as the manufacturers that sell to them. In order to facilitate the development of open standards, however, organizations are needed that will coordinate the creation and publishing of these documents. Generally, these are non-profit organizations that specifically take a neutral stance regarding technologies and work for the betterment of the industry as a whole.

Here are some of the standards organizations that you are likely to encounter when reading about networking and the Internet:

- 🕒 **International Organization for Standardization (ISO):** Probably the biggest standards organization in the world, the ISO is really a federation of standards organizations from dozens of nations. In the networking world, the ISO is best known for its [OSI Reference Model](#).

**Note:** The shortened name of the International Organization for Standardization is indeed “ISO”, and not “IOS” as you might imagine. In fact, it is not an acronym at all. Since the full name of the body differs from one language to the next, any acronym for that name would differ as well. Instead, the organization chose the name “ISO” from the Greek word “isos”, meaning “equal”. Many people, especially in the United States, think “ISO” is short for “International Standards Organization”, but this is incorrect.

- 🕒 **American National Standards Institute (ANSI):** ANSI is the main organization responsible for coordinating and publishing computer and information technology standards in the United States. While they are commonly thought of as developing and maintaining standards, they do neither. Instead, they oversee and accredit the organizations that actually create the standards, qualifying them as *Standards Developing Organizations* or *SDOs*. ANSI also publishes the standards documents created by the SDOs, and serves as the United States' representative to the ISO.
- 🕒 **Information Technology Industry Council (ITIC):** ITIC is a group of several dozen companies in the information technology (computer) industry. ITIC is the SDO approved by ANSI to develop and process standards related to many computer-related topics. It was formerly known as the *Computer and Business Equipment Manufacturers Association (CBEMA)*.

- 
- ☉ **National Committee for Information Technology (NCITS):** A committee established by the ITIC to develop and maintain standards related to the information technology world. NCITS was formerly known by the name *Accredited Standards Committee X3, Information Technology*, or more commonly, just X3. It maintains several sub-committees that develop and maintain standards for various technical subjects.
  - ☉ **Institute of Electrical and Electronics Engineers (IEEE):** The IEEE (pronounced “eye-triple-ee”) is a well-known professional organization for those in the electrical or electronics fields, including computers and networking. IEEE’s main claim to fame in the networking industry is the IEEE 802 Project, which encompasses many popular networking technologies including Ethernet.
  - ☉ **Electronic Industries Alliance (EIA):** The EIA is an international industry association that is best known for publishing electrical wiring and transmission standards.
  - ☉ **Telecommunications Industry Association (TIA):** The TIA is the communications sector of the EIA, and is responsible for developing communications standards. Since communications, wiring and transmission are all related, and since the TIA and EIA organizations are also related, standards produced by the EIA or TIA are often labeled with the combined prefixes “EIA/TIA” or “TIA/EIA”.
  - ☉ **International Telecommunication Union - Telecommunication Standardization Sector (ITU-T):** ITU-T is another large international body that develops standards for the telecommunications industry. The ITU-T was formerly named the *International Telephone and Telegraph Consultative Committee* or *CCITT* (the abbreviation was of the French version of the organization’s name, *Comité consultatif international téléphonique et télégraphique*.)
  - ☉ **European Telecommunications Standards Institute (ETSI):** An organization with members from dozens of countries both within and outside Europe that is dedicated to developing telecommunications standards for the European market (and elsewhere). ETSI is known for, among other things, regulating the use of radio bandwidth in Europe and developing standards such as HiperLAN.

This list represents some of the more important organizations that are responsible for establishing and publishing standards in the networking world. It is not an exhaustive list, however. I should also point out that the set of related organizations responsible for creating Internet standards is not shown in this list as I have covered them in two dedicated topics on [Internet standards organizations](#) and [registration authorities](#).

I want to emphasize that many of the organizations above do not actually develop the various standards. Generally, these are oversight organizations—“high level management” if you will—that work with many other smaller groups who actually develop the standards. Also, in many cases a particular standard may be published by more than one standards organization, so it may be labeled with more than one name.

**Key Concept:** There are a number of well-known international organizations that play an important role in the development of open networking standards. Some of the most important of these are ISO, ANSI, ITIC, IEEE, EIA/TIA, ITU-T and ETSI. These are oversight organizations, responsible for overall management of the standards development process, rather than for the particulars of creating individual standards.

---

## Networking Industry Groups

As I explained in the [previous topic](#), most open standards are coordinated and published by a small number of large, often international standards organizations. However, these are not the only groups of people who are involved in the development of standards for networking and Internet technologies. There are also many different networking *industry groups* that play an important role in the standard creation process.

Networking industry groups differ in a few ways from standards organizations. They are typically dedicated to the promotion of a specific technology, where standards organizations are more generic and handle the oversight of hundreds of different ones. Industry groups are also generally smaller than standards organizations, with members drawn primarily from the field of developers and manufacturers that create products for the particular technology the group promotes.

Perhaps most importantly, industry groups often actually write and maintain the standards, where standards organizations are generally more “supervisors” who ensure that the standards meet, well, the standards for the development of standards. Some industry groups, however, are concerned only with marketing and promotion activities.

Obviously, these industry groups work closely together with the standards organizations. In some cases, they may even be part of the same overall organization, and all of the different groups are related in some ways. For example, the IEEE 802 project consists of a number of working groups that are charged with maintaining and developing specific technology standards, which the larger IEEE organization approves and publishes.

One of these working groups is the 802.11 working group, which develops wireless Ethernet technology. At the same time that this group “does its thing”, there is an industry group called the *Wireless Ethernet Compatibility Alliance (WECA)*. This group works to ensure the cross-vendor compatibility of 802.11b wireless networking hardware and software.

Other industry groups are formed specifically to develop independent standards that are not approved through a formal standardization process. Examples include groups such as HomePNA, IrDA and HomeRF. One of the problems with these groups is that they usually do not make their standards open to the public. This is undoubtedly due to some sort of security concern or desire to keep the “inner workings” of their technology “secret”.

---

Unfortunately for these groups, this policy harms the ability of regular people to learn about how their technologies work. For example, in writing this and other reference works, I am almost always unable to obtain specifications from most of the private industry groups. They either refuse to allow me to get the document at all, or want to charge me a great deal of money for the privilege (well into the thousands of dollars in some cases). In doing this, these groups harm their own cause, by making it more difficult for those interested in their technologies to learn about them. This is another key advantage of open standards managed by public organizations such as ANSI or the IEEE.

## Internet Standards Organizations (ISOC, IAB, IESG, IETF, IRSG, IRTF)

High-quality, widely-accepted [open standards](#) become more important the larger the number of people that use a network. The largest network of all is of course the *Internet*, which connects millions of people on thousands of individual networks into a globe-spanning internetwork. The Internet has revolutionized not only networking and computing, but communication, business, and even society as a whole. One of the critical factors in the success of the Internet has been its development using open standards.

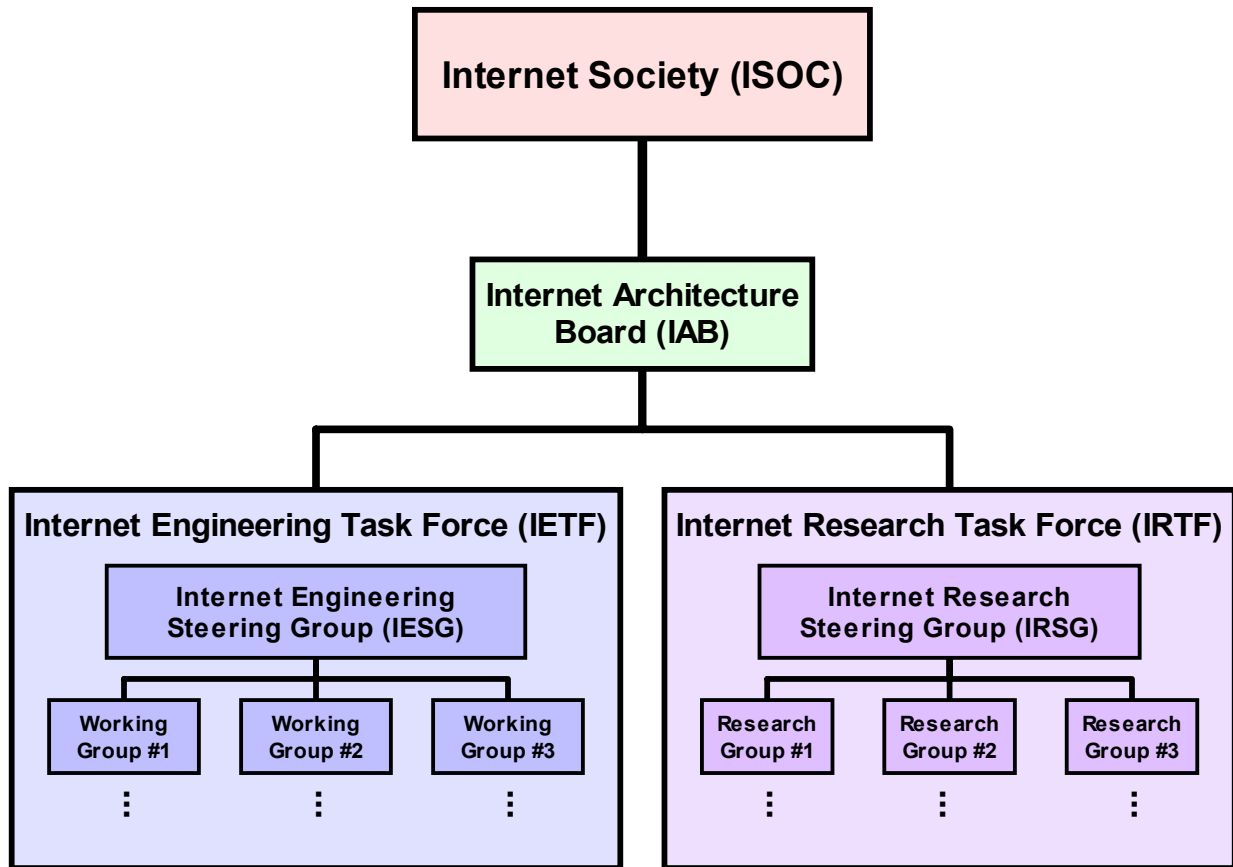

Of course, nobody sat down one day and said “hey, let’s create the Internet!” (No, not even Al Gore. ☺) It began as a small research network, and was developed over time concurrently with the technology set that implemented it: [TCP/IP](#). At first, a relatively small organization was sufficient to manage the development of Internet standards and oversee its activities, but as the Internet continued to grow, this became inadequate. Eventually a more formalized structure of organizations was required, to manage the Internet development process and other activities to ensure the continued success and growth of the Internet and the TCP/IP technologies that power it.

Today, there are six organizations that are responsible for the development of the Internet’s architecture, standards and policies, and related activities. They are closely-related, with certain organizations being responsible for oversight of others, as shown in [Figure 7](#). These organizations perform many tasks, and can be somewhat confusing to understand, since many have similar-sounding names and responsibilities. Therefore, I will concentrate mostly on their role in the development of Internet standards, since that is our primary interest in this discussion.

### **Key Internet Standards Organizations**

Here is a brief description, rather simplified, of the key Internet standards organizations:

- ☉ **Internet Society (ISOC):** A professional society responsible for general, high-level activities related to the management, development and promotion of the Internet. ISOC has thousands of individual and organizational members that engage in activities such as research, education, public policy development and standardization. It is responsible for providing financial and administrative support to the other organizations listed below. From the standpoint of standards development, ISOC’s key role is its responsibility for oversight of the IAB.

**Figure 7: Internet Standards Organizations**

The *Internet Society (ISOC)* oversees the *IAB*, which in turn directs the *IETF* and *IRTF*. The *IETF* develops current Internet and TCP/IP standards, and is headed by the *IESG*, which manages *IETF working groups (WGs)*. The *IRTF* is the *IETF*'s research counterpart, containing *research groups (RGs)* led by the *IRSG*.

- 🕒 **Internet Architecture Board (IAB):** Formerly the *Internet Activities Board*, the IAB is charged with overall management of the development of Internet standards. It makes “big picture” policy decisions related to how Internet technologies and structures should work, to ensure that various standardization efforts are coordinated and consistent with overall development of the Internet. It is responsible for publishing [Internet standards \(RFCs\)](#). It advises the ISOC, and oversees the IETF and IRTF; it also acts as an appeals body for complaints about the standardization activities performed by the IETF. The charter of the IAB is described in RFC 2850.
- 🕒 **Internet Engineering Task Force (IETF):** The IETF focuses on issues related to the development of current Internet and TCP/IP technologies. It is divided into a number of *working groups (WGs)*, each of which is responsible for developing standards and technologies in a particular area, such as routing or security. Each area is managed by an *area director (AD)*, who serves on the IESG. The IETF is overseen directly by the IESG and in turn by the IAB; it is described in RFC 3160.

- 
- ☉ **Internet Engineering Steering Group (IESG):** The IESG is directly responsible for managing the IETF and the Internet standards development process. It consists of each of the area directors of the IETF, who make final decisions about the approval of proposed standards, and works to resolve any issues that may arise in the standardization process. The IESG is technically considered part of the IETF and is also described in RFC 3160.
  - ☉ **Internet Research Task Force (IRTF):** Where the IETF is focused primarily on short-term development issues, the IRTF is responsible for longer-term research related to the Internet and TCP/IP technologies. It is a much smaller organization than the IETF, consisting of a set of *research groups (RGs)*, which are analogous to the IETF's working groups. The IRTF is overseen by the IRSG and IAB. It is described in RFC 2014.
  - ☉ **Internet Research Steering Group (IRSG):** The IRSG manages the IRTF in a similar way to how the IESG manages the IETF. It consists of the chairs of each of the IRTF research groups and works with the chair of the whole IRTF to make appropriate decisions on research activities. It is also discussed in RFC 2014.

### ***The Importance of the IETF***

Of these organizations, the IETF is the one that you will most often hear referenced, because that is the organization directly responsible for the development of the majority of Internet standards. It is for this reason that throughout this Guide, whenever I mention Internet standards development efforts, I refer to the IETF as doing the work. This is of course a bit of an oversimplification, since all of these organizations play a role in the standards development process, [described in more detail in a separate topic](#).

### ***Other Responsibilities of Standards Organizations***

I also feel I should re-emphasize that many of these organizations are responsible for a great deal more than just standards development. This is especially true of the Internet Society, for which standardization is just one of many activities. The IAB also performs a number of functions not strictly associated with standards development, including managing [the assignment of protocol values done by IANA](#) and acting as a liaison between the Internet standards organizations and other standards bodies.

**Key Concept:** A group of related organizations is responsible for the development of TCP/IP standards and Internet technologies. The *Internet Society (ISOC)* has overall responsibility for many Internet activities including standards development. It oversees the *Internet Architecture Board (IAB)*, which makes high-level decisions about Internet technology development. Most of the actual work of creating current Internet standards is performed by the *Internet Engineering Task Force (IETF)*, which is managed by the *Internet Engineering Steering Group (IESG)*. Longer-term research is done by the IETF's sibling organization, the *Internet Research Task Force (IRTF)*, led by the *Internet Research Steering Group (IRSG)*.

---

---

## Internet Registration Authorities and Registries (IANA, ICANN, APNIC, ARIN, LACNIC, RIPE NCC)

The success of the global Internet relies on the development of universally-accepted standards for protocols and other technologies. [Internet standards organizations](#) such as the IETF are thus critically important; they manage the standards development process, to ensure that everyone agrees on how to create hardware and software that will work together to communicate world-wide.

### ***Important Standardization Functions***

While the need to standardize protocols seems obvious, there are a couple of other aspects to Internet standardization that are equally important but perhaps not quite as well understood:

- ☉ **Parameter Standardization:** Most protocols rely on the use of parameters that control how they function. As just two of many, many examples, the [Internet Protocol](#) has a set of numbers that define different IP options, and the [Address Resolution Protocol \(ARP\)](#) has an *Operation Code* field that can take on many different values. Just as it is essential for devices to agree on what protocols to use, they must also agree on what parameters to use for those protocols, if communication is to be successful.
- ☉ **Global Resource Allocation and Identifier Uniqueness:** There are a number of resources that are used on the Internet that must be allocated from a fixed set of values and where uniqueness in assignment is essential. The most obvious example is that each TCP/IP host must have a unique [IP address](#); another important example is ensuring that only one organization uses a given [DNS domain name](#). If two devices have the same IP address or two organizations try to use the same domain name, the results would be unpredictable, but almost certainly bad.

### ***Internet Centralized Registration Authorities***

In both of the cases above, some sort of centralized organization is required. We need a group to take responsibility for managing parameters and ensuring that everyone uses the same ones, just as they use the same protocols. We also need to coordinate the assignment of identifiers such as addresses and names, to ensure that they are created and allocated in a way that is acceptable to all. In the world of the Internet, these are sometimes called *management authorities* or *registration authorities*.

The organization originally responsible for this task was the *Internet Assigned Numbers Authority (IANA)*. Amazingly, while the name makes it sound like the IANA was a huge bureaucracy, it was effectively one man: Jonathan B. (Jon) Postel, one of the most important pioneers of Internet and TCP/IP technologies. Jon Postel ran IANA until his untimely and unfortunate death in 1998.

IANA was originally charged with the task of managing which IP address blocks had been assigned to different companies and groups, and maintaining periodically-published lists of Internet parameters such as [UDP and TCP port numbers](#). It also was in charge of registrations of DNS domain names, which were more directly handled by the *Internet Network*

---

*Information Center (InterNIC)*, a service managed by the United States government. *Network Solutions Inc. (NSI)* was later granted the contract to manage the InterNIC, and was eventually purchased by Verisign.

As the Internet continued to grow, an effort commenced in the mid-1990s to define a new organization that would be responsible for the central registration of Internet addresses and names. This took the form of a new private, non-profit company called the *Internet Corporation for Assigned Names and Numbers (ICANN)*. ICANN is officially charged with all of the centralized registration tasks I have mentioned so far in this topic, including IP address assignment, DNS domain name assignment, and protocol parameters management.

In a simpler world, this development would have meant that ICANN would have replaced IANA, which would no longer exist. Instead, ICANN kept IANA around, leaving that organization in charge of overseeing IP address registration and Internet parameters. ICANN is of course now in charge of IANA, so really both organizations are responsible for IP addresses and parameters. This often leads to confusion, and to make things worse, it is common to see IANA and ICANN mentioned in conjunction as “IANA/ICANN” or “ICANN/IANA”.

**Key Concept:** Internet registration authorities are centralized organizations responsible for coordinating protocol parameters and globally-assigned resources such as IP addresses. The first such organization was the *Internet Assigned Numbers Authority (IANA)*, which was initially in charge of IP address assignment, DNS domain name management and protocol parameters. Today the *Internet Corporation for Assigned Names and Numbers (ICANN)* has overall responsibility for these activities; the IANA operates under the auspices of ICANN and is still responsible for IP address assignment and parameter coordination.

---

### ***Modern Hierarchy of Registration Authorities***

In the original “[classful](#)” [IP addressing scheme](#), addresses were assigned to organizations directly by IANA in address blocks: Class A, Class B and Class C addresses. Today, a hierarchical, classless addressing system called [Classless Inter-Domain Routing \(CIDR\)](#) is used instead. Address assignment in CIDR involves the hierarchical allocation of blocks of addresses, starting with large blocks that are given to big organizations, which split them to assign to smaller groups. (Much more detail on these methods can be found in the [large section on IP addressing](#).)

IANA, as the organization in charge of all IP addresses, assigns the largest blocks of addresses to *regional Internet registries (RIRs)* that are responsible for further allocation activities. Each RIR manages IP addresses and other Internet number resources (such as [autonomous system](#) numbers) for a particular region. The four regional registries are:

- 🌐 **Asia Pacific Network Information Centre (APNIC):** Covers the Asia/Pacific region.
- 🌐 **American Registry for Internet Numbers (ARIN):** Manages North America, part of the Caribbean, and sub-equatorial Africa.

- 
- ☉ **Latin American and Caribbean Internet Addresses Registry (LACNIC):** Responsible for Latin America and part of the Caribbean.
  - ☉ **Réseaux IP Européens Network Coordination Center (RIPE NCC):** Takes care of Europe, the Middle East, Central Asia, and Africa north of the equator.

Each registry may assign address blocks to Internet service providers (ISPs) directly, or further delegate them to *national Internet registries (NIRs)* or smaller *local Internet registries (LIRs)*. [See the topic on IP address allocation issues for more details.](#)

Name registration has changed over the last several years. It is no longer part of IANA's responsibilities, and ICANN has opened up the name registration business so it is no longer the province of a single organization such as InterNIC/Network Solutions/Verisign. Now, many different accredited registrars can be used for name registration in many of the popular top-level domains. [This is discussed in the topic on DNS public registration.](#)

**On The Web:** The complete list of documents containing Internet and TCP/IP protocol parameters can be found on the IANA's web site at: <http://www.iana.org/numbers.html>

---

## Internet Standards and the Request For Comment (RFC) Process

[The precursors of the modern Internet](#) were diminutive networks developed and run by a small group of computer scientists and engineers. These technologists knew that developing [open, widely-adopted standards](#) would be essential to the eventual growth of the Internet and the [TCP/IP protocol suite](#). But there was no formalized standards development mechanism back then.

### ***Consensus-Based Standardization Using Requests For Comments (RFCs)***

Standardization was achieved largely through building consensus through discussion about new technologies and protocols. If someone had a proposal for a new protocol or technology, or an idea for a change to an existing one, that person would create a memorandum describing it and circulate it to others. Since the goal was to solicit comments on the proposal, these memos were called *requests for comments (RFCs)*. Not all RFCs described formalized standards: many were just descriptive documents, clarifications or miscellaneous information.

**Note:** The documents defining early standards were originally called *Internet Engineering Notes (IENs)* before they were called RFCs.

---

---

Today, of course, the Internet is enormous and there is an official [structure of Internet standards organizations](#) that is responsible for creating new Internet and TCP/IP standards. Due to the many thousands of people who play an active role in developing Internet technologies, having an informal system where anyone could just write an RFC would lead to chaos. Thus, Internet and TCP/IP standards are still called RFCs, but the process of creating one is much more formal and organized today.

The Internet Engineering Task Force (IETF) is the standards body that is most directly responsible for the creation of Internet standards. The IETF's working groups, overseen by the Internet Engineering Steering Group (IESG) and the Internet Architecture Board (IAB), develop new protocols and technologies continuously, and these developments are formalized in RFCs.

The publishing of RFCs is handled by the office of the *RFC Editor*. From nearly thirty years, starting in 1969, "the" RFC Editor was Internet pioneer Jon Postel. After his death in 1998, the function was assigned to the Networking Division of the USC Information Sciences Institute (ISI), where Jon Postel was once director. The function of the RFC Editor is to publish and archive RFCs, and maintain an online repository of these documents so that they can be accessed and used by the Internet community.

The open and free access to RFCs has greatly contributed to the Internet's success. If you consider that even today there are standards bodies that charge thousands of dollars for access to a single standard, the ability to log on and immediately retrieve any of the thousands of RFCs is noteworthy.

**On The Web:** An up-to-date list of RFCs with hyperlinks to each document (except for some of the early ones) can be found at the office of the RFC Editor: <http://www.rfc-editor.org/rfc-index.html>

---

## ***RFC Categories***

As before, not all RFCs are official Internet standards, which is important to remember. Each RFC has a *category* or *status* associated with it that indicates its disposition:

- 🕒 **Proposed Standard / Draft Standard / Standard:** These are documents that describe technologies said to be on the "standards track". That means they are either already formally approved as standards, or they are likely to become standards in the future. In many cases, the document is just given as "Standards Track" as opposed to one of those three precise labels. See below for more information.
- 🕒 **Best Current Practice:** A document providing guideline information or recommendations from the IETF that is not a formal standard.
- 🕒 **Informational:** A document that provides general information or commentary.
- 🕒 **Experimental:** A proposal for an experimental standard that is not on the standards track. In some cases, protocols or proposed changes to existing protocols that are not accepted as formal standards are changed to "experimental" status.

---

☹ **Historic:** Former standards that have been obsoleted.

### ***The Internet Standardization Process***

The full process for creating and publishing an Internet standard is lengthy and beyond the scope of this Guide. It is interesting, however, so I will outline it here briefly. The full details of the standards process can be found in... where else, an Internet RFC: 2026. ☺

Before a proposal will be considered for the Internet standardization process, it must be published as an *Internet Draft (ID)*. The IETF publishes a set of guidelines that specify how IDs must be created and submitted. Most IDs are written by members of working groups within the IETF who are involved in specific projects. However, since the standards process is open, any member of the public can make an independent submission for review as a standard, by creating an ID for consideration by the IETF and IESG. Internet Drafts are usually revised many times based on feedback from others in various working groups within the IETF.

If an Internet Draft has been reviewed and is considered valuable, well-understood and stable (meaning that it is not being rapidly updated with new revisions) it may become a candidate for standardization. The IESG can place the Draft on the Internet standards track by changing its status to *Proposed Standard*. Documents of this status are considered mostly complete, but may still be revised based on further review, testing and experimentation with the technology.

Once the specification is sufficiently mature and widely accepted, it may be elevated from Proposed Standard to *Draft Standard*. A key requirement for such advancement is that the technology must be demonstrated to be functional on at least two independent and interoperable implementations. This proves that the standard is sufficiently clear and complete that at least two different groups have been able to implement it compatibly.

A document only reaches Draft Standard when the IETF community believes it is technically mature and the specification is complete. Changes are usually made to Draft Standards only to correct problems encountered in testing, or resolve new issues that arise.

The final “station” on the Internet standards track is *Internet Standard*. This designation is only applied to very mature specifications that are popular and that have been widely implemented. A document that reaches this status often describes a technology that is or will become universally-implemented, and is assigned an “STD” (“standard”) number.

The RFC development process can take months or even years, depending on how complex the technology is, how many changes are required to the documents, and whether or not the proposal is considered important or interesting. Many RFCs never make it officially to Internet Standard status; Draft Standard status is generally considered sufficiently stable that the technology is often just implemented by companies when that level is reached. Some RFCs never even make it to Draft Standard status and the technologies they describe are still used in products.

---

Once an RFC is published, it cannot be changed. This is a specific policy decision intended to avoid the confusion that would otherwise result due to there being multiple versions of the same RFC. The RFC publication process incorporates a number of steps at which RFC authors can revise their documents, and check for editorial omissions and errors.

This need for a new document whenever a change is made is also why proposals are typically published with a category designation of “Standards Track” rather than “Proposed Standard”, “Draft Standard” and “Internet Standard”. This eliminates the need to publish a new RFC that has no changes other than a different category designation, if a proposal advances down the standards track without requiring any real changes.

**Key Concept:** Internet standards are described in a series of documents called *requests for comments (RFCs)*. The *RFC process* describes how an Internet standard is usually created. An idea for a new technology or enhancement begins with the creation of an *Internet Draft (ID)*. After review and feedback, if the proposal has support, it may be placed on the Internet standards track, and its status changed to *Proposed Standard*. As the fledgling standard matures, its status may advance to *Draft Standard* and eventually, *Internet Standard*. However, many RFCs are implemented in products without reaching *Internet Standard* status. There are also other RFCs that define experimental technologies or provide information without describing official Internet standards.

---

---

## **Backgrounder: Data Representation and the Mathematics of Computing**

Humans use decimal (base 10) numbers to represent numeric information, and various alphabets and symbol systems to represent other types of information. In contrast, computers understand only one basic type of information: ones and zeroes, which themselves are representative of either an “on” or “off” electrical or light state within the hardware of the device. These ones and zeroes are combined in various ways to form all the more common data elements we are used to finding in computers: regular numbers, characters and files. However, all of these are really only abstractions; the ones and zeroes are always “underneath” whatever logical structures used within the computer.

This same basic foundation of ones and zeroes applies to networking as well. Even though most of the information in a network is exchanged in a logical fashion between higher-layer protocols, underlying all networking structures are the ones and zeroes sent over the network medium. Understanding how data is represented and manipulated in computer systems is important background information that will help you comprehend many of the different technologies. Not only are computer data representation and mathematics important for explaining how low-level physical layer modulation and encoding techniques work, they come into play even for higher-level concepts, such as how IP addresses are set up and used on the Internet.

In this section I provide some general background information on how numerical data is represented, stored and manipulated within computers and networking hardware. I begin with a description of binary numbers and the different terms used to refer to collections of binary information of various sizes. I describe the different types of numbering systems used in computer systems, such as octal, decimal and hexadecimal, and how data can be converted between these different types. I explain how arithmetic is performed on binary and hexadecimal numbers. I then discuss boolean logic and how logical functions are used to manipulate binary data.

These explanations then form the basis for a discussion of how logical functions are used for setting, clearing, inverting and masking bits. These operations are employed extensively in certain networking technologies and protocols. Masking operations are especially often used in IP addressing, so even though this section seems rather low-level it is quite relevant to the world of TCP/IP.

Needless to say, many of you reading this Guide know most or all of the information in this section, so feel free to skip (or just skim) those topics that you already know. However, I wanted to provide this background detail for the sake of those new to computing, or those needing a refresher. The pages are somewhat long and I try to assume little in the descriptions, so you may want to breeze through the parts that seem familiar. However, even those of you who know what a bit and byte are and the difference between binary and decimal numbers may find the discussion of bit masking worth perusing.

**Note:** There is only so much detail on the rudimentary basics of computing that I can cover in a Guide of this sort without getting too far afield. If the contents of this section are not sufficient to get you up to speed, I would recommend consulting a more comprehensive reference specific to computing theory and mathematics.

---

## **Binary Information and Representation: Bits, Bytes, Nibbles, Octets and Characters**

The essence of computing is *information*. Computer hardware and software products are designed to allow the input, storage, transfer and expression of various types of information. A primary way in which types of information are differentiated is based on whether they are *analog* or *digital*. In highly simplified terms, analog information is continuous, while digital is discrete. The distinction between them can be seen by considering, for example, a light switch and a dimmer. A light switch allows a light to be turned on or off only—no “in-between” states. That’s digital information—on or off. In contrast, a dimmer allows you to fine-tune the light output from fully on to fully off, with an infinite number of intermediate states in between: this is analog.

### ***Binary Information***

Modern digital computers store all of their information in digital form, because of how they work at a fundamental level. Much the way a light bulb has only an “on” or “off” value, so too do the components that store and manipulate information within computers. Millions of *transistors* comprise computer processors and other circuits, and are, in highly-simplified form, digital switches. Thus, all information in computers is manipulated as collections of information pieces that can be only “on” or “off”, like a switch.

Since there are only two possible states, “on” or “off”, this is called *binary* information (the prefix “bi” meaning “two”, of course.) There are several advantages to using binary representation for information. It is a simple way to represent many types of information, such as the state of a light bulb, or whether a file has been successfully copied, or whether a temperature should be expressed in Celsius or Fahrenheit. It is also possible to collect multiple binary values together to represent more complex information.

Perhaps most importantly, binary information is ***unambiguous***. “On” is “on” and “off” is “off”, and this is important as it allows devices to detect clearly the value of a particular piece of information. Computers like black and white; they are not particularly good at dealing with “shades of gray”. This becomes especially important in the field of networking when transmission of data can cause signals to become polluted by noise.

The “on” or “off” condition of a binary value can be expressed in a number of different ways. In logical expressions, we may consider the value to be “true” or “false”. For representing mathematical values, the most common representation is “one” (“on”) or “zero” (“off”).

---

## Binary Information Representation and Groups

The fundamental building block of computer information is the *bit* (a contraction of *binary digit*). Every bit can be either 0 or 1. Making the value of a bit 1 is commonly called *setting* the bit; changing it to 0 is *resetting* or *clearing* it.

Of course, bits represent only a very small amount of information: a single fact or value. We must make collections of these bits so we can use them to store large amounts of information and more complex data types. The most common grouping is to take eight bits and reference them as a single unit. A collection of eight bits is technically called an *octet*, but is more commonly called a *byte*. (More on that in a moment.)

“Byte” is a jocular play on the term “bit”. Over time, other sizes of “bit collections” have also been defined. Some geek comedian decided that if eight bits made a “byte”, then four bits must be a “nybble” (or “nibble”). Hilarious. ☺ Larger collections have also been defined and given various names. [Table 2](#) summarizes the most common representations of groups of bits, and the terms used for them; their relative sizes are also shown graphically in [Figure 8](#).

**Table 2: Binary Information Group Representations and Terms**

Number of Bits	Common Representation Terms
1	Bit / Digit / Flag
4	Nybble / Nibble
8	Byte / Octet / Character
16	Double Byte / Word
32	Double Word / Long Word
64	Very Long Word

A few of these terms are worth special mention. Bit and byte we have already discussed, of course. A bit is also sometimes called a *flag*; this term is most often heard when a bit is used by itself to represent a particular information state. For example, a computer might use a “changed flag” to represent whether a particular file has been modified; this is an analogy to a flag either being raised or lowered to indicate a condition. These “flags” are often seen in networking message formats.

The term *character* is also used to express a set of eight bits. This use comes from the fact that computers often store alphanumeric characters, such as letters and numbers, one to a byte. The 16-bit *word* is fairly often used, but not nearly as much as “byte”. The larger collections of bits, such as double word and so on, are not often encountered in every-day parlance; they are used to represent chunks of data in technical fields such as hardware design or programming.

You may also have noticed the number of bits used for each of these terms is a power of two. This is of course not a coincidence. As we will see in the subsequent topics in this section, this occurs because when bits come in sets that are a power of two in size, they are

**Figure 8: Binary Information Representations and Terms**

This diagram shows the relative sizes of the most commonly-sized “collections” of binary information.

easier to represent and manipulate in a convenient manner. The number of bits in the term can itself be easily expressed using binary numbers. This will make more sense after you read [the topic that follows on decimal binary, octal and hexadecimal numbers](#).

**Key Concept:** Computers store all information in *binary digital* form, which means all data—be it text, photographs, audio or whatever else—is comprised only of collections of ones and zeroes. The fundamental building block of digital information is the *binary digit* or *bit*, which represents a single zero or one state. To represent larger amounts of information, bits can be collected into groups of four, eight, sixteen, 32 or 64, called *nybbles*, *bytes*, *words*, *long words* and *very long words* respectively.

### **Byte versus Octet**

There has been some disagreement, and even controversy, surrounding the use of the words *byte* and *octet*. The former term has traditionally been the most popular in common parlance for a set of eight bits, especially in North America. However, it is **technically** not the correct term.

---

A byte is, formally, the smallest unit of data that can be read from or written to at one time in a computer system. In almost all cases today, that is indeed eight bits, but there have been some systems where a byte was not eight bits. Some older 36-bit computers used 9-bit bytes, and there were also systems that had byte sizes of 6 or 7 bits, or even variable-sized bytes. For this reason, many people, especially techie professionals, prefer the term *octet*, which clearly and unambiguously implies “eight”. This term is much more common outside North America.

This matter of *octets* and *bytes* is another of the little “tempests in tea pots” that computer people seem to love so much. The bottom line in modern computer systems, however, is that an octet is a byte and a byte in an octet, and the terms can be used interchangeably without too much danger. You will more often see *octets* used in technical standards. In this Guide, I use the term bytes for a simple reason: it is the term that most people are familiar with, including myself (though bear in mind that I live in North America; if I were European I might have rather different views on this!)

**Key Concept:** Formally, an *octet* is the correct term for exactly eight bits, while a *byte* is the smallest number of bits that can be accessed in a computer system, which may or may not equal eight. In practice, modern computers use 8-bit bytes, and the terms are used interchangeably (with byte being more common in North America, and octet often being preferred in Europe).

---

## Decimal, Binary, Octal and Hexadecimal Numbers

The numbers we are used to using in every-day life are called *decimal numbers*, where the word “decimal” refers to the number ten. The reason for this is rather obvious: every digit can take on one of ten values: 0 to 9. Arithmetic performed on decimal numbers is also called *base 10* mathematics, because of this orientation around the number 10. (Why is the number 10 the foundation of our normal mathematical system? Hold both hands up and count...)

Computer systems, however, don’t have fingers or toes; they deal only with binary numbers. Each bit can represent not a value from 0 to 9, but from, well, 0 to 1. A single “0 or 1” value is sufficient for encoding a single fact, such as whether your car currently is using summer tires or snow tires. It’s not nearly enough to hold more complex information, such as your bank account balance, or a text document, or a picture of the Yellowstone canyon.

### ***Binary Numbers and their Decimal Equivalents***

For this reason, larger collections of bits have been defined by computer scientists, such as bytes (octets), words, and so forth. When individual bits are collected into sets in this way, they can be used together to represent larger integers, which are called *binary numbers*. Since there are only two possible values for each digit, binary numbers are also called *base 2* numbers.

A lot of people are intimidated by binary numbers, because at first they seem quite confusing. The key to understanding them is realizing that they are exactly the same as decimal numbers, except that instead of each digit having a value in the range of 0 to 9, each has a value in the range of 0 to 1. For example, when you count in decimal, you go up to 9 in the one's place, and then you need a second place for "tens". If you go above 99, you need a third place for "hundreds". Each additional place added on the left is a higher power of ten. Binary is the same, except the limit for each place is 1 instead of 9. In binary, you go up to 1 in the one's place, and then need a second place for "twos". If you go above 3, you need a third place for "fours". Each added place is a subsequent higher power of two, rather than ten.

Thus, where counting in decimal goes 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13 and so on, counting in binary goes 0, 1, 10, 11, 100, 101, 110, 111, 1000, 1001, 1010, 1011, 1100, 1101. The concept is identical—you just need a lot more digits for binary numbers because there are so many fewer values allowed for each digit. For example, the number "13" in decimal is the same as "1101" in binary. How? Well, in decimal, we have a 3 in the one's place, plus a "1" in the "tens" place, which has a value of 10. This is  $3+10=13$ . In binary, we have a "1" in the "ones" place, plus a "1" in the "fours" place, plus a "1" in the "eights" place, which is  $1+4+8$  or 13.

To take a more complex example, 211 in decimal is 11010011 in binary. Table 3 shows how the two are equivalent, by adding the values for each binary digit place where there is a 1. Read it from left to right, going top to bottom. Starting in the left-most column, we see that the example number has a 1 in the "128s" place. So we start with a sum of 128. In the next column there is a 1 in the "64s" place, so we add 64 for a running sum of 192. But in the "32s" place the binary digit value is 0, so we don't add 32 to the sum. We continue down to the "ones" place to get the decimal equivalent of the binary number.

**Table 3: Binary and Decimal Number Equivalents**

Binary Number	1	1	0	1	0	0	1	1
Power of Two	$2^7$	$2^6$	$2^5$	$2^4$	$2^3$	$2^2$	$2^1$	$2^0$
Value of Digit Place	128	64	32	16	8	4	2	1
Value For This Number	128	64	0	16	0	0	2	1
Running Sum (from left to right)	128	$128+64 = 192$	192	$192+16 = 208$	208	208	$208+2 = 210$	$210+1 = 211$

As you can see from this, a binary number with N digits can hold up to  $2^N$  values. So, a byte, with eight bits, can hold  $2^8$  or 256 different values, which are numbered from 0 to 255. A 16-bit word can hold  $2^{16}$  or 65,536 values.

### ***Making Binary Numbers Easier to Use By Grouping Bits***

One problem with binary numbers is that while computers love them, they are unintuitive for humans, who are used to decimal numbers. One reason for this is that they quickly get very, very long and cumbersome to deal with. For example, 1,000,000 in decimal is

---

11110100001001000000 in binary. To make binary numbers easier to work with, two different shorthand notations have been defined. In both of these, instead of working with each bit individually, they are collected into subgroups, each of which is assigned a single digit in an alternative numbering system.

## Octal Numbers

Let's take the binary number 11110100, which is 244 in decimal. Now, instead of looking at each bit individually, let's chop them into groups of three, starting from the right. So, 11110100 becomes (11)(110)(100). Now, each of those groups has three bits, so each can have  $2^3$  values: from 0 to 7. In this case, (11)(110)(100) = (3)(6)(4), or 364 in the *octal* or *base-8* numbering system (see [Figure 9](#)). Just as with binary, octal numbers are the same as decimal numbers, except they are base 8 instead of base 10. So, 364 in octal is just 3 times 64 plus 6 times 8 plus 4, or 244. The advantage that octal has over binary is obvious: it's a lot less cumbersome to deal with larger numbers. 1,000,000 in decimal is 3641100 in octal.

**Figure 9: Binary, Octal and Hexadecimal Number Representations**

A binary number can be represented in octal form by grouping its bits into sets of three, or in hexadecimal by using sets of four bits. These base-8 and base-16 numbers have the advantage of being far shorter than binary numbers, and hence much easier to work with.

## Hexadecimal Numbers

Octal numbers were at one time quite commonly used, but are much less popular today. The problem with octal is that it divides bits into groups of three, but sets of binary numbers typically use a number of bits that is a multiple of *four*. An alternative method was defined that does the same thing but using groups of four. Since there are four bits in each group, each can have one of sixteen values, and this is called the *hexadecimal* or *base 16* numbering system. It is also commonly called just *hex* for short.

**Note:** As an interesting “sidebar”, the term *hexadecimal* was not the first one used for base-16 numbers in computing. Originally, these were called *sexadecimal* numbers. This is actually the correct term, since Latin prefixes (*sex*-) are normally used for numbers, not Greek ones (*hexa*-). However, in the early 1950s, IBM decided that the word “sexadecimal” was just a little too “provocative” for their tastes, so they changed it to *hexadecimal*. IBM being IBM—especially back then—meant everyone else followed suit. As I understand it, neither term is etymologically perfect, but well, this note is long enough already. ☺

---

Now, let's go back to the example just above, 11110100 in binary, 244 in decimal. We divide this into groups of four, to get (1111)(0100). The binary value “1111” is 15, and “0100” is four, so we have (15)(4). Hmm, now we have a bit of a problem, don't we? We need to be able to represent “15”, but we only have 10 numerals. To get around this, in hexadecimal numbers the values 10, 11, 12, 13, 14, or 15 are represented by the letters “A”, “B”, “C”, “D”, “E” and “F” respectively. So, 11110100 in binary is (15)(4), or “F4” in hexadecimal (also shown in [Figure 9](#)).

Hexadecimal numbers are in some ways even less intuitive than binary ones. After all, it takes some practice to get used to thinking of letters as numbers. However, they are very useful due to the way they compactly represent binary information. Where 1,000,000 in decimal is 11110100001001000000 in binary, it is only “F4240” in hexadecimal—even shorter than the decimal number, since 16 is larger than 10. Also, a single byte has eight bits, so it can be represented using only two hexadecimal digits. Due to this convenience factor, hex numbers are widely used in the field of computing, including networking. For example, you will often see values expressed in hexadecimal for items such as MAC addresses, and for representing different types of information in frame or packet formats.

**Key Concept:** Regular numbers are called *decimal numbers* because they are built upon our base-10 system of mathematics. Computers use collections of one-or-zero bits called *binary numbers*, which can be treated just like regular numbers except that each digit can only be 0 or 1 instead of 0 to 9. Bits in a binary number can be expressed as *octal numbers* by grouping three bits into an octal digit that ranges from 0 to 7, or taking sets of four bits to create a single *hexadecimal* digit from 0 to 15. To represent the values 10 through 15 in hexadecimal using a single character, the letters A through F are used.

---

If you see a number that has a letter from “A” to “F” in it, you know it is a hex number, but not all hex numbers have those digits. Hex numbers are usually displayed in a special notation, to avoid confusing them with decimal numbers. That notation is either a prefix of “0x” or a suffix of “h” (sometimes both). Thus, the number “54” is just “54”, but “0x54” is “54” in hexadecimal, which is 5 times 16 plus 4, or “84” in decimal. Be sure to watch for these representations.

---

## Decimal, Binary, Octal and Hexadecimal Number Conversion

---

Humans are accustomed to dealing with decimal numbers, while computers use binary digits. Octal and hexadecimal numbers are “short forms” for binary numbers, where each hexadecimal digit takes the place of either three or four binary digits. Since people and computers speak different “number languages”, it is often necessary to convert numbers from one of these systems to the other. If you spend any amount of time dealing with computers or networks, you will find yourself needing to do this on occasion, so it's worth taking a quick look at how it is done.

First of all, let me say this: the easiest way to convert between decimal, binary, octal and hexadecimal numbers is to use a scientific calculator. This is what most people do, and I highly recommend it. However, there are cases where you may need to be able to do this by hand—we don't all always have a calculator on us. Also, understanding the manual conversion process will help you comprehend more intuitively how binary, octal and hexadecimal numbers work. So, let's take a look.

**Note:** If you don't have a scientific calculator, there is a reasonable facsimile built into most versions of Windows: the *Calculator* program, which can usually be found in your Accessories folder. Open it, go to the *View* menu, and change the setting from “Standard” to “Scientific”. Click the button next to a numbering system. Then enter a number, and if you click a button next to a different numbering type, the number will be converted for you. Easy. (I would bet Apple and UNIX machines have similar tools, I just have more experience with Windows.)

---

### ***Conversions Between Binary, Octal and Hexadecimal***

Okay, let's start with the easy stuff first. Conversion between binary, octal and hexadecimal is very simple, as you may have noticed in [the preceding topic, where I introduced them](#). Each octal digit is three binary digits, and each hexadecimal digit is four binary digits. Thus, to convert from binary to octal or hex, just group the digits, and convert each group into an octal or hex digit. To go the other way, convert each hex or octal digit into a set of bits. [Table 4](#) shows the conversions from each of the octal and hexadecimal single-digit values to binary (with decimal digits thrown in for convenience):

**Table 4: Binary, Octal and Hexadecimal Digit Conversion (Page 1 of 2)**

Binary Digits	Octal Digit	Hexadecimal Digit	Decimal Digit
0000	0	0	0
0001	1	1	1
0010	2	2	2
0011	3	3	3
0100	4	4	4

**Table 4: Binary, Octal and Hexadecimal Digit Conversion (Page 2 of 2)**

Binary Digits	Octal Digit	Hexadecimal Digit	Decimal Digit
0101	5	5	5
0110	6	6	6
0111	7	7	7
1000		8	8
1001		9	9
1010		A	
1011		B	
1100		C	
1101		D	
1110		E	
1111		F	

Let's look at some specific examples using larger numbers:

- ☉ **Binary to Octal:** Suppose we start with the binary number 110101001010. We divide this into groups of three: (110)(101)(001)(010). Each of these, we convert to a number from 0 to 7 (which is easy to do in your head if you practice a bit). The result is (6)(5)(1)(2) or 6512 octal.
- ☉ **Hexadecimal to Binary:** Let's start with the hex number 0x4D1B. We convert each digit as given in the table above. So, we have 0x4D1B = (0100)(1101)(0001)(1011) or 0100110100011011.

### ***Conversions From Binary, Octal and Hexadecimal to Decimal***

Conversions to and from decimal are more complicated than conversions between binary, octal and hexadecimal, because 2, 8 and 16 are powers of two but ten is not. Of the two directions, conversions **to** decimal are easier: you take the value of each binary, octal or hexadecimal digit, convert it to decimal, and then multiply it by the power of 2, 8 or 16 represented by the digit's place in the number. Then you add all the numbers together. I did this in [the previous topic](#) with the example of the decimal number 211 (see [Table 3](#)).

Let's take an example of going from hexadecimal to decimal. [Table 5](#) shows the hexadecimal number 0x830C converted to decimal (octal uses a similar process). Read the table from left to right, top to bottom; each digit's value is multiplied by the appropriate power of 16 and added together, yielding the result 33,548 decimal.

**Table 5: Hexadecimal to Decimal Number Conversion (Page 1 of 2)**

Hexadecimal Number	8	3	0	C
Decimal Value of Digit	8	3	0	12

---

**Table 5: Hexadecimal to Decimal Number Conversion (Page 2 of 2)**

Power of 16	$16^3$	$16^2$	$16^1$	$16^0$
Value of Digit Place	4096	256	16	1
Value For This Number	$4096 \times 8 = 32768$	$3 \times 256 = 768$	$0 \times 16 = 0$	$12 \times 1 = 12$
Running Sum (from left to right)	32768	$32768 + 768 = 33536$	33536	$33536 + 12 = 33548$

### ***Conversions From Decimal to Binary, Octal and Hexadecimal***

Now let's consider conversions **from** decimal. These require that you perform the opposite of the calculation above: you divide and subtract instead of multiplying and adding.

#### **Conversion From Decimal to Binary**

The easiest of the three conversions from decimal is to binary—since the maximum value of each digit is one, there is no dividing, just subtraction. All you do is the following:

1. Find the largest power of two that is smaller than the number.
2. Put a “1” in the digit place for that power of two and subtract that power of two from the decimal number.
3. Repeat steps #1 and #2 until you are reduced to zero.

This is easier to explain using an example and a table, of course. Let's convert the decimal number 689, as shown in [Table 6](#). Again, read the table starting from the upper left, and going down and then across. We start by noticing that 1024 is not less than or equal to 689, so the “1024s” place gets a 0. In the next place, 512 is less than 689, so we make the “512s” place a 1 and subtract 512 from 689 to leave 177. The calculation continues, eventually showing shows that 689 decimal is 1010110001 binary.

**Table 6: Decimal to Binary Number Conversion**

<b>Decimal Value Before Considering This Digit Place</b>	<b>689</b>	689	177	177	49	49	17	1	1	1	1
<b>Power of Two</b>	$2^{10}$	$2^9$	$2^8$	$2^7$	$2^6$	$2^5$	$2^4$	$2^3$	$2^2$	$2^1$	$2^0$
<b>Value of Digit Place</b>	1024	512	256	128	64	32	16	8	4	2	1
<b>Value of Digit Place Equal To or Less Than Current Decimal Number?</b>	No	Yes	No	Yes	No	Yes	Yes	No	No	No	Yes
<b>Subtraction Step</b>	skip	689-512 = 177	skip	177-128 = 49	skip	49-32 = 17	17-16 = 1	skip	skip	skip	1-1 = 0
<b>Binary Digits</b>	<b>0</b>	<b>1</b>	<b>0</b>	<b>1</b>	<b>0</b>	<b>1</b>	<b>1</b>	<b>0</b>	<b>0</b>	<b>0</b>	<b>1</b>

**Conversion From Decimal to Octal or Hexadecimal**

The process for octal and hexadecimal is almost the same, except you must divide by powers of two instead of just subtracting:

1. Start with the highest power of 16 (hexadecimal) or 8 (octal) that is smaller than the number.
2. Divide the decimal number by that power, keeping only the integer part of the result.
3. Keep the remainder after the division is done, for the next step.
4. Repeat steps #1 to #3 until you get to the “ones” place, and then put there whatever is left after the higher digits were done.

Table 7 shows the same example as Table 6 but goes from decimal to hexadecimal instead of decimal to binary: 689 in decimal is 0x2B1 hexadecimal.

**Table 7: Decimal to Hexadecimal Number Conversion**

<b>Decimal Value Before Considering This Digit Place</b>	<b>689</b>	689	177	1
<b>Power of 16</b>	$16^3$	$16^2$	$16^1$	$16^0$
<b>Value of Digit Place</b>	4096	256	16	1
<b>Value of Digit Place Smaller Than Current Decimal Number?</b>	No	Yes	No	n/a
<b>Division Step</b>	skip	689/256 = 2.691; use “2” for this digit.	177/16 = 11.0625; use “B” for this digit.	n/a
<b>Remainder After Division</b>	skip	177	1	n/a
<b>Hexadecimal Digits</b>	<b>0</b>	<b>2</b>	<b>B</b>	<b>1</b>

---

## Binary, Octal and Hexadecimal Arithmetic

Many of us use arithmetic every day as part of our regular lives without really noticing it, to give us the information we need to make decisions. In a similar way, computers perform arithmetic operations all the time as part of their normal operation. The main differences between how computers do it and how we do it are two-fold: computers use binary numbers, and computers are *much* faster.

As I said in my [introduction to binary, octal and hexadecimal numbers](#), those forms are different representations of numbers, and are not really much different than decimal numbers. They just have a different number of values per digit. In a similar vein, arithmetic with binary, octal or hexadecimal numbers is not that much different from the equivalent operations with decimal numbers. You just have to keep in mind that you are working with powers of 2, 8 or 16, instead of 10, which isn't always easy to do.

As was the case with [conversions](#), calculators are usually the way to go if you need to do math with binary, octal or hexadecimal numbers. If your calculator only does math with decimal numbers, one trick is to convert the numbers to decimal, then perform the operation, and convert back the result. However, you can fairly easily do the same addition, subtraction, multiplication and division on binary, octal or hex numbers that you do with decimal numbers, by using the Windows *Calculator* program or equivalent.

Multiplication and division of binary numbers is a common operation within computers, but isn't a calculation that often needs to be done by people who are working with them. Addition and subtraction are much more common (especially addition), and have the added bonus of being much easier to explain. You probably won't need to do this type of arithmetic that often, but it's good to understand it, at least a little. I am going to provide just a couple of examples to give you the general idea.

### Binary Arithmetic

Let's start with binary. Adding binary numbers is the same as adding decimal ones, but you end up doing a *lot* of carrying of ones since there are so few values allowed per digit. [Table 8](#) shows an example, with one digit in each column; read it from right to left and top to bottom, just as you would usually do manual addition. So we start by adding the "1" in the "ones" place from the first number with the "1" in that place from the second number, yielding a raw digit sum of 2. This means the result for the "ones" digit is "1" and we carry a 1 to the "twos" place. We continue with this process until we have added all the digits.

**Table 8: Binary Addition**

Carry		1	1			1	1	—
First Binary Number	1	0	1	1	0	0	1	1
Second Binary Number	0	0	1	1	1	0	0	1
Raw Digit Sum	1	1	3	2	1	1	2	2

---

**Table 8: Binary Addition**

Result	1	1	1	0	1	1	0	0
Carry to Next Higher Digit			1	1			1	1

### ***Octal and Hexadecimal Arithmetic***

Octal and hexadecimal are pretty much the same, except that you carry if the sum in a particular digit exceeds either 8 or 16, respectively. Hexadecimal is more common, and more interesting, so let's take an example of adding two hex numbers together. While performing the operation, you will need to do conversions of single-digit hex numbers to decimal and back again, but this isn't too difficult.

This example is shown in [Table 9](#), which again should be read from right to left. We start by adding "8" (decimal 8) to "A" (decimal 10) in the "ones" place. This yields a raw sum of 18, from which we carry 16 as a "1" to the "16s" place and leave a result of 2. We add this 1 to the "D" (value 13) and "E" (14 value) of the "16s" place. This is a total of 28, leaving 12 ("C" in hexadecimal) and we carry a 1 to the "256s" place. This continues until we are left with a sum of 6DC2h.

**Table 9: Hexadecimal Addition**

Carry		1	1	
First Hex Number	2	C	D	8
Second Hex Number	4	0	E	A
Raw Digit Sum	2+4 = 6	1+12+0 = 13	1+13+14 = 28	8+10 = 18
Result	6	D	C	2
Carry to Next Higher Digit			1	1

## **Boolean Logic and Logical Functions**

Every bit in a computer system can hold a value of either "one" or "zero", which represent the basic "on" or "off" states inherent in a binary digital system. In the preceding topics in this section, I demonstrated how groups of these bits can be collected into sets to represent larger binary numbers, and then how those can be used for performing various mathematical operations.

However, as I mentioned when I [introduced the concept of binary information](#), we can also interpret the "on" and "off" values of a binary digit as "true" or "false" respectively. These can represent various logical conditions within a computer or other system. Furthermore, there are various logical operations that can be used to manipulate and combine these "true" or "false" values to represent more complex logical states. One of the pioneers of using binary values in logical thought was British mathematician George Boole (1815-1864), and in recognition of his contribution to this field, this system of binary values and conditions is commonly called *boolean logic*.

---

## Boolean Logical Functions

Boolean logic defines a number of *boolean logical functions*, which are also sometimes called *operators*. Each of these uses a logical algorithm to compute an output value based on the value of one or more inputs. The algorithm determines when the output is a “true” value, based on what combination of “true” and “false” values the inputs take. For this reason, the table that shows the inputs and outputs for a logical function is called a *truth table*. Each of the logical functions is analogous to a “real world” logical operation that we use to define various logical situations, as we will see.

It is much easier to see how boolean logic works by looking at examples, rather than reading these types of formal descriptions. So, let's just jump right in and see it in action, by looking at the different functions and how they work.

### The **NOT** Function

Let's start with the simplest, the *NOT function*. As you might expect, this is just a negation; the output is the opposite of the input. The *NOT* function takes only one input, so it is called a *unary* function or operator. The truth table for *NOT* is shown in [Table 10](#). As you can see, the output is true when the input is false, and vice-versa.

**Table 10: NOT Operator Truth Table**

Input	Output
False	True
True	False

The *NOT* function logically represents the opposite of a condition. For example, suppose we have a bit called “B1” whose logical meaning is that when the bit is “true”, a particular pixel on a screen is lit up. Then the *boolean expression* “NOT B1” would be the opposite: it would be false when the pixel is lit up, and thus true only when the pixel is **not** lit up. Pretty straight-forward.

Now, before proceeding further, I am going to play a little trick on you. ☺ As I said above, boolean logic is based on “true” and “false” values. However, I also said that “true” and “false” are represented in computers by “one” or “zero” values. For this reason, boolean logic is often expressed in terms of ones and zeroes, instead of “true” and “false”. The circuits inside computer processors and other devices manipulate one and zero bits directly using these functions. In some (but not all) cases they interpret “one” and “zero” as “true” and “false”, but in either case the two representations are functionally equivalent.

---

[Table 11](#) shows the same truth table as [Table 10](#), but using bit values: each "True" is represented as a 1 and each "False" as a 0.

**Table 11: *NOT* Operator Truth Table (Using Bit Values)**

Input	Output
0	1
1	0

### The *AND* and *OR* Functions

There are two other primary boolean functions that are widely used: the *AND function* and the *OR function*. The output of an *AND* function is true only if its first input **and** its second input **and** its third input (etc.) are all true. The output of an *OR* function is true if the first input is true **or** the second input is true **or** the third input is true (again, etc.)

Both *AND* and *OR* can have any number of inputs, with a minimum of two. [Table 12](#) shows the truth table for the *AND* function, with two inputs. You can see that the output is a 1 only when both inputs are 1, and is 0 otherwise.

**Table 12: *AND* Operator Truth Table**

Input #1	Input #2	Output
0	0	0
0	1	0
1	0	0
1	1	1

Like the *NOT* function, the *AND* function represents a logical operation similar to how we use the word in our every day lives. For example, at lunch time, I might suggest to a colleague "let's go out for lunch *and* stop at the post office".

The truth table for the *OR* function (again with two inputs) is shown in [Table 13](#). Here, the output is 1 whenever a 1 appears in at least one input, not necessarily both as in the previous table.

**Table 13: *OR* Operator Truth Table**

Input #1	Input #2	Output
0	0	0
0	1	1
1	0	1
1	1	1

---

Interestingly, unlike the *AND* function, the boolean *OR* function in fact does **not** have the same meaning as the way that we routinely use the word “or” in English. When we say “or”, we usually mean one “or” the other, but not both: “you can have apple pie *or* chocolate cake for dessert”. In the boolean *OR* however, the output is true as long as **any** of the inputs is true, even if more than one is.

### Exclusive-OR (*XOR* or *EOR*)

A modification of *OR* called *Exclusive-OR* (abbreviated either *XOR* or *EOR*) represents the way we normally use “or” in the real world. Its output is only true if one input is true or the other, but **not both**. The truth table for *XOR* is as shown in [Table 14](#). Notice the difference between this table and [Table 13](#): the output is 0 in the case where both inputs is 1.

**Table 14: Exclusive OR (*XOR*) Operator Truth Table**

Input #1	Input #2	Output
0	0	0
0	1	1
1	0	1
1	1	0

### Combining Boolean Functions to Create Boolean Expressions

The functions described above can also be combined in arbitrary ways to produce more complex logical conditions. Boolean logic expressions are used in many different contexts in the computing field. A common place that most people use them is in a World Wide Web search engine. For example, if you enter “cheese *AND* (cheddar *OR* swiss) *NOT* wisconsin” into a search engine, the program will return pages that contain the word “cheese” that also contain the word “cheddar” or “swiss” (or both), but that do **not** contain the word “wisconsin”.

(Sorry, Wisconsinite cheese lovers—but I live in Vermont! ☺)

Boolean functions are the building blocks of much of the circuitry within computer hardware. The functions are implemented as tiny *gates* that are designed to allow electrical energy to flow to the output only based on certain combinations of inputs as described by the truth tables for functions like *NOT*, *AND*, *OR* and others. In networking, boolean logic is important for describing certain conditions and functions in the operation of networks. Boolean functions are also very important because they are used to set, clear and mask strings of binary digits, which we will explore in the next topic.

**Key Concept:** *Boolean logic* is a system that uses boolean functions to produce outputs based on varying conditions in their input data. The most common boolean functions are *NOT*, which produces as output the opposite of its input; *AND*, which is true (1) only if all of its inputs are true (1); *OR*, which is true if any of its inputs is true; and *XOR*, which is true only if exactly one of its inputs is true (or put another way, if the inputs are different). These functions can be used in boolean logic expressions that represent conditional states for making decisions, and can also be used for bit manipulation.

---

## Bit Masking (Setting, Clearing and Inverting) Using Boolean Logical Functions

The [boolean functions](#) *NOT*, *AND*, *OR* and *XOR* describe different ways that logical expressions can be used to manipulate “true” and “false” values to represent both simple and complex decisions or conditions. However, these functions can also be used in a more mundane manner, to allow the direct manipulation of binary data. This use of boolean logic is very important in a number of different applications in networking.

As I mentioned in [the topic introducing binary numbers](#), giving a bit a value of one is called *setting* the bit, while giving it a value of zero is either *resetting* or *clearing* it. In some situations bits are handled “individually”, and are set or cleared simply by assigning a one or zero value to each bit. However, it is common to have large groups of bits that are used collectively to represent a great deal of information, where many bits need to be set or cleared at once. In this situation, the boolean functions “come to the rescue”.

### ***Setting Groups of Bits Using the OR Function***

Setting bits en masse can be done by exploiting the properties of the *OR* function. Recall that the *OR* function's output is true (one) if any of its inputs is true (one). Thus, if you “OR” a bit with a value known to be one, the result is always going to be a one, no matter what the other value is. In contrast, if you “OR” with a zero, the original value, one or zero, is not changed.

By using a string with zeroes and ones in particular spots, you can set certain bits to 1 while leaving others unchanged. This procedure is comparable to how a painter masks areas that he does not want to be painted, using plastic or perhaps masking tape. Thus, the process is called *masking*. The string of digits used in the operation is called the *bit mask*, or more simply, just the *mask*.

An example will illustrate. Suppose we have the 12-bit binary input number 101001011010, and we want to set the middle six bits to be all ones. To do this, we simply *OR* the number with the 12-bit mask 000111110000. Table 15 shows how this works, with the changed bits in the result highlighted—we simply *OR* each bit in the input with its corresponding bit in the mask:

**Table 15: Setting Bits Using an *OR* Bit Mask**

Input	1	0	1	0	0	1	0	1	1	0	1	0
Mask	0	0	0	1	1	1	1	1	1	0	0	0
Result of OR Operation	1	0	1	1	1	1	1	1	1	0	1	0

### ***Clearing Groups of Bits Using the AND Function***

To clear a certain pattern of bits, you do a similar masking operation, but using the *AND* function instead. If you *AND* a bit with zero, it will clear it to zero regardless of what the bit was before, while *AND*ing with one will leave the bit unchanged. So, to take the same example above and clear the middle six bits, we *AND* with the reverse bit mask, 11100000111. This is shown in Table 16 and illustrated in Figure 10.

**Figure 10: Clearing Bits Using an *AND* Bit Mask**

This diagram shows how a bit mask can be used to clear certain bits in a binary number while preserving others. The mask shown here can be likened to a painter's mask; each 1 represents a "transparent" area that keeps the corresponding input bit value, while each 0 is a bit where the original value is to be cleared. After performing an *AND* on each bit pair, the first three and last three bits are preserved while the middle six, since they were each *AND*ed with 0, are forced to 0 in the output.

---

**Table 16: Clearing Bits Using an AND Bit Mask**

Input	1	0	1	0	0	1	0	1	1	0	1	0
Mask	1	1	1	0	0	0	0	0	0	1	1	1
Result of AND Operation	1	0	1	0	0	0	0	0	0	0	1	0

We can also look at this “clearing” function a different way. We are clearing the bits where the mask is a zero, and in so doing “selecting” the bits where the mask is a one. Thus, *AND*ing with a bit mask means that you “keep” the bits where the mask is a one and “remove” the bits where it is a zero.

### ***Inverting Groups of Bits Using the XOR Function***

There are also situations in which we want to *invert* some bits; that is, change a one value to a zero, or a zero value to a one. To do this, we use the *XOR* function. While this is not as intuitive as the way masking works with *OR* and *AND*, if you refer to the *XOR* truth table (Table 14) you will see that if you *XOR* with a one, the input value is flipped, while *XOR*ing with a zero causes the input to be unchanged. To see how this works, let's take the same input example and invert the middle six bits, as shown in Table 17.

**Table 17: Inverting Bits Using an XOR Bit Mask**

Input	1	0	1	0	0	1	0	1	1	0	1	0
Mask	0	0	0	1	1	1	1	1	1	0	0	0
Result of XOR Operation	1	0	1	1	1	0	1	0	0	0	1	0

In the world of networking, bit masking is most commonly used for the manipulation of addresses. In particular, masking is perhaps best known for its use in differentiating between the host and subnetwork (subnet) portions of [Internet Protocol \(IP\) addresses](#), a process called *subnet masking* and described in [the section on IP subnet addressing](#).

**Note:** Masks are often expressed in either hexadecimal or decimal notation for simplicity of expression, as shown in the [IP subnetting summary tables](#). However, the masks are always applied in binary, as described above. You should convert the mask to binary if you want to see exactly how the masking operation is going to work.

---

**Key Concept:** The properties of the *OR* and *AND* boolean functions make them useful when certain bits of a data item need to be set (changed to 1) or cleared (changed to 0), a process called *bit masking*. To set bits to one, a mask is created and used in a bit-by-bit *OR* with the input; where the mask has a value of 1, the bit is forced to a 1, while each 0 bit leaves the corresponding original bit unchanged. Similarly, a mask used with *AND* clears certain bits; each 1 bit in the mask leaves the original bit alone, while each 0 forces the output to 0. Finally, *XOR* can be used to invert selected bits using a mask.

---

---

# The Open System Interconnection (OSI) Reference Model

---

Models are useful because they help us understand difficult concepts and complicated systems. When it comes to networking, there are several models that are used to explain the roles played by various technologies, and how they interact. Of these, the most popular and commonly used is the *Open Systems Interconnection (OSI) Reference Model*.

The idea behind the OSI Reference Model is to provide a framework for both designing networking systems and for explaining how they work. As you read about networking, you will frequently find references to the various levels, or *layers*, of the OSI Reference Model. The existence of the model makes it easier for networks to be analyzed, designed, built and rearranged, by allowing them to be considered as modular pieces that interact in predictable ways, rather than enormous, complex monoliths.

In fact, it's pretty much impossible to read a lot about networking without encountering discussions that presume at least some knowledge of how the OSI Reference Model works. This is why I strongly advise that if you are new to the OSI Reference Model, you read this chapter carefully. While it is all arguably “background material”, reading it will help form an important foundation in your understanding of networks, and will make the rest of the Guide make more sense at the same time.

If you are quite familiar with the OSI Reference Model, you may wish to skip this chapter of the Guide, or just skim through it. You can always return later to brush up on particular issues, as needed. There are also many links that come back to the descriptions of the individual layers from various parts of the Guide.

In the pages that follow, I describe the OSI Reference Model in detail. I begin with a history of the model, and a discussion of some general concepts related to the OSI model and networking models overall. I provide a useful analogy to help you understand how the reference model works to explain the interaction of networks on multiple levels. I then describe each of the seven layers of the OSI Reference Model, and conclude with a summary of the layers and their respective functions.

**Note:** This section describing the OSI Reference Model is geared to a discussion of networks and internetworks in general, and not specifically to the TCP/IP protocol suite. Therefore, not all of the material in this section is directly relevant to learning about TCP/IP, though much of it is. You may also wish to refer to [the topic covering the reference model that describes TCP/IP](#), which also discusses how the TCP/IP and OSI models compare.

---

---

## History of the OSI Reference Model

---

Looking at the origins of the OSI Reference Model takes us back to several issues that were discussed in the [Networking Fundamentals](#) chapter of this Guide; specifically, I am talking about [standards and standards organizations](#). The idea behind the creation of networking standards is to define widely-accepted ways of setting up networks and connecting them together. The OSI Reference Model represented an early attempt to get all of the various hardware and software manufacturers to agree on a framework for developing various networking technologies.

In the late 1970s, two projects began independently, with the same goal: to define a unifying standard for the architecture of networking systems. One was administered by the *International Organization for Standardization (ISO)*, while the other was undertaken by the *International Telegraph and Telephone Consultative Committee*, or *CCITT* (the abbreviation is from the French version of the name). These two [international standards bodies](#) each developed a document that defined similar networking models.

In 1983, these two documents were merged together to form a standard called *The Basic Reference Model for Open Systems Interconnection*. That's a mouthful, so the standard is usually referred to as the *Open Systems Interconnection Reference Model*, the *OSI Reference Model*, or even just the *OSI Model*. It was published in 1984 by both the ISO, as standard ISO 7498, and the renamed CCITT (now called the *Telecommunications Standardization Sector of the International Telecommunication Union* or *ITU-T*) as standard X.200. (Incidentally, isn't the new name for the CCITT ***much*** catchier than the old one? Just rolls off the old tongue, doesn't it. ☺)

One interesting aspect of the history of the OSI Reference Model is that the original objective was ***not*** to create a model primarily for educational purposes—even though many people today think that this was the case. The OSI Reference Model was intended to serve as the foundation for the establishment of a widely-adopted suite of protocols that would be used by international internetworks—basically, what the Internet became. This was called, unsurprisingly, the OSI Protocol Suite.

However, things didn't quite work out as planned. The rise in popularity of the Internet and its [TCP/IP protocols](#) met the OSI suite head on, and in a nutshell, TCP/IP won. Some of the OSI protocols were implemented, but as a whole, the OSI protocols lost out to TCP/IP when the Internet started to grow.

The OSI model itself, however, found a home as a device for explaining the operation of not just the OSI protocols, but networking in general terms. It was used widely as an educational tool—much as I use it myself in this Guide—and also to help describe interactions between the components of other protocol suites and even hardware devices. While most technologies were not designed specifically to meet the dictates of the OSI model, many are described in terms of how they fit into its layers. This includes networking protocols, software applications, and even different types of hardware devices, such as switches and

---

routers. The model is also useful to those who develop software and hardware products, by helping to make clear the roles performed by each of the components in a networking system.

**Key Concept:** The *Open Systems Interconnection Reference Model* (*OSI Reference Model* or *OSI Model*) was originally created as the basis for designing a universal set of protocols called the *OSI Protocol Suite*. This suite never achieved widespread success, but the model became a very useful tool for both education and development. The model defines a set of layers and a number of concepts for their use that make understanding networks easier.

---

---

## General Reference Model Issues

Before getting into the details of how the OSI Reference Model works, I think it is a good idea to first discuss some of the basic issues related to reference models. In part, I want to explain why I place so much emphasis on the OSI model in this Guide, even going so far as to organize much of the document on the basis of this model. I also want you to understand why the model is important, and how it benefits networking not only on a conceptual level, but in reality as well.

So, in this section I describe several issues that relate to reference models in general terms, and of course, to the OSI Reference Model as well. I begin with some overview explanation of why networking models are beneficial, and why it is important for you to understand how the OSI model works. I then talk about how best to use the OSI Reference Model, and also contrast it to some “real-world” network architectures and protocol stacks.

## The Benefits of Networking Models

In my [introduction to this Guide](#), I said that networking was complicated—in fact, I probably said it too often. ☺ Well, I wouldn't lie to you—it is. And in fact, it is for that exact reason that special pains must be taken to try to **simplify** it. One of the ways in which networking technology is made easier to understand is by splitting it into pieces, each of which plays a particular role, or is responsible for a specific job or function.

However, if this is to be done, we must have a way of ensuring that these various pieces can interoperate; that is, each must know what is expected of it, and also what it can expect from the other pieces. This is one of the important roles of networking models. They split the multitude of tasks required to implement modern networks, into smaller chunks that can be more easily managed. Just as importantly, they establish “walls” between those pieces, and rules for passing information over those walls.

A good analogy of a networking model is to that of an assembly line at a manufacturer. No company attempts to have one person build an entire car; even if they did, they wouldn't expect that individual to be able to learn how to do it all at once. The division of labor offers several advantages to a company that builds a complex product, such as an automobile. Generally speaking, these include the following:

- ☉ **Training and Documentation:** It is easier to explain how to build a complex system by breaking the process into smaller parts. Training can be done for a specific job without everyone needing to know how everything else works.
- ☉ **Specialization:** If everyone is responsible for doing every job, nobody gets enough experience to become an expert at anything. Through specialization, certain individuals develop expertise at particular jobs.

- 
- ☛ **Easier Design Modification and Enhancement:** Separating the automobile into systems, and particular jobs required to build those systems, makes it easier to make changes in the future. Without such divisions, it would be much more difficult to determine what the impact might be of a change, which would serve as a disincentive for innovation.
  - ☛ **Modularity:** This is related to each of the items above. If the automobile's systems and manufacturing steps are broken down according to a sensible architecture or model, it becomes easier to interchange parts and procedures between vehicles. This saves time and money.

Networking models yield very similar benefits to the networking world. They represent a framework for dividing up the tasks needed to implement a network, by splitting the work into different levels, or *layers*. Hardware and software running at each layer is responsible for interacting with its corresponding hardware and software running on other devices at the same layer. The responsibilities of each hardware or software element are defined in part by specifically delineating lines that exist between the layers.

The result is that you get all of the benefits listed in the bullet points above: easier training, specialized capabilities at each layer, improved capabilities for modification, and modularity. Modularity is particularly important, as it allows you to interchange technologies that run at different layers. While nobody would try to build a vehicle that is partly a compact sedan, partly an SUV and partly a motorcycle, there are situations in networking where you may want to do something surprisingly similar to this. Networking models help make this possible.

**Key Concept:** Networking models such as the OSI Reference Model provide a framework for breaking down complex internetworks into components that can more easily be understood and utilized. The model defines networking functions not as a large, complicated whole, but as a set of layered, modular components, each of which is responsible for a particular function. The result is better comprehension of network operations, improved performance and functionality, easier design and development, and the ability to combine different components in the way best suited to the needs of the network.

---

## Why Understanding The OSI Reference Model Is Important To You

A lot of networking books and other resources gloss over the OSI Reference Model, including only passing mention of it, or relegating it to an appendix. The usual stated reason for this is that the OSI model is “too theoretical” and “doesn't apply to modern networking protocols like TCP/IP”.

I believe that this is a misguided notion. While it is certainly true the OSI model is primarily theoretical, and that networking protocols aren't always designed to fit strictly within the confines of its layers, it's **not** true that the OSI model has little applicability to the “real

---

world”. In fact, it is difficult to read about networking technology today without seeing references to the OSI model and its layers, because the model’s structure helps to frame discussions of protocols and contrast various technologies.

As just a few examples: the OSI Reference Model provides the basis for understanding how technologies like Ethernet and HomePNA have some important similarities; it explains how a PC can communicate using any of several different sets of protocols, even simultaneously; it is an important part of understanding the differences between interconnection devices such as repeaters, hubs, bridges, switches and routers; and it also explains how many WAN technologies interoperate.

Far from being obsolete, the OSI model layers are now showing up more than ever in discussions of technology. In fact, some protocols are even **named** specifically in terms of their place in the OSI Reference Model! For an example, consider the Layer Two Tunneling Protocol. Also, switches are now commonly categorized as being layer 2, layer 3 or even higher-layer switches.

In theoretical discussions, the OSI Reference Model helps you understand how networks and network protocols function. In the “real world”, it also helps you figure out which protocols and devices can interact with each other. So, I encourage you to read on. It’s time well spent.

**Key Concept:** While many people scoff at the notion of studying the OSI Reference Model, understanding it is very helpful in making sense of networking protocols and technologies. The model is theoretical, but its concepts are employed regularly to describe the operation of real-world networks.

---

## How To Use The OSI Reference Model

I have been trying to make the point in this section that the OSI Reference Model is a very important tool in understanding how networks function. However, while some people tend to play down the OSI model too much, suggesting that it really isn’t very relevant today, there are others who go to the other extreme. They use it too much, overanalyzing and trying to use the model in a way that was never intended.

The most common mistake is attempting to try to “make everything fit” into the layered structure of the OSI model. (I must confess to falling into this trap myself on occasion.) When I first started laying out the [structure of this Guide](#), I wanted to organize **everything** based on where it fell in terms of OSI model layers. I quickly discovered that this was like attempting to put pegs of various shapes into a board containing only round holes. I had to change my approach. I ended up organizing the Guide based on the OSI layers where it made sense, and using a different structure where it did not.

---

I recommend that you learn from my experience. A simple rule of thumb is this: refer the OSI Reference Model if it helps you make sense of technologies and understand how they work; **don't** use it if it makes things more complicated instead of more clear. In particular, bear the following in mind:

- ☹ It can be very hard to even figure out where some technologies fall within the model. Many protocols were designed without the OSI model in mind, and they may not fall neatly into one layer or another. Some overlap two or more layers; other protocol suites may have two protocols that share a layer.
- ☹ The boundaries between the upper layers (session, presentation and application) get particularly fuzzy. Some protocols are clearly designed to fit at one of these layers, while others may overlap all three. It is for this reason that [I do not categorize higher-level protocols by layer in this Guide](#). (The OSI Reference Model was in fact designed to take into account the fact that differentiating between these layers might not make sense.)
- ☹ The OSI Reference Model was designed primarily with LANs in mind. WAN technologies often fit very poorly into the OSI model, with lots of overlapping and partial layer coverage. However, it's still useful in most cases to look at these protocols in terms of their approximate fit in the OSI model, since parts of WAN technologies are sometimes interchanged.
- ☹ The people who design products don't generally worry about ensuring that their latest inventions implement only specific layers of the model. Thus, sometimes new products come out that “break the rules” and implement functions across more than one layer that used to be done by multiple devices at the individual layers. This is usually progress, a good thing. 😊

Finally, an observation... I have noticed that people learning about networking—especially those trying to memorize easy answers to difficult questions so they can pass exams—often ask “at what layer does this piece of hardware operate?” The problem here is not the answer but rather the question, which is simplistic. With the exception of simple physical devices such as connectors and cables, pretty much **all** networking devices operate at many layers. While a router, for example, is usually associated with layer three; it has two or more device interfaces that implement layers two and one. A better question is what is the **highest** layer at which a device functions.

The bottom line is that the OSI Reference Model is a tool. If you use it wisely, it can be immensely helpful to you. Just remember not to be too inflexible in how you apply it, and you'll be fine.

**Key Concept:** It is just as much a mistake to assign too much importance to the OSI Reference Model as too little. While the model defines a framework for understanding networks, not all networking components, protocols and technologies will necessarily fall into the model's strict layering architecture. There are cases where trying to use the model to describe certain concepts can lead to less clarity rather than more. One should remember that the OSI model is a *tool*, and should be used accordingly.

---

---

## Comparing the OSI Reference Model to Network Architectures and Protocol Stacks

The OSI Reference Model is not the only model used to describe the structure of networks. There are several other models and systems that are used to describe various sets of networking technologies that work together. These are generally not theoretical models, but rather describe groupings of protocols that are actively used in actual networks. They are, therefore, more often called *networking architectures* and *protocol suites* than models.

As I mentioned in [the previous topic](#), many technologies and protocols don't "fit" well into the specific layers used in the OSI model. Similarly, most of the protocol suites used in the "real world" don't fit the OSI model exactly. This happens, of course, because they were developed independently of the OSI model. Still, most of these architectures and suites still use layers—they are just different ones than the OSI model uses.

Since the OSI model is so often referenced, it can be very helpful in making sense of other architectures, and even comparing them. Regardless of what the individual layers and technologies are called, networking protocol suites all try to accomplish the same goals in implementing a network. Thus, even though the layers are not the same, they are often comparable.

In the case of TCP/IP, a [special model called the DOD model or TCP/IP model](#) is usually used in discussions of the suite. This model has many similarities to the OSI model, but also some important differences. In other areas in the field of networking, still other models are used, such as the IEEE 802 networking architecture model. These too are similar in some ways to the OSI model but have their own unique characteristics.

Even within the scope of some individual specific technologies, a layered structure of related protocols can be seen. There are technologies that are generally considered to implement a single level of the OSI model that actually have portions that overlap several layers; examples include Ethernet and ATM. In fact, some protocols even have **subprotocols** that are layered within the confines of what is considered a single layer under OSI; a good example is the [TCP/IP Point-to-Point Protocol \(PPP\)](#), which, despite the name, is not a single protocol but a protocol suite unto itself.

---

## Key OSI Reference Model Concepts

The OSI Reference Model is valuable as a tool for explaining how networks function, and for describing the relationships between different networking technologies and protocols. To accomplish this, the model relies on a number of important concepts and terms. To understand the model, then, I need to explain what these are and how they relate to the model as a whole.

In this section, I describe the key concepts that define how the OSI Reference Model works. I begin with a discussion of how the model uses layers, perhaps the single most important model concepts. I then talk about some of the notation and jargon you are likely to see used in general discussions of the model. I define in more detail what “interfaces” and “protocols” are in the context of the model. I then explain the important concept of data encapsulation and the terminology used to refer to messages in the OSI Reference Model: PDUs and SDUs. Finally, I put together most of the preceding issues by describing how the various layers work to handle the routing of messages on a theoretical basis.

**Note:** Many of the concepts discussed in this section are also used by many people in describing the details of various individual technologies. The best example is the word “protocol”, which is used [just about everywhere](#) to refer to just about anything. My focus here is on the conceptual definitions of such terms. However, the conceptual discussions here often also apply to real-world technologies. For example, data encapsulation is performed as data is sent between protocols and technologies at various OSI layers, pretty much as I describe it here.

---

## OSI Reference Model Networking Layers, Sublayers and Layer Groupings

The most important OSI Reference Model concept is that of networking *layers*. It’s not an exaggeration to say that layers are really the heart of the OSI model—the entire point of the model is to separate networking into distinct functions that operate at different levels. Each layer is responsible for performing a specific task or set of tasks, and dealing with the layers above and below it. The rest of this section will deal with many of the different nuances of this layer orientation.

### ***OSI Reference Model Layers***

The OSI Reference Model is comprised of seven conceptual layers, each assigned a “ranking” number from one to seven. The layer number represents the position of the layer in the model as a whole, and indicates how “close” the layer is to the actual hardware used to implement a network. The first and lowest layer is the *physical layer*, which is where low-

---

level signaling and hardware are implemented. The seventh and highest layer is the *application layer*, which deals with high-level applications employed by users: both end users and the operating system software.

You can see that as we proceed from the first layer to the seventh, we move up the *layer stack* and in so doing, increase our level of *abstraction*. This means that the higher a layer is in the stack, the more it deals with logical concepts and software, and the less it deals with the hardware of a network and the “nuts and bolts” of making it work.

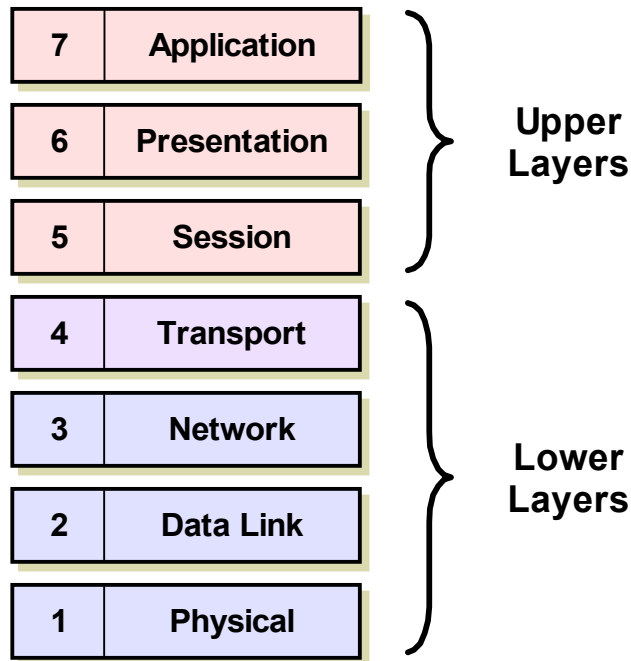

The first layer is the most concrete, as it deals with the actual hardware of networks, and the specific methods of sending bits from one device to another. It is the domain of hardware engineers and signaling experts. The second layer is a bit more abstract but still deals with signaling and hardware. As you proceed through the third, fourth and subsequent layers, the technologies at those layers become increasingly abstract. By the time you reach the seventh layer, you are no longer dealing with hardware or even operating system concepts very much; you are in the realm of the user and high-level programs that rely on lower levels to do the “heavy lifting” for them.

### ***OSI Reference Model Layer Groupings***

The OSI Reference Model does not formally assign any relationship between groups of adjacent layers. However, to help explain how the layers work, it is common to categorize them into two *layer groupings*:

- ☛ **Lower Layers (Layers 1, 2, 3 and 4):** The lower layers of the model—*physical*, *data link*, *network* and *transport*—are primarily concerned with the formatting, encoding and transmission of data over the network. They don't care that much about what the data is or what it is being used for, just about moving it around. They are implemented in both hardware and software, with the transition from hardware to software occurring as you proceed up from layer 1 to layer 4.
- ☛ **Upper Layers (Layers 5, 6 and 7):** The higher layers of the model—*session*, *presentation* and *application*—are the ones that are concerned primarily with interacting with the user, and implementing the applications that run over the network. The protocols that run at higher layers are less concerned with the low-level details of how data gets sent from one place to another; they rely on the lower layers to provide delivery of data. These layers are almost always implemented as software running on a computer or other hardware device.

There are some who would not necessarily agree with how I have chosen to divide the layers above. In particular, valid arguments can be made for including the transport layer in the upper layer group, since it is usually implemented as software and is fairly abstract. I believe it is better as part of the lower layer group since its primary job is still providing services to higher layers for moving data, however. Really, layer 4 is somewhat of a “transition zone” and is hard to categorize. [Figure 11](#) shows how I divide the OSI Reference Model layers into groups and indicates the special position of layer 4 in the stack.

**Figure 11: OSI Reference Model Layers**

The OSI Reference Model divides networking functions into a stack of seven layers, numbered 1 through 7 from the bottom up. To help illustrate the differing levels of abstraction between layers near the top and those on the bottom, they are sometimes divided into two *layer groupings*—the *lower layers* and the *upper layers*. Of course, not everyone agrees on exactly how the division should be accomplished. In particular, the transport layer is sometimes considered an upper layer and sometimes a lower layer.

**Key Concept:** The most fundamental concept in the OSI Reference Model is the division of networking functions into a set of *layers*, from layer one at the bottom to layer seven at the top. As you go up the layer stack, you move away from concrete, hardware-specific functions to ones that are increasingly abstract, until reaching the realm of user applications at layer seven. The seven layers are sometimes divided into groupings: the lower layers (one, two and three) and the upper layers (four through seven). There is some disagreement on whether layer four is a lower or upper layer.

---

### ***Relationships Between OSI Reference Model Layers***

There are also certain OSI layers that have “natural” relationships to each other. The physical and data link layers, in particular, are closely related. For example, most people talk about Ethernet as being a “layer two technology”, but Ethernet specifications really deal with both layer 2 and layer 1. Similarly, layers three and four are often related; protocol suites are often designed so that layer three and four protocols work together; examples being TCP and IP in the [TCP/IP protocol suite](#) and IPX and SPX in the Novell suite.

---

In some areas, the layers are so closely related that the lines between them become *blurry*. This is particularly the case when looking at the higher layers; many technologies implement two or even all three of these layers, which is another reason why I feel they best belong in a group together. One important reason why the distinctions between layers five through seven are blurry is that the TCP/IP protocols are based on the [TCP/IP model](#), which combines the functions of layers five through seven in a single, thick layer.

**Key Concept:** The four lower layers of the OSI model are most often discussed individually, because the boundaries between them are reasonably clear-cut. In contrast, the lines between the session, presentation and application layers are somewhat blurry. As a result, sometimes protocols span two or even all three of these layers; this is especially true of TCP/IP application protocols, since the TCP/IP model treats layers five through seven as a single layer.

---

### ***Sublayers***

Finally, note that some OSI Reference Model layers are further divided into *sublayers* to help define more precisely the internal details of protocols and technologies at those layers. This is commonly done at the lower layers, especially the physical layer and the data link layer.

## **"N" Notation and Other OSI Model Layer Terminology**

As a theoretical model, the OSI Reference Model comes complete with a set of terminology that is used to describe it and its constituent parts. This is sort of both good news and bad. The good news is that if you understand this terminology, it can help you comprehend much better most OSI model discussions, and also how technologies relate to the model. The bad news is that the terminology can also increase confusion—especially since it isn't always used consistently.

### ***Common OSI Model Terminology Concepts***

Let's discuss a few of the terminology concepts you will often see used to refer to the OSI Reference Model. Many of these are illustrated in [Figure 12](#).

#### **Layer Names and Numbers**

The various layers of the OSI Reference Model are referred to in a variety of ways. They may have their names spelled out in full, or they may be abbreviated. They are also often simply referenced by their layer number. So for example, all of these refer to the same thing: "data link layer", "Data Link Layer", "DLL", "L2", "layer two", "layer 2".

Similarly, you will often see layer names being used as adjectives to describe protocols and technologies. A "layer 3 technology" is one that operates primarily at the network layer.

**Figure 12: OSI Reference Model Layer Relationships and Terminology**

This diagram shows the relationships between OSI model layers and the terminology used to refer to adjacent layers in the context of any particular layer. Each layer (except layer 7) provides services the layer above it; each layer (other than layer 1) uses services provided by the layer below. Another way of saying this is that each layer “N” provides services to layer “N+1” and uses the services of layer “N-1”. Taking the example of layer three, the network layer, we see that it provides services to layer four, and uses services of layer two. From the standpoint of the network layer, the transport layer is layer “N+1” and the data link layer “N-1”.

### “N” Notation

The letter “N” is often used to generically refer to a number within the computer world. With respect to the OSI Reference Model, it’s common to see this letter used in discussions that relate generically to individual layers without mentioning a specific layer. You will hear terms like “N-functions” and “N-services”, which just refer to the functions and services provided within a particular layer.

As another example, you might see someone say that a particular technology “provides a useful service to the N+1 layer”. This just means it provides a function to the layer above the one at which it operates. Conceptually, every layer but the first and seventh have an “N-1” layer and an “N+1” layer, and so on. If you are looking at the network layer (layer 3) then the “N+2 layer” is the session layer (layer 5). [See the discussion of model layer interfaces for more information.](#)

---

## Protocols and Interfaces

These words have special meaning within the context of the OSI model: a *protocol* represents communication between logical or physical devices at the same layer of the model while an *interface* represents information moving between adjacent layers within the same device.

Thus, in “N” notation, protocols represent communication between layer N on one device and layer N on another device, while interfaces deal with communication between layer N and N+1 or Layer N and N-1 on the same device. The topics on [OSI protocols](#) and [OSI interfaces](#) describe these issues much better.

## Network Stacks

What do you get when you take a bunch of layers and put them all one on top of each other? Well, you get a *stack*. This term is used to refer to either the entire set of layers in a model or suite of technologies, or a partial set. Since each layer has protocols associated with it, this is also sometimes called the *protocol stack*.

## Entities, Functions, Facilities and Services

These often-interchanged, somewhat vague terms refer to specific tasks or jobs performed at various layers in the model. An *N-entity* is a term that refers to a specific operation or job done at “layer N”. A *function* is basically the same thing. *Facilities* and *services* are what a layer provides to the layers above it. This is often expressed in N-notation as well: the “N+1” layer often uses a set of “N services” or “N facilities” provided by the “N” layer.

## Making Sense of OSI Terminology

You may have just read all of that and said to yourself “why do they bother making this so **complicated** anyway?” Well, I can’t really argue with you. Remember, I **did** say there was bad news here. Now that you know what all of this stuff is about, should you run into it you won’t be... uh... *too* badly confused. ☺

Fortunately, the use of the buzzwords above is somewhat limited. Most references are to specific layer names or numbers, and in particular, the “N-1” and “N+1” stuff is rarely used in discussions of real-world technologies. However, it can be very useful in explaining the model itself, so you will see some of these terms as you read the rest of this chapter on the OSI model.

## Interfaces: Vertical (Adjacent Layer) Communication

[The seven layers of the OSI Reference Model](#) are used to split up the various functions that are required to implement a networking system. On any given device in a network, different software and hardware routines and devices may be functioning on any or all of these

---

layers simultaneously. Since in general, all of these are supposed to be working together to implement networking functions, there is a need for layers to communicate *vertically* between the layers within a particular host.

## **OSI Interfaces**

In OSI Reference Model parlance, the mechanism for communication between adjacent layers in the model is called an *interface*. Of course, the term “interface” is also used widely in other contexts in the computer and networking worlds, since its generic meaning refers to connecting just about *anything* together. However, when someone talks about an interface between OSI model layers, that person typically refers to the process by which data is passed between layer N of the model and layer N-1 or layer N+1.

These relationships are demonstrated in [Figure 13](#). For example, the layer 2/3 interface is used by a layer two and layer three protocol to pass data and control information; the layer 3/4 interface connects layers 3 and 4 together.

---

**Note:** Remember that not all layers may be implemented in every system or protocol stack in the “real world”. So it's possible that a process that is technically running at layer 7 might communicate with one running at layer 5. However, I am talking about the theoretical model here.

---

## **Vertical Communication**

Vertical communication is done up and down the protocol stack every time anything is sent across the network, and of course, whenever anything is received. This occurs because the higher levels are implemented as logical functions, in software; there is no actual physical connection. The higher layers package data and send it down to the lower layers for it to be sent across the network. At the very lowest level, the data is sent over the network. On the receiving end, the process is reversed, with the data traveling back up to the higher layers on the receiving device. [The next topic dealing with horizontal communication](#) explains more about this logical interaction between corresponding layers.

## **Modularity and Inter-Layer Interactions**

One of the primary goals of the OSI Reference Model is to allow the interconnection of different implementations of various layers. Thus, the intention is to have somewhat autonomous individual layers that you can “mix and match”—to a point. The only way to make this work is to have well-defined ways that the layers connect together, and that brings us back to the matter of interfaces. Each layer must present a consistent, well-documented interface to the layers above it so that any upper layer implementation can use the lower layer properly.

I'll provide an example from the world of TCP/IP to illustrate what I mean. The heart of the TCP/IP protocol suite is the Internet Protocol (IP). Whenever you use any application on the Internet—email, Web sites, FTP, chat rooms, and so on—you are indirectly using IP.

**Figure 13: OSI Reference Model Interfaces for Vertical Communication**

In OSI model terminology, an *interface* is a conduit for communication between adjacent layers in the layer stack.

However, you never use IP directly—you generally use one of two transport layer (layer 4) protocols: the [Transmission Control Protocol \(TCP\)](#) or the [User Datagram Protocol \(UDP\)](#). A standard interface exists between the network layer and the transport layer in the TCP/IP protocol stack, which defines how IP is to be used by upper layer protocols; this enables TCP and UDP to interface to it. Similarly, both TCP and UDP present a particular interface to the hundreds of higher-layer protocols and applications that use them at higher layers.

Many different types of communication actually take place between layers. Control information is passed to enable the higher layers to utilize the lower ones, and for the lower ones to pass status and results information back to the higher ones. Data is also passed in both directions across the interface. For transmission, it flows down to the lower layer, each time normally resulting in [data encapsulation](#). Upon reception, the process is reversed, with data being sent back up across the interface from lower to higher layer.

**Key Concept:** In the OSI Reference Model, an interface defines the mechanism for vertical communication between adjacent layers. The existence of well-defined interfaces between layers is what permits a higher layer to use the services of any of a number of lower layers, without requiring knowledge of how those layers are implemented.

---

## Protocols: Horizontal (Corresponding Layer) Communication

Each layer in the OSI Reference Model has a particular role (or roles)—a set of general tasks for which it is responsible. On each system on the network, hardware and software are running at many of the different levels in the model. The routines doing a particular job on machine “A” are designed to communicate with similar or complementary ones that are running on machine “B”. This *horizontal communication* is the very heart of what networking is about. It is what enables Web browsers and Web servers to talk, email applications to exchange messages, and so much more.

### **OSI Protocols**

Of course, all types of communication function only if everyone agrees to the same methods of accomplishing it. Each set of rules describing one type of communication is called a *protocol*. You can think of a protocol as being like a language or a set of instructions. Each function or service of a network has its own language; like human languages, some are similar to each other while others are quite unique.

If you've done any reading at all about networks, you have probably seen the term “protocol” many, many times. Like the word “interface”, the word “protocol” can have many meanings. In fact, it is so fundamental to networking, and used in so many different ways, that [I have a topic devoted to it](#) in the chapter on Networking Fundamentals.

All that aside, we must remember that the OSI Reference Model is intended to be a formal way of describing networks. As such, the term “protocol” has a formal meaning in the context of the model. It refers specifically to a set of communication rules, instructions and/or procedures that describe communication between specific software or hardware elements running *at the same layer* on different machines within a network.

### **Horizontal Communication**

Let's consider how these corresponding layers communicate using protocols. First, recall that every layer in the model, except the bottom (physical) layer, is really a program or algorithm running on a computer. There is no way for, say, a Web browser and a Web server to actually connect together directly—they are just software programs, after all. Instead, the software running at various layers communicates **logically**. That is to say, through the use of software and procedures, a process running at layer 5 on one machine can accomplish *logical communication* with a similar process running at layer 5 on another machine.

---

Since machines are only physically connected at layer 1, this means that in order for a protocol at layer 5 to function, the data on the sending machine must “pass down” the data through the layers between layer 5 and layer 1. The data is then transmitted over the physical connection to layer 1 of the other machine, and “passed up” the protocol stack of the receiving machine to layer 5. This is how the two machines are logically linked at layer 5, even though they have no physical connection at that layer.

Thus, with the exception of the actual physical connection at layer 1, all horizontal communication also requires vertical communication—down the stack on one machine, and then back up the stack on the other. This process is illustrated in [Figure 14](#). (The communication doesn’t always go all the way back up the stack for each connection, however, as in the case of [routing](#).)

**Key Concept:** In the OSI Reference Model, a *protocol* refers specifically to a set of rules or procedures that define communication between software or hardware elements running at the same layer on network devices. Physical layer protocols are responsible for the actual transmission and reception of data at layer one. Protocols at higher layers pass data down through the layers below them to layer one for transmission, then across the network and back up to the corresponding entity at the same layer on the receiving device. The result is that software processes running at say, layer four on each of two devices can communicate *logically* as if they were directly connected at layer four, when they are not.

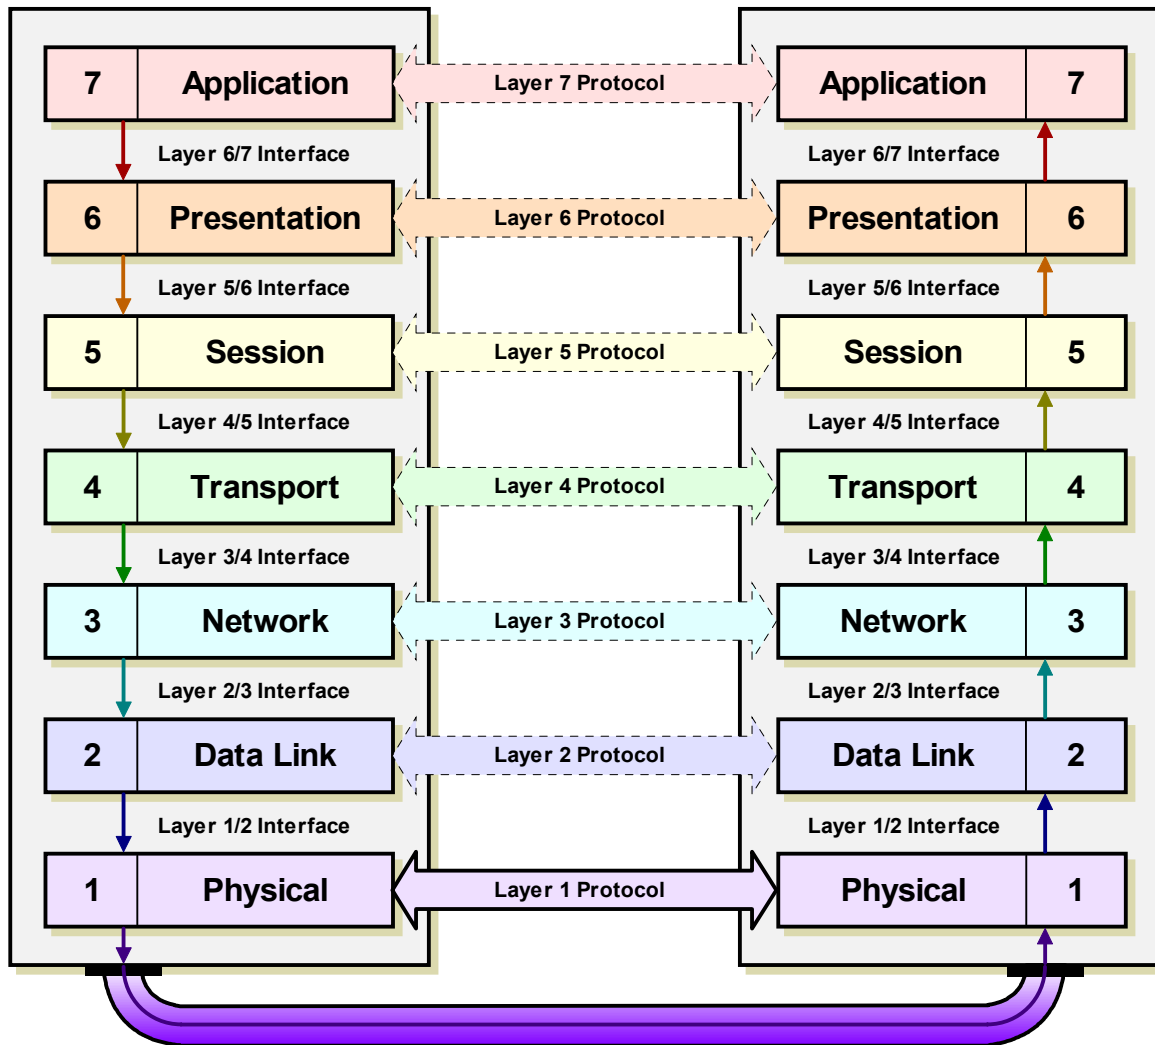

---

## Data Encapsulation, Protocol Data Units (PDUs) and Service Data Units (SDUs)

Protocols are what describe the rules that control [horizontal communication](#), that is, conversations between processes that run at corresponding layers within the OSI Reference Model. At every layer (except layer one) these communications ultimately take the form of some sort of message that is sent between corresponding software elements on two or more devices. Since these messages are the mechanism for communicating information between protocols, they are most generally called *protocol data units (PDUs)*. Each PDU has a specific format that implements the features and requirements of the protocol.

### ***Layer Services and Data Encapsulation***

As we’ve already discussed in [our look at protocols](#), the communication between layers higher than layer one is *logical*; the only hardware connection is at the physical layer. Thus, in order for a protocol to communicate, it must pass down its PDU to the next lower layer for transmission. We’ve also already seen that [using OSI terminology](#), lower layers are said to provide *services* to the layers immediately above them. One of the services each layer provides is this function: to handle and manage data received from the layer above.

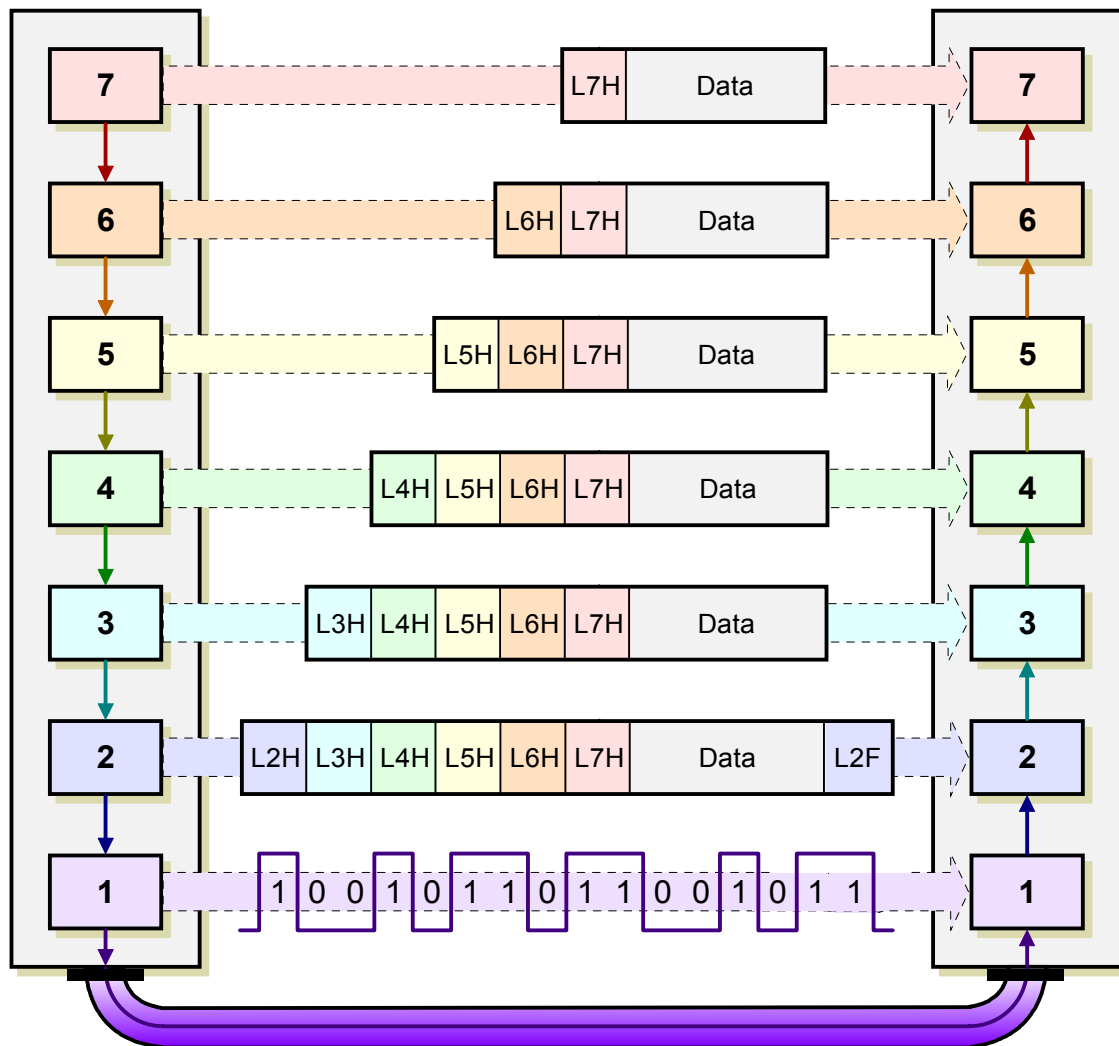

**Figure 14: OSI Reference Model Protocols: Horizontal Communication**

The term “protocol” has many meanings; in the context of the OSI Reference Model, it refers specifically to software or hardware elements that accomplish communication between corresponding layers on two or more devices. For example, the Internet Protocol is said to be a layer 3 protocol because each device uses IP software to communicate at layer 3. The actual transmission and reception of data only occurs at the lowest, physical layer; higher-layer protocols communicate *logically*, by passing data down interfaces until it reaches layer 1, transmitting at layer 1, and then passing the data back up to the appropriate layer at the recipient.

At any particular layer N, a PDU is a complete message that implements the protocol at that layer. However, when this “layer N PDU” is passed down to layer N-1, it becomes the **data** that the layer N-1 protocol is supposed to **service**. Thus, the layer N protocol data unit (PDU) is called the layer N-1 *service data unit (SDU)*. The job of layer N-1 is to transport this SDU, which it does in turn by placing the layer N SDU into its own PDU format, preceding the SDU with its own headers and appending footers as necessary. This process is called *data encapsulation*, because the entire contents of the higher-layer message are encapsulated as the data payload of the message at the lower layer.

What does layer N-1 do with its PDU? It of course passes it down to the next lower layer, where it is treated as a layer N-2 SDU. Layer N-2 creates a layer N-2 PDU containing the layer N-1 SDU and layer N-2's headers and footers. And so the process continues, all the way down to the physical layer. In the theoretical model, what you end up with is a message at layer 1 that consists of application-layer data that is encapsulated with headers and/or footers from each of layers 7 through 2 in turn, as shown in [Figure 15](#).

**Figure 15: OSI Reference Model Data Encapsulation**

Each protocol creates a *protocol data unit (PDU)* for transmission that includes headers required by that protocol and data to be transmitted. This data becomes the *service data unit (SDU)* of the next layer below it. This diagram shows a layer 7 PDU consisting of a layer 7 header (“L7H”) and application data. When this is passed to layer 6, it becomes a layer 6 SDU. The layer 6 protocol prepends to it a layer 6 header (“L6H”) to create a layer 6 PDU, which is passed to layer 5. The encapsulation process continues all the way down to layer 2, which creates a layer 2 PDU—in this case shown with both a header and a footer—that is converted to bits and sent at layer 1.

---

## Data Encapsulation in TCP/IP

The “N-1, N-2” stuff makes this seem more difficult than it really is, so let’s use a real-world (simplified) example instead. The [Transmission Control Protocol \(TCP\)](#) operates at layer 4 of the OSI model. It transmits messages called *segments* that contain data encapsulated from higher-layer protocols. The layer below TCP is the [Internet Protocol \(IP\)](#) at layer 3. It receives data from TCP and encapsulates it for transmission.

So, in the formal language of the OSI Reference Model, TCP segments are created as layer 4 PDUs. When passed to IP, they are treated as layer 3 SDUs. The IP software packages these SDUs into messages called *IP packets* or *IP datagrams*, which are layer 3 PDUs. These are in turn passed down to a layer 2 protocol, say Ethernet, which treats IP datagrams as layer 2 SDUs, and packages them into layer 2 PDUs (Ethernet frames) which are sent on layer 1. (Actually, in some technologies further encapsulation even occurs at layer one prior to transmission.)

On the receiving device, the process of encapsulation is reversed. The Ethernet software inspects the layer 2 PDU (Ethernet frame) and removes from it the layer 2 SDU (IP datagram) which it passes up to IP as a layer 3 PDU. The IP layer removes the layer 3 SDU (TCP segment) and passes it to TCP as a layer 4 PDU. TCP in turn continues the process, going back up the protocol layer stack. The complete process is illustrated in [Figure 16](#).

This whole matter of passing data up and down the protocol stack, encapsulation and so on may seem needlessly complex. It also may appear to be rather inefficient; why send a message with so many headers and footer? However, the notion of data encapsulation is critical to creating modular, flexible networks.

### Use of PDU and SDU Terminology

The term “protocol data unit” is rather formal. You will see it used in standards and sometimes in discussions, but more often, the “plain” message terms, such as “frame” and “datagram”, are encountered, as discussed in the [networking fundamentals topic on messages](#). Similarly, data encapsulated by these messages is not normally called a “service data unit” but rather simply the *message body* or *payload*, as discussed in [the topic on message formatting](#). There are cases, however, where knowing the difference between an SDU and a PDU is important to understanding the technology. One example is the IEEE 802.11 physical layer; the 802.11 standards talk about SDUs and PDUs constantly.

**Related Information:** See the [OSI Reference Model analogy](#) if you want to see an example that compares networking encapsulation to a type done in a real-world, non-networking context.

---

**Figure 16: OSI Reference Model PDU and SDU Encapsulation**

This example shows in more detail how OSI PDUs and SDUs are created and encapsulated. A TCP segment (layer 4 PDU) becomes a layer 3 SDU, which is encapsulated into a layer 3 PDU through the addition of an IP header. This becomes the payload of an Ethernet frame, which is a layer 2 PDU containing an Ethernet header, layer 2 SDU (the IP datagram) and Ethernet footer. The receiving device extracts the IP datagram from the Ethernet header and passes it to layer 3; the IP software extracts the TCP segment and passes it up to the TCP software.

**Key Concept:** The message used to communicate information for a particular protocol is called its *protocol data unit (PDU)* in OSI model terminology. That PDU is passed down to the next lower layer for transmission; since that layer is providing the service of handling that PDU, it is called the lower layer's *service data unit (SDU)*. The SDU is *encapsulated* into that layer's own PDU and in turn sent to the next lower layer in the stack, proceeding until the physical layer is reached. The process is reversed on the recipient device. In summary: a layer N PDU is a layer N-1 SDU, which is encapsulated into a layer N-1 PDU.

---

## Indirect Device Connection and Message Routing

Most of the explanations that I have provided in the other topics of this section have discussed the mechanisms by which machines connect to each other over a network *directly*. However, one of the most powerful aspects of networking is that it is possible to create internetworks—networks of networks—which allow devices to be connected *indirectly*. For example, machine “A” may send a message to machine “B” without really even knowing where it is on the network at all.

If a message is being sent between devices that are not on the same network, then it must be passed between directly-connected networks until it reaches its final destination. The process of transmitting a message from one network to another is called *forwarding*, and the collective process of forwarding from one device to another is *routing*. These concepts are fundamental to all internetworking, including the Internet itself. Every time you access an Internet resource such as a Web site, you are sending messages that get routed to that site, and the responses you receive get routed back.

**Note:** Even though the technically-correct term for moving a message from one network to an adjacent network is “forwarding”, over time the term “routing” has come to often be used both for a single network-to-network transfer as well as the overall process of transmitting a message from one device to another.

---

In the context of the OSI Reference Model, routing is an activity that generally takes place at the network layer—layer 3. Recall that [data encapsulation](#) causes a higher-layer message to be surrounded by headers and/or footers at the lower layers. When a message is routed, here's what happens:

- ☉ A high-level application on a machine decides to send a datagram to a distant computer. The datagram is packaged, and then [passed down vertically](#) through the protocol stack on the originating machine. Each layer encapsulates the data as described earlier. The datagram is addressed to the final destination device. When the message gets to the network layer and below, however, it is not packaged for local

---

delivery directly to its ultimate destination, but rather to an *intermediate device*. This is the device that is responsible for routing to that destination network. The message is passed down to the data link layer and then the physical layer for transmission to that intermediate device.

- ☉ The intermediate device (often called a *router*) receives the message at the physical layer. It is passed up to the data link layer, where it is processed, checked for errors and so on, and the data link layer headers are removed. The resulting packet is passed up to the network layer. There, the intermediate device determines if the destination machine is on its local network, or if it needs to be forwarded to another intermediate device. It then repackages the message and passes it back *down* to the data link layer to be sent on the next leg of its journey.
- ☉ After several potential intermediate devices “handle” the message, it eventually reaches its destination. Here, it travels back up the protocol stack until it reaches the same layer as the one of the application that generated the message on the originating machine.

The key to this description is that in the intermediate devices, the message travels back up the OSI layers *only to the network layer*. It is then repackaged and sent back along its way. The higher layers are only involved on the source and destination devices. The protocol used at layer 3 must be common across the internetwork but each individual network can be different. This demonstrates some of the power of layering, by enabling even rather dissimilar physical networks to be connected together. The process is illustrated in [Figure 17](#).

**Key Concept:** In the OSI model, the process of *routing* occurs when data is sent not directly from transmitter to ultimate recipient, but indirectly through the use of an intermediate system. That device, normally called a *router*, connects to two or more physical networks and thus has multiple interfaces to layer two. When it receives data, the data passes up only to the network layer, where it is repackaged and then sent on the next leg of its journey over the appropriate layer two interface.

---

**Figure 17: Message Routing in the OSI Reference Model**

This diagram shows how routing is accomplished conceptually in the OSI model. The intermediate device connects the networks of the message transmitter and recipient. When data is sent, it is passed up to the network layer on the intermediate device, where it is repackaged and sent back down the stack for the next leg of its transmission. Note that the intermediate device actually has two different layer 1 and 2 implementations; one for the interface to each network. Also note that while the layer 3 protocol must be the same across the internetwork, each network can use different technologies at layers 1 and 2.

---

## Understanding The OSI Reference Model: An Analogy

---

I have attempted in this discussion of the OSI Reference Model to provide as much “plain English” explanation of how it works as I could. However, there are situations where a good analogy can accomplish what lots of descriptions cannot. So, I am going to attempt to illustrate the key OSI model concepts ([layers](#), [vertical communication](#), [horizontal communication](#), [data encapsulation](#) and [message routing](#)) by way of a real-life analogy. You can be the judge of whether it is a **good** analogy or not. Just remember that no analogy is perfect.

Our scenario seems relatively simple and common: the CEO of a Fortune 500 company needs to send a letter to the CEO of another large company. Simple, right? Just like firing up your browser and connecting to your favorite Web site is simple. However, in both cases, a lot goes on “behind the scenes” to make the communication happen. In the analogy shown in [Table 18](#) below, I compare these real-world and “cyber-world” communications.

**Note:** (Yes, the first CEO *could* fly to the other one's town in his Lear Jet, take him out for a lobster-and-martini dinner and hand him the letter there. Please play along, will you? Oh, and sorry to any CEOs for the blatant stereotyping. ☺)

---

**Table 18: OSI Reference Model Real-World Analogy (Page 1 of 3)**

Phase	OSI Layer	CEO Letter	Web Site Connection (Simplified)
Transmission	7	The CEO of a company in Phoenix decides he needs to send a letter to a peer of his in Albany. He dictates the letter to his administrative assistant.	You decide you want to connect to the web server at IP address 10.0.12.34, which is within your organization but not on your local network. You type the address into your browser.
	6	The administrative assistant transcribes the dictation into writing.	(Generally, with a web site connection, nothing happens at this layer, but format translation may be done in some cases.)
	5	The administrative assistant puts the letter in an envelope and gives it to the mail room. The assistant doesn't actually know how the letter will be sent, but he knows it is urgent so he says, “get this to its destination quickly”.	The request is sent via a call to an application program interface (API), to issue the command necessary to contact the server at that address.
	4	The mail room must decide how to get the letter where it needs to go. Since it is a rush, the people in the mail room decide they must use a courier. The envelope is given to the courier company to send.	The Transmission Control Protocol (TCP) is used to create a segment to be sent to IP address 10.0.12.34.

**Table 18: OSI Reference Model Real-World Analogy (Page 2 of 3)**

Phase	OSI Layer	CEO Letter	Web Site Connection (Simplified)
Routing	3	The courier company receives the envelope, but it needs to add its own handling information, so it places the smaller envelope in a courier envelope (encapsulation). The courier then consults its airplane route information and determines that to get this envelope to Albany, it must be flown through its hub in Chicago. It hands this envelope to the workers who load packages on airplanes.	Your computer creates an IP datagram encapsulating the TCP datagram created above. It then addresses the packet to 10.0.12.34. but discovers that it is not on its local network. So instead, it realizes it needs to send the message to its designated routing device at IP address 10.0.43.21. It hands the packet to the driver for your Ethernet card (the software that interfaces to the Ethernet hardware).
	2	The workers take the courier envelope and put on it a tag with the code for Chicago. They then put it in a handling box and then load it on the plane to Chicago.	The Ethernet card driver forms a frame containing the IP datagram and prepares it to be sent over the network. It packages the message and puts the address 10.0.43.21 (for the router) in the frame.
	1	The plane flies to Chicago.	The frame is sent over the twisted pair cable that connects your local area network. (I'm ignoring overhead, collisions, etc. here, but then I also ignored the possibility of collisions with the plane. ☺)
	2	In Chicago, the box is unloaded, and the courier envelope is removed from it and given to the people who handle routing in Chicago.	The Ethernet card at the machine with IP address 10.0.43.21 receives the frame, strips off the frame headers and hands it up to the network layer.
	3	The tag marked "Chicago" is removed from the outside of the courier envelope. The envelope is then given back to the airplane workers to be sent to Albany.	The IP datagram is processed by the router, which realizes the destination (10.0.12.34) can be reached directly. It passes the datagram back down to the Ethernet driver.
	2	The envelope is given a new tag with the code for Albany, placed in another box and loaded on the plane to Albany.	The Ethernet driver creates a new frame and prepares to send it to the device that uses IP address 10.0.12.34.
	1	The plane flies to Albany.	The frame is sent over the network.
	2	The box is unloaded and the courier envelope is removed from the box. It is given to the Albany routing office.	The Ethernet card at the device with IP address 10.0.12.34 receives the frame, strips off the headers and passes it up the stack.

**Table 18: OSI Reference Model Real-World Analogy (Page 3 of 3)**

Phase	OSI Layer	CEO Letter	Web Site Connection (Simplified)
<b>Reception</b>	<b>3</b>	The courier company in Albany sees that the destination is in Albany, and delivers the envelope to the destination CEO's company.	The IP headers are removed from the datagram and the TCP segment handed up to TCP.
	<b>4</b>	The mail room removes the inner envelope from the courier envelope and delivers it to the destination CEO's assistant.	TCP removes its headers and hands the data up to the drivers on the destination machine.
	<b>5</b>	The assistant takes the letter out of the envelope.	The request is sent to the Web server software for processing.
	<b>6</b>	The assistant reads the letter and decides whether to give the letter to the CEO, transcribe it to email, call the CEO on her cell phone, or whatever.	(Again, in this example nothing probably happens at the Presentation layer.)
	<b>7</b>	The second CEO receives the message that was sent by the first one.	The Web server receives and processes the request.

As you can see, the processes have a fair bit in common. The vertical communication and encapsulation are pretty obvious, as is the routing. Also implied is the horizontal communication that occurs logically—the two CEOs seem to be “connected” despite all that happens to enable this to occur. Similarly, the two assistants are logically connected as well, in a way, even though they never actually converse. Of course, this example is highly simplified in just about every way imaginable, so please don’t use it as a way of trying to learn about how TCP/IP works—or courier services, for that matter.

Anyway, I hope the example helps make some sense of all of this OSI stuff!

---

## OSI Reference Model Layers

Finally, after much ado—hopefully not **too** much!—it is time to take a look at the actual individual layers of the OSI Reference Model. As discussed in [the section on OSI model concepts](#), each layer has certain characteristics that define it, and also various protocols normally associated with it. Understanding the nuances of each layer will help you understand all the technologies that use them.

In this section, I describe each of the OSI Reference Model layers individually. For each one I provide its name and layer number, describe its general function in the OSI layer stack, and outline the specific types of activities for which each is normally responsible. I also provide some examples of the technologies and protocols that reside at each layer. Keep in mind, however, that the descriptions in this section are *generic*. To really comprehend the various layers and how they are used, there is no substitute for reading the details of the individual protocols that function at each layer, covered elsewhere in this Guide.

**Related Information:** For assistance in remembering the correct order of the layers, see [the topic that describes common mnemonics used for the OSI Reference Model](#). To easily compare the key characteristics of the seven layers, refer to the [OSI model layer summary](#).

---

### Physical Layer (Layer 1)

The lowest layer of the OSI Reference Model is layer 1, the *physical layer*; it is commonly abbreviated “PHY”. The physical layer is special compared to the other layers of the model, because it is the only one where data is physically moved across the network interface. All of the other layers perform useful functions to create messages to be sent, but they must all be transmitted down the protocol stack to the physical layer, where they are actually sent out over the network.

**Note:** The physical layer is also “special” in that it is the only layer that really does not apply specifically to TCP/IP. Even in studying TCP/IP, however, it is still important to understand its significance and role in relation to the other layers where TCP/IP protocols reside.

---

#### ***Understanding the Role of the Physical Layer***

The name “physical layer” can be a bit problematic. Because of that name, and because of what I just said about the physical layer actually transmitting data, many people who study networking get the impression that the physical layer is only about actual network hardware.

---

Some people may say the physical layer is “the network interface cards and cables”. This is not actually the case, however. The physical layer defines a number of network functions, not just hardware cables and cards.

A related notion is that “all network hardware belongs to the physical layer”. Again, this isn't strictly accurate. All hardware must have **some** relation to the physical layer in order to send data over the network, but hardware devices generally implement multiple layers of the OSI model, including the physical layer but also others. For example, an Ethernet network interface card performs functions at both the physical layer and the data link layer.

### ***Physical Layer Functions***

The following are the main responsibilities of the physical layer in the OSI Reference Model:

- ☛ **Definition of Hardware Specifications:** The details of operation of cables, connectors, wireless radio transceivers, network interface cards and other hardware devices are generally a function of the physical layer (although also partially the data link layer; see below).
- ☛ **Encoding and Signaling:** The physical layer is responsible for various encoding and signaling functions that transform the data from bits that reside within a computer or other device into signals that can be sent over the network.
- ☛ **Data Transmission and Reception:** After encoding the data appropriately, the physical layer actually transmits the data, and of course, receives it. Note that this applies equally to wired and wireless networks, even if there is no tangible cable in a wireless network!
- ☛ **Topology and Physical Network Design:** The physical layer is also considered the domain of many hardware-related network design issues, such as LAN and WAN topology.

In general, then, physical layer technologies are ones that are at the very lowest level and deal with the actual ones and zeroes that are sent over the network. For example, when considering network interconnection devices, the simplest ones operate at the physical layer: repeaters, conventional hubs and transceivers. These devices have absolutely no knowledge of the contents of a message. They just take input bits and send them as output. Devices like switches and routers operate at higher layers and look at the data they receive as being more than voltage or light pulses that represent one or zero.

### ***Relationship Between the Physical Layer and Data Link Layer***

It's important to point out that while the physical layer of a network technology primarily defines the hardware it uses, the physical layer is closely related to the data link layer. Thus, it is not generally possible to define hardware at the physical layer “independently” of the technology being used at the data link layer. For example, Ethernet is a technology that describes specific types of cables and network hardware, but the physical layer of Ethernet can only be isolated from its data link layer aspects to a point. While Ethernet cables are “physical layer”, for example, their maximum length is related closely to message format rules that exist at the data link layer.

---

Furthermore, some technologies perform functions at the physical layer that are normally more closely associated with the data link layer. For example, it is common to have the physical layer perform low-level (bit level) repackaging of data link layer frames for transmission. Error detection and correction may also be done at layer 1 in some cases. Most people would consider these “layer two functions”.

In many technologies, a number of physical layers can be used with a data link layer. Again here, the classic example is Ethernet, where dozens of different physical layer implementations exist, each of which uses the same data link layer (possibly with slight variations.)

### ***Physical Layer Sublayers***

Finally, many technologies further subdivide the physical layer into *sublayers*. In order to increase performance, physical layer encoding and transmission methods have become more complex over time. The physical layer may be broken into layers to allow different network media to be supported by the same technology, while sharing other functions at the physical layer that are common between the various media. A good example of this is the physical layer architecture used for Fast Ethernet, Gigabit Ethernet and 10-Gigabit Ethernet.

**Note:** In some contexts, the physical layer technology used to convey bits across a network or communications line is called a *transport method*. Don't confuse this with the functions of the [OSI transport layer \(layer 4\)](#).

---

**Key Concept:** The lowest layer in the OSI Reference Model is the *physical layer*. It is the realm of networking hardware specifications, and is the place where technologies reside that perform data encoding, signaling, transmission and reception functions. The physical layer is closely related to the data link layer.

---

## **Data Link Layer (Layer 2)**

The second-lowest layer (layer 2) in the OSI Reference Model stack is the *data link layer*, often abbreviated “DLL” (though that abbreviation has other meanings as well in the computer world). The data link layer, also sometimes just called the *link layer*, is where many wired and wireless local area networking (LAN) technologies primarily function. For example, Ethernet, Token Ring, FDDI and 802.11 (“wireless Ethernet” or “Wi-Fi”) are all sometimes called “data link layer technologies”. The set of devices connected at the data link layer is what is commonly considered a simple “[network](#)”, as opposed to an [internetwork](#).

---

## **Data Link Layer Sublayers: Logical Link Control (LLC) and Media Access Control (MAC)**

The data link layer is often conceptually divided into two sublayers: *logical link control (LLC)* and *media access control (MAC)*. This split is based on the architecture used in the IEEE 802 Project, which is the IEEE working group responsible for creating the standards that define many networking technologies (including all of the ones I mentioned above except FDDI). By separating LLC and MAC functions, interoperability of different network technologies is made easier, as explained in our earlier discussion of networking model concepts.

### **Data Link Layer Functions**

The following are the key tasks performed at the data link layer:

- ① **Logical Link Control (LLC):** Logical link control refers to the functions required for the establishment and control of logical links between local devices on a network. As mentioned above, this is usually considered a DLL sublayer; it provides services to the network layer above it and hides the rest of the details of the data link layer to allow different technologies to work seamlessly with the higher layers. Most local area networking technologies use the IEEE 802.2 LLC protocol.
- ② **Media Access Control (MAC):** This refers to the procedures used by devices to control access to the network medium. Since many networks use a shared medium (such as a single network cable, or a series of cables that are electrically connected into a single virtual medium) it is necessary to have rules for managing the medium to avoid conflicts. For example, Ethernet uses the CSMA/CD method of media access control, while Token Ring uses token passing.
- ③ **Data Framing:** The data link layer is responsible for the final encapsulation of higher-level messages into *frames* that are sent over the network at the physical layer.
- ④ **Addressing:** The data link layer is the lowest layer in the OSI model that is concerned with addressing: labeling information with a particular destination location. Each device on a network has a unique number, usually called a *hardware address* or *MAC address*, that is used by the data link layer protocol to ensure that data intended for a specific machine gets to it properly.
- ⑤ **Error Detection and Handling:** The data link layer handles errors that occur at the lower levels of the network stack. For example, a cyclic redundancy check (CRC) field is often employed to allow the station receiving data to detect if it was received correctly.

### **Physical Layer Requirements Definition and Network Interconnection Device Layers**

As I mentioned in [the topic discussing the physical layer](#), that layer and the data link layer are very closely related. The requirements for the physical layer of a network are often part of the data link layer definition of a particular technology. Certain physical layer hardware and encoding aspects are specified by the DLL technology being used. The best example of this is the Ethernet standard, IEEE 802.3, which specifies not just how Ethernet works at the data link layer, but also its various physical layers.

---

Since the data link layer and physical layer are so closely related, many types of hardware are associated with the data link layer. Network interface cards (NICs) typically implement a specific data link layer technology, so they are often called “Ethernet cards”, “Token Ring cards”, and so on. There are also a number of network interconnection devices that are said to “operate at layer 2”, in whole or in part, because they make decisions about what to do with data they receive by looking at data link layer frames. These devices include most bridges, switches and routers, though the latter two also encompass functions performed by layer three.

Some of the most popular technologies and protocols generally associated with layer 2 are Ethernet, Token Ring, FDDI (plus CDDI), HomePNA, IEEE 802.11, ATM, and TCP/IP's Serial Link Interface Protocol (SLIP) and Point-To-Point Protocol (PPP).

**Key Concept:** The second OSI Reference Model layer is the *data link layer*. This is the place where most LAN and wireless LAN technologies are defined. Layer two is responsible for logical link control, media access control, hardware addressing, error detection and handling, and defining physical layer standards. It is often divided into the logical link control (LLC) and media access control (MAC) sublayers, based on the IEEE 802 Project that uses that architecture.

---

## Network Layer (Layer 3)

The third-lowest layer of the OSI Reference Model is the *network layer*. If the data link layer is the one that basically defines the boundaries of what is considered a network, the network layer is the one that defines how *internetworks* (interconnected networks) function. The network layer is the lowest one in the OSI model that is concerned with actually getting data from one computer to another even if it is on a remote network; in contrast, the data link layer only deals with devices that are local to each other.

While all of layers 2 through 6 in the OSI Reference Model serve to act as “fences” between the layers below them and the layers above them, the network layer is particularly important in this regard. It is at this layer that the transition really begins from the more abstract functions of the higher layers—which don't concern themselves as much with data delivery—into the specific tasks required to get data to its destination. The [transport layer](#), which is related to the network layer in a number of ways, continues this “abstraction transition” as you go up the OSI protocol stack.

### ***Network Layer Functions***

Some of the specific jobs normally performed by the network layer include:

- 
- ☛ **Logical Addressing:** Every device that communicates over a network has associated with it a logical address, sometimes called a *layer three* address. For example, on the Internet, the Internet Protocol (IP) is the network layer protocol and every machine has an IP address. Note that addressing is done at the data link layer as well, but those addresses refer to local physical devices. In contrast, logical addresses are independent of particular hardware and must be unique across an entire internetwork.
  - ☛ **Routing:** Moving data across a series of interconnected networks is probably the defining function of the network layer. It is the job of the devices and software routines that function at the network layer to handle incoming packets from various sources, determine their final destination, and then figure out where they need to be sent to get them where they are supposed to go. I discuss routing in the OSI model more completely in this topic on [the topic on indirect device connection](#), and show how it works by way of an [OSI model analogy](#).
  - ☛ **Datagram Encapsulation:** The network layer normally [encapsulates](#) messages received from higher layers by placing them into *datagrams* (also called *packets*) with a network layer header.
  - ☛ **Fragmentation and Reassembly:** The network layer must send messages down to the data link layer for transmission. Some data link layer technologies have limits on the length of any message that can be sent. If the packet that the network layer wants to send is too large, the network layer must split the packet up, send each piece to the data link layer, and then have pieces reassembled once they arrive at the network layer on the destination machine. A good example is [how this is done by the Internet Protocol](#).
  - ☛ **Error Handling and Diagnostics:** Special protocols are used at the network layer to allow devices that are logically connected, or that are trying to route traffic, to exchange information about the status of hosts on the network or the devices themselves.

### ***Network Layer Connection-Oriented and Connectionless Services***

Network layer protocols may offer either [connection-oriented or connectionless services](#) for delivering packets across the network. Connectionless ones are by far more common at the network layer. In many protocol suites, the network layer protocol is connectionless, and connection-oriented services are provided by the transport layer. For example, in TCP/IP, the Internet Protocol (IP) is connectionless, while the layer four Transmission Control Protocol (TCP) is connection-oriented.

The most common network layer protocol is of course the [Internet Protocol \(IP\)](#), which is why I have already mentioned it a couple of times. IP is the backbone of the Internet, and the foundation of the entire TCP/IP protocol suite. There are also several protocols directly related to IP that work with it at the network layer, such as [IPsec](#), [IP NAT](#) and [Mobile IP](#). [ICMP](#) is the main error-handling and control protocol that is used along with IP. Another notable network layer protocol outside the TCP/IP world is the Novell IPX protocol.

**Key Concept:** The OSI Reference Model's third layer is called the *network layer*. This is one of the most important layers in the model; it is responsible for the tasks that link together individual networks into *internetworks*. Network layer functions include internetwork-level addressing, routing, datagram encapsulation, fragmentation and reassembly, and certain types of error handling and diagnostics. The network layer and transport layer are closely related to each other.

---

The network interconnection devices that operate at the network layer are usually called *routers*, which at this point should hopefully come as no surprise to you. They are responsible for the routing functions I have mentioned, by taking packets received as they are sent along each “hop” of a route and sending them on the next leg of their trip. They communicate with each other using routing protocols, to determine the best routes for sending traffic efficiently. So-called “brouters” also reside at least in part at the network layer, as do the rather obviously named “layer three switches”. ☺

## Transport Layer (Layer 4)

The fourth and “middle” layer of the OSI Reference Model protocol stack is the *transport layer*. I consider the transport layer in some ways to be part of both the [lower and upper “groups” of layers](#) in the OSI model. It is more often associated with the lower layers, because it concerns itself with the **transport** of data, but its functions are also somewhat high-level, resulting in the layer having a fair bit in common with layers 5 through 7 as well.

Recall that layers 1, 2 and 3 are concerned with the actual packaging, addressing, routing and delivery of data; the physical layer handles the bits; the data link layer deals with local networks and the network layer handles routing between networks. The transport layer, in contrast, is sufficiently conceptual that it no longer concerns itself with these “nuts and bolts” matters. It relies on the lower layers to handle the process of moving data between devices.

The transport layer really acts as a “liaison” of sorts between the abstract world of applications at the higher layers, and the concrete functions of layers one to three. Due to this role, the transport layer's overall job is to provide the necessary functions to enable communication between software application processes on different computers. This encompasses a number of different but related duties

Modern computers are multitasking, and at any given time may have many different software applications all trying to send and receive data. The transport layer is charged with providing a means by which these applications can all send and receive data using the same lower-layer protocol implementation. Thus, the transport layer is sometimes said to be responsible for *end-to-end* or *host-to-host* transport (in fact, the equivalent layer in the [TCP/IP model](#) is called the “host-to-host transport layer”).

---

## ***Transport Layer Services and Transmission Quality***

Accomplishing this communication between processes requires that the transport layer perform several different, but related jobs. For transmission, the transport layer protocol must keep track of what data comes from each application, then combine this data into a single flow of data to send to the lower layers. The device receiving information must reverse these operations, splitting data and funneling it to the appropriate recipient processes. The transport layer is also responsible for defining the means by which potentially large amounts of application data are divided into smaller blocks for transmission.

Another key function of the transport layer is to provide *connection services* for the protocols and applications that run at the levels above it. These can be categorized as either [connection-oriented services](#) or [connectionless services](#). Neither is better or worse than the other; they each have their uses. While connection-oriented services can be handled at the network layer as well, they are more often seen in the transport layer in the “real world”. Some protocol suites, such as TCP/IP, provide both a connection-oriented and a connectionless transport layer protocol, to suit the needs of different applications.

The transport layer is also the place in the layer stack where functions are normally included to add features to end-to-end data transport. Where network layer protocols are normally concerned with just “best effort” communications, where delivery is not guaranteed. Transport layer protocols are given intelligence in the form of algorithms that ensure that reliable and efficient communication between devices takes place. This encompasses several related jobs, including lost transmission detection and handling, and managing the rate at which data is sent to ensure that the receiving device is not overwhelmed.

Transmission quality, meaning ensuring that transmissions are received as sent, is so important that some networking references define the transport layer on the basis of reliability and flow-control functions. However, not all transport layer protocols provide these services. Just as a protocol suite may have a connection-oriented and a connectionless transport layer protocol, it may also have one that provides reliability and data management services, and one that does not. Again, this is the case with TCP/IP: there is one main transport layer protocol, TCP, that includes reliability and flow control features, and a second, UDP, that doesn't.

## ***Transport Layer Functions***

Let's look at the specific functions often performed at the transport layer in more detail:

- ☉ **Process-Level Addressing:** Addressing at layer two deals with hardware devices on a local network, and layer three addressing identifies devices on a logical internetwork. Addressing is also performed at the transport layer, where it is used to differentiate between software programs. This is part of what enables many different software programs to use a network layer protocol simultaneously, as mentioned above. The best example of transport-layer process-level addressing is the [TCP and UDP port mechanism](#) used in TCP/IP, which allows applications to be individually referenced on any TCP/IP device.

- 
- ④ **Multiplexing and Demultiplexing:** Using the addresses I just mentioned, transport layer protocols on a sending device *multiplex* the data received from many application programs for transport, combining them into a single stream of data to be sent. The same protocols receive data and then *demultiplex* it from the incoming stream of datagrams, and direct each package of data to the appropriate recipient application processes.
  - ④ **Segmentation, Packaging and Reassembly:** The transport layer segments the large amounts of data it sends over the network into smaller pieces on the source machine, and then reassemble them on the destination machine. This function is similar conceptually to the fragmentation function of the network layer; just as the network layer fragments messages to fit the limits of the data link layer, the transport layer segments messages to suit the requirements of the underlying network layer.
  - ④ **Connection Establishment, Management and Termination:** Transport layer connection-oriented protocols are responsible for the series of communications required to establish a connection, maintain it as data is sent over it, and then terminate the connection when it is no longer required.
  - ④ **Acknowledgments and Retransmissions:** As mentioned above, the transport layer is where many protocols are implemented that guarantee reliable delivery of data. This is done using a variety of techniques, most commonly the combination of *acknowledgments* and *retransmission timers*. Each time data is sent a timer is started; if it is received, the recipient sends back an acknowledgment to the transmitter to indicate successful transmission. If no acknowledgment comes back before the timer expires, the data is retransmitted. Other algorithms and techniques are usually required to support this basic process.
  - ④ **Flow Control:** Transport layer protocols that offer reliable delivery also often implement *flow control* features. These features allow one device in a communication to specify to another that it must "throttle back" the rate at which it is sending data, to avoid bogging down the receiver with data. These allow mismatches in speed between sender and receiver to be detected and dealt with.

### ***Relationship Between the Transport Layer and Network Layer***

In theory, the transport layer and network layer are distinct, but in practice, they are often very closely related to each other. You can see this easily just by looking at the names of common protocol stacks—they are often named after the layer three and four protocols in the suite, implying their close relationship. For example, the name "TCP/IP" comes from the suite's most commonly used transport layer protocol (TCP) and network layer protocol (IP). Similarly, the Novell NetWare suite is often called "IPX/SPX" for its layer three (IPX) and layer four (SPX) protocols. Typically, specific transport layer protocols use the network layers in the same family. You won't often find a network using the transport layer protocol from one suite and the network layer protocol from another.

The most commonly used transport layer protocols are the Transmission Control Protocol (TCP) and User Datagram Protocol (UDP) in the TCP/IP suite, the Sequenced Packet Exchange (SPX) protocol in the NetWare protocol suite, and the NetBEUI protocol in the NetBIOS/NetBEUI/NBF suite (though NetBEUI is more difficult to categorize.)

**Key Concept:** The fourth and middle OSI Reference Model layer is the *transport layer*. This is another very important conceptual layer in the model; it represents the transition point between the lower layers that deal with data delivery issues, and the higher layers that work with application software. The transport layer is responsible for enabling *end-to-end communication* between application processes, which it accomplishes in part through the use of process-level addressing and multiplexing/demultiplexing. Transport layer protocols are responsible for dividing application data into blocks for transmission, and may be either connection-oriented or connectionless. Protocols at this layer also often provide data delivery management services such as reliability and flow control.

---

## **Session Layer (Layer 5)**

The fifth layer in the OSI Reference Model is the *session layer*. As we proceed up the OSI layer stack from the bottom, the session layer is the first one where pretty much all practical matters related to the addressing, packaging and delivery of data are left behind—they are functions of layers four and below. It is the lowest of the three upper layers, which collectively are concerned mainly with software application issues and not with the details of network and internet implementation.

The name of this layer tells you much about what it is designed to do: to allow devices to establish and manage *sessions*. In general terms, a session is a persistent logical linking of two software application processes, to allow them to exchange data over a prolonged period of time. In some discussions, these sessions are called *dialogs*; they are roughly analogous to a telephone call made between two people.

### ***Application Program Interfaces (APIs)***

The primary job of session layer protocols is to provide the means necessary to set up, manage, and end sessions. In fact, in some ways, session layer software products are more sets of tools than specific protocols. These session-layer tools are normally provided to higher layer protocols through command sets often called *application program interfaces* or *APIs*.

Common APIs include NetBIOS, TCP/IP Sockets and Remote Procedure Calls (RPCs). They allow an application to accomplish certain high-level communications over the network easily, by using a standardized set of services. Most of these session-layer tools are of primary interest to the developers of application software. The programs use the APIs to write software that is able to communicate using TCP/IP without having to know the implementation details of how TCP/IP works.

For example, the Sockets interface lies conceptually at layer five and is used by TCP/IP application programmers to create sessions between software programs over the Internet on the UNIX operating system. Windows Sockets similarly lets programmers create

---

Windows software that is Internet-capable and able to interact easily with other software that uses that interface. (Strictly speaking, Sockets is not a protocol, but rather a programming method.)

### ***Session Layer Functions***

As I have mentioned in a few places in this Guide, the boundaries between layers start to get very fuzzy once you get to the session layer, which makes it hard to categorize what exactly belongs at layer 5. Some technologies really span layers 5 through 7, and especially in the world of TCP/IP, it is not common to identify protocols that are specific to the OSI session layer.

The term “session” is somewhat vague, and this means that there is sometimes disagreement on the specific functions that belong at the session layer, or even whether certain protocols belong at the session layer or not. To add to this potential confusion, there is the matter of differentiating between a “connection” and a “session”. Connections are normally the province of layer four and layer three, yet a [Transmission Control Protocol \(TCP\)](#) connection, for example, can persist for a long time. The longevity of TCP connections makes them hard to distinguish from “sessions” (and in fact there are some people who feel that the [TCP/IP host-to-host transport layer](#) really straddles OSI layers four and five).

**Key Concept:** The fifth layer in the OSI Reference Model layer is the *session layer*. As its name suggests, it is the layer intended to provide functions for establishing and managing sessions between software processes. Session layer technologies are often implemented as sets of software tools called *application program interfaces (APIs)*, which provide a consistent set of services that allow programmers to develop networking applications without needing to worry about lower-level details of transport, addressing and delivery.

---

## **Presentation Layer (Layer 6)**

The *presentation layer* is the sixth layer of the OSI Reference Model protocol stack, and second from the top. It is different from the other layers in two key respects. First, it has a much more limited and specific function than the other layers; it's actually somewhat easy to describe, hurray! Second, it is used much less often than the other layers; in many types of connections it is not required.

The name of this layer suggests its main function as well: it deals with the *presentation* of data. More specifically, the presentation layer is charged with taking care of any issues that might arise where data sent from one system needs to be viewed in a different way by the other system. It also takes care of any special processing that must be done to data from the time an application tries to send it until the time it is sent over the network.

---

## Presentation Layer Functions

Here are some of the specific types of data handling issues that the presentation layer handles:

- ☉ **Translation:** Networks can connect very different types of computers together: PCs, Macintoshes, UNIX systems, AS/400 servers and mainframes can all exist on the same network. These systems have many distinct characteristics and represent data in different ways; they may use different character sets for example. The presentation layer handles the job of hiding these differences between machines.
- ☉ **Compression:** Compression (and decompression) may be done at the presentation layer to improve the throughput of data. (There are some who believe this is not, strictly speaking, a function of the presentation layer.)
- ☉ **Encryption:** Some types of encryption (and decryption) are performed at the presentation layer. This ensures the security of the data as it travels down the protocol stack. For example, one of the most popular encryption schemes that is usually associated with the presentation layer is the Secure Sockets Layer (SSL) protocol. Not all encryption is done at layer 6, however; some encryption is often done at lower layers in the protocol stack, in technologies such as [IPSec](#).

## Presentation Layer Role in the OSI Model

The reason that the presentation layer is not always used in network communications is that the jobs mentioned above are simply not always needed. Compression and encryption are usually considered “optional”, and translation features are also only needed in certain circumstances. Another reason why the presentation layer is sometimes not mentioned is that its functions may be performed as part of the application layer.

The fact that the translation job done by the presentation layer isn't always needed means that it is common for it to be “skipped” by actual protocol stack implementations. This means that protocols at layer seven may talk directly with those at layer five. Once again, this is part of the reason why all of the functions of layers five through seven may be included together in the same software package, as described in the [overview of layers and layer groupings](#).

**Key Concept:** The sixth OSI model layer is called the *presentation layer*. Protocols at this layer take care of manipulation tasks that transform data from one representation to another, such as translation, compression and encryption. In many cases, no such functions are required in a particular networking stack; if so, there may not be any protocol active at layer six.

---

---

## **Application Layer (Layer 7)**

At the very top of the OSI Reference Model stack of layers, we find layer 7, the *application layer*. Continuing the trend that we saw in layers 5 and 6, this one too is named very appropriately: the application layer is the one that is used by network applications. These programs are what actually implement the functions performed by users to accomplish various tasks over the network.

It's important to understand that what the OSI model calls an “application” is not exactly the same as what we normally think of as an “application”. In the OSI model, the application layer provides services for user applications to employ. For example, when you use your Web browser, that actual software is an application running on your PC. It doesn't really “reside” at the application layer. Rather, it makes use of the services offered by a protocol that operates at the application layer, which is called the [Hypertext Transfer Protocol \(HTTP\)](#). The distinction between the browser and HTTP is subtle, but important.

The reason for pointing this out is because not all user applications use the application layer of the network in the same way. Sure, your Web browser does, and so does your e-mail client and your Usenet news reader. But if you use a text editor to open a file on another machine on your network, that editor is not using the application layer. In fact, it has no clue that the file you are using is on the network: it just sees a file addressed with a name that has been mapped to a network somewhere else. The operating system takes care of *redirecting* what the editor does, over the network.

Similarly, not all uses of the application layer are by applications. The operating system itself can (and does) use services directly at the application layer.

That caveat aside, under normal circumstances, whenever you interact with a program on your computer that is designed specifically for use on a network, you are dealing directly with the application layer. For example, sending an e-mail, firing up a Web browser, or using an IRC chat program—all of these involve protocols that reside at the application layer.

There are dozens of different application layer protocols that enable various functions at this layer. Some of the most popular ones include HTTP, FTP, SMTP, DHCP, NFS, Telnet, SNMP, POP3, NNTP and IRC. Lots of alphabet soup, sorry. ☺ I describe all of these and more in [the chapter on higher-layer protocols and applications](#).

As the “top of the stack” layer, the application layer is the only one that does not provide any services to the layer above it in the stack—there isn't one! Instead, it provides services to programs that want to use the network, and to you, the user. So the responsibilities at this layer are simply to implement the functions that are needed by users of the network. And, of course, to issue the appropriate commands to make use of the services provided by the lower layers.

**Key Concept:** The seventh and highest layer in the OSI Reference Model is the *application layer*. Application protocols are defined at this layer, which implement specific user applications and other high-level functions. Since they are at the top of the stack, application protocols are the only ones that do not provide services to a higher layer; they make use of services provided by the layers below.

---

As we've [discussed elsewhere](#), the distinctions between the top layers are not very clear, and this is largely because of the decision made to not separate out session, presentation and application layer functions in the important [TCP/IP protocol suite](#). All of the protocols mentioned above are from the TCP/IP protocol family, and some may cover all three of the top three OSI layers, two of them, or one; in the [TCP/IP model](#), they are all applications.

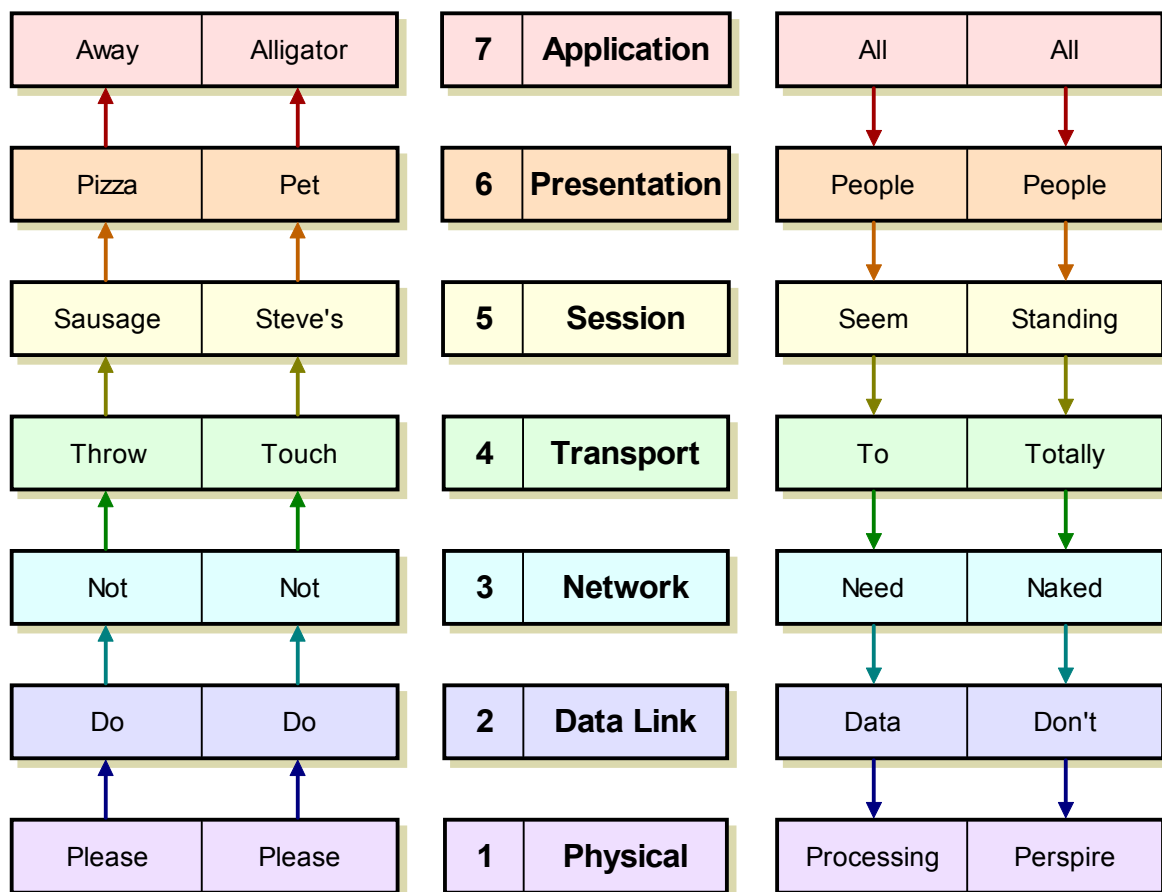

---

## OSI Reference Model Layer Mnemonics

If you spend any amount of time at all dealing with networking design or implementation issues, or learning about how the various protocols operate, the names and numbers of the various layers will eventually become “second nature”. Trust me, I know this from experience!

Many people, however, especially those just learning about networks, find it difficult to recall the names of all the layers, and especially, what their exact order is. To help these people, a number of *mnemonics* (pronounced “neh-MON-iks”—another wonder of the English language) have been created as memory aids. These are cute phrases where each word starts with the first letter of an OSI model layer, arranged in the correct order.

**Figure 18: OSI Reference Model Mnemonics**

These mnemonics may help you to remember the order of the OSI Reference Model layers.

I have seen a few of them in my time, some of which go in ascending layer number order, and some of which go in the other direction. These two go from physical layer to application layer:

- ☯ Please Do Not Throw Sausage Pizza Away
- ☯ Please Do Not Touch Steve's Pet Alligator

---

And these ones go the other direction (application to physical):

- ☯ All People Seem To Need Data Processing (this is a popular one)
- ☯ All People Standing Totally Naked Don't Perspire (hmm, that's interesting...)

For your convenience, I have illustrated all four of these in [Figure 18](#).

Oh, and here's one I just made up: All People Should Teach Networking Daily Please.

(Well, / like it! ☺)

---

## OSI Reference Model Layer Summary

To assist you in quickly comparing the layers of the OSI Reference Model, and understanding where they are different and how they relate to each other, I have created the summary chart shown in [Table 19](#). It shows each layer's name and number, describes its key responsibilities, talks about what type of data is generally handled at each layer, and also what the scope of each layer is in approximate terms. I also show some of the more common protocols that are associated with each layer.

I will say here that “standard disclaimers apply”. I don't want to repeat all of the caveats I mentioned elsewhere in discussions of the OSI model, but know that they apply here as well. Namely: the layers aren't always hard-fast, I haven't listed every single protocol here, some may really fit into more than one layer, and so on. In particular, note that many of the technologies listed as being in the data link layer are there because that is the layer where their primary functionality resides. In reality, most of these technologies include components in other layers, especially the physical layer.

**Table 19: OSI Reference Model Layer Summary (Page 1 of 2)**

Group	#	Layer Name	Key Responsibilities	Data Type Handled	Scope	Common Protocols and Technologies
Lower Layers	1	Physical	Encoding and Signaling; Physical Data Transmission; Hardware Specifications; Topology and Design	Bits	Electrical or light signals sent between local devices	(Physical layers of most of the technologies listed for the data link layer)
	2	Data Link	Logical Link Control; Media Access Control; Data Framing; Addressing; Error Detection and Handling; Defining Requirements of Physical Layer	Frames	Low-level data messages between local devices	IEEE 802.2 LLC, Ethernet Family; Token Ring; FDDI and CDDI; IEEE 802.11 (WLAN, Wi-Fi); HomePNA; HomeRF; ATM; SLIP and PPP
	3	Network	Logical Addressing; Routing; Datagram Encapsulation; Fragmentation and Reassembly; Error Handling and Diagnostics	Datagrams / Packets	Messages between local or remote devices	IP; IPv6; IP NAT; IPsec; Mobile IP; ICMP; IPX; DLC; PLP; Routing protocols such as RIP and BGP
	4	Transport	Process-Level Addressing; Multiplexing/Demultiplexing; Connections; Segmentation and Reassembly; Acknowledgments and Retransmissions; Flow Control	Datagrams / Segments	Communication between software processes	TCP and UDP; SPX; NetBEUI/NBF

**Table 19: OSI Reference Model Layer Summary (Page 2 of 2)**

Group	#	Layer Name	Key Responsibilities	Data Type Handled	Scope	Common Protocols and Technologies
Upper Layers	5	Session	Session Establishment, Management and Termination	Sessions	Sessions between local or remote devices	NetBIOS, Sockets, Named Pipes, RPC
	6	Presentation	Data Translation; Compression and Encryption	Encoded User Data	Application data representations	SSL; Shells and Redirectors; MIME
	7	Application	User Application Services	User Data	Application data	DNS; NFS; BOOTP; DHCP; SNMP; RMON; FTP; TFTP; SMTP; POP3; IMAP; NNTP; HTTP; Telnet

---

# TCP/IP Protocol Suite and Architecture

Just as Ethernet rules the roost when it comes to LAN technologies and IEEE 802.11 is the boss of the wireless LAN world, modern internetworking is dominated by the suite known as *TCP/IP*. Named for two key protocols of the many that comprise it, TCP/IP has been in continual development and use for about three decades. In that time, it has evolved from an experimental technology used to hook together a handful of research computers, to the powerhouse of the largest and most complex computer network in history: the global Internet, connecting together millions of networks and end devices.

In this section I begin our magical tour through the mystical world of TCP/IP. ☺ I begin with an overview of TCP/IP and a brief look at its very interesting history. I discuss the services provided in TCP/IP networks, and then explain the architectural model used under TCP/IP. I then provide a brief description of each of the most important TCP/IP protocols that are discussed in this Guide.

You may have noticed that this section is relatively small, even though its title seems to encompass the entire subject of this TCP/IP Guide. The reason is that this section only provides a high-level overview of TCP/IP. Most of the content of the Guide is concerned with explaining the several dozen individual protocols that comprise TCP/IP; these can be found in other sections and subsections of the Guide. For convenience, you can also find direct links to the descriptions of these protocols in the [TCP/IP Protocols](#) topic in this section.

## TCP/IP Overview and History

The best place to start looking at TCP/IP is probably the name itself. TCP/IP in fact consists of dozens of different protocols, but only a few are the “main” protocols that define the core operation of the suite. Of these key protocols, two are usually considered the most important. The *Internet Protocol (IP)* is the primary OSI network layer (layer three) protocol that provides addressing, datagram routing and other functions in an internetwork. The *Transmission Control Protocol (TCP)* is the primary transport layer (layer four) protocol, and is responsible for connection establishment and management and reliable data transport between software processes on devices.

Due to the importance of these two protocols, their abbreviations have come to represent the entire suite: “TCP/IP”. (In a moment we'll discover exactly the history of that name.) IP and TCP are important because many of TCP/IP's most critical functions are implemented at layers three and four. However, there is much more to TCP/IP than just TCP and IP. The protocol suite as a whole requires the work of many different protocols and technologies to make a functional network that can properly provide users with the applications they need.

TCP/IP uses its own four-layer architecture that corresponds roughly to the OSI Reference Model and provides a framework for the various protocols that comprise the suite. It also includes numerous high-level applications, some of which are well-known by Internet users

---

who may not realize they are part of TCP/IP, such as [HTTP](#) (which runs the World Wide Web) and [FTP](#). In the topics on [TCP/IP architecture](#) and [protocols](#) I provide an overview of most of the important TCP/IP protocols and how they fit together.

### ***Early TCP/IP History***

As I said earlier, the Internet is a primary reason why TCP/IP is what it is today. In fact, the Internet and TCP/IP are so closely related in their history that it is difficult to discuss one without also talking about the other. They were developed together, with TCP/IP providing the mechanism for implementing the Internet. TCP/IP has over the years continued to evolve to meet the needs of the Internet and also smaller, private networks that use the technology. I will provide a brief summary of the history of TCP/IP here; of course, whole books have been written on TCP/IP and Internet history, and this is a technical Guide and not a history book, so remember that this is just a quick look for sake of interest.

The TCP/IP protocols were initially developed as part of the research network developed by the United States *Defense Advanced Research Projects Agency* (*DARPA* or *ARPA*). Initially, this fledgling network, called the *ARPAnet*, was designed to use a number of protocols that had been adapted from existing technologies. However, they all had flaws or limitations, either in concept or in practical matters such as capacity, when used on the ARPAnet. The developers of the new network recognized that trying to use these existing protocols might eventually lead to problems as the ARPAnet scaled to a larger size and was adapted for newer uses and applications.

In 1973, development of a full-fledged system of internetworking protocols for the ARPAnet began. What many people don't realize is that in early versions of this technology, there was only one core protocol: TCP. And in fact, these letters didn't even stand for what they do today; they were for the *Transmission Control Program*. The first version of this predecessor of modern TCP was written in 1973, then revised and formally documented in RFC 675, *Specification of Internet Transmission Control Program*, December 1974.

**Note:** Note: Internet standards are defined in documents called *Requests For Comments (RFCs)*. These documents, and the process used to create them, are described in [their own topic of the section on networking fundamentals](#).

---

### ***Modern TCP/IP Development and the Creation of TCP/IP Architecture***

Testing and development of TCP continued for several years. In March 1977, version 2 of TCP was documented. In August 1977, a significant turning point came in TCP/IP's development. Jon Postel, one of the most important pioneers of the Internet and TCP/IP, published a set of comments on the state of TCP. In that document (known as *Internet*

---

*Engineering Note number 2, or IEN 2*), he provided what I consider superb evidence that [reference models and layers aren't just for textbooks](#), and really **are** important to understand:

We are screwing up in our design of internet protocols by violating the principle of layering. Specifically we are trying to use TCP to do two things: serve as a host level end to end protocol, and to serve as an internet packaging and routing protocol. These two things should be provided in a layered and modular way. I suggest that a new distinct internetwork protocol is needed, and that TCP be used strictly as a host level end to end protocol.

-- Jon Postel, IEN 2, 1977

What Postel was essentially saying was that the version of TCP created in the mid-1970s was trying to do too much. Specifically, it was encompassing both layer three and layer four activities (in terms of [OSI Reference Model layer numbers](#)). His vision was prophetic, because we now know that having TCP handle all of these activities would have indeed led to problems down the road.

Postel's observation led to the creation of [TCP/IP architecture](#), and the splitting of TCP into TCP at the transport layer and IP at the network layer; thus the name "TCP/IP". (As an aside, it's interesting, given this history, that sometimes the entire TCP/IP suite is called just "IP", even though TCP came first.) The process of dividing TCP into two portions began in version 3 of TCP, written in 1978. The first formal standard for the versions of IP and TCP used in modern networks (version 4) were created in 1980. This is why the first "real" version of IP is version 4 and not version 1. TCP/IP quickly became the standard protocol set for running the ARPAnet. In the 1980s, more and more machines and networks were connected to the evolving ARPAnet using TCP/IP protocols, and the TCP/IP Internet was born.

**Key Concept:** TCP/IP was initially developed in the 1970s as part of an effort to define a set of technologies to operate the fledgling Internet. The name "TCP/IP" came about when the original Transmission Control Program (TCP) was split into the Transmission Control Protocol (TCP) and Internet Protocol (IP). The first modern versions of these two key protocols were documented in 1980 as TCP version 4 and IP version 4.

---

### ***Important Factors in the Success of TCP/IP***

TCP/IP was at one time just "one of many" different sets of protocols that could be used to provide network-layer and transport-layer functionality. Today there are still other options for internetworking protocol suites, but TCP/IP is the universally-accepted world-wide standard. Its growth in popularity has been due to a number of important factors. Some of

---

these are historical, such as the fact that it is tied to the Internet as described above, while others are related to the characteristics of the protocol suite itself. Chief among these are the following:

- ☉ **Integrated Addressing System:** TCP/IP includes within it (as part of the [Internet Protocol](#), primarily) [a system for identifying and addressing devices](#) on both small and large networks. The addressing system is designed to allow devices to be addressed regardless of the lower-level details of how each constituent network is constructed. Over time, the mechanisms for addressing in TCP/IP have improved, to meet the needs of growing networks, especially the Internet. The addressing system also includes a [centralized administration capability](#) for the Internet, to ensure that each device has a unique address.
- ☉ **Design For Routing:** Unlike some network-layer protocols, TCP/IP is specifically designed to [facilitate the routing of information](#) over a network of arbitrary complexity. In fact, TCP/IP is conceptually concerned more with the connection of networks, than with the connection of devices. TCP/IP routers enable data to be delivered between devices on different networks by moving it one step at a time from one network to the next. A number of [support protocols](#) are also included in TCP/IP to allow routers to exchange critical information and manage the efficient flow of information from one network to another.
- ☉ **Underlying Network Independence:** TCP/IP operates primarily at layers three and above, and includes provisions to allow it to function on almost any lower-layer technology, including LANs, wireless LANs and WANs of various sorts. This flexibility means that one can mix and match a variety of different underlying networks and connect them all using TCP/IP.
- ☉ **Scalability:** One of the most amazing characteristics of TCP/IP is how scalable its protocols have proven to be. Over the decades it has proven its mettle as the Internet has grown from a small network with just a few machines to a huge internetwork with millions of hosts. While some changes have been required periodically to support this growth, these changes have taken place as part of the TCP/IP development process, and the core of TCP/IP is basically the same as it was 25 years ago.
- ☉ **Open Standards and Development Process:** The TCP/IP standards are not proprietary, but [open standards](#) freely available to the public. Furthermore, the process used to develop TCP/IP standards is also completely open. TCP/IP standards and protocols are developed and modified using the unique, democratic [“RFC” process](#), with all interested parties invited to participate. This ensures that anyone with an interest in the TCP/IP protocols is given a chance to provide input into their development, and also ensures the world-wide acceptance of the protocol suite.
- ☉ **Universality:** Everyone uses TCP/IP because everyone uses it!

This last point is, perhaps ironically, arguably the most important. Not only is TCP/IP the “underlying language of the Internet”, it is also used in most private networks today. Even former “competitors” to TCP/IP such as NetWare now use TCP/IP to carry traffic. The Internet continues to grow, and so do the capabilities and functions of TCP/IP. Preparation for the future continues, with the move to [the new IP version 6 protocol](#) in its early stages. It is likely that TCP/IP will remain a big part of internetworking for the foreseeable future.

**Key Concept:** While TCP/IP is not the only internetworking protocol suite, it is definitely the most important one. Its unparalleled success is due to a wide variety of factors. These include its technical features, such as its routing-friendly design and scalability, its historical role as the protocol suite of the Internet, and its open standards and development process, which reduce barriers to acceptance of TCP/IP protocols.

---

## TCP/IP Services and Client/Server Operation

TCP/IP is most often studied in terms of its layer-based architecture and the protocols that it provides at those different layers. And we're certainly going to do that, don't worry. These protocols, however, represent the technical details of **how** TCP/IP works. They are of interest to us as students of technology, but are normally hidden from users who do not need to see the "guts" of how TCP/IP works to know that it works. Before proceeding to these details, I think it might be instructive to take a "bigger picture" look at **what** TCP/IP does.

### **TCP/IP Services**

In [the section describing the OSI Reference Model](#) I mentioned that the theoretical operation of the model is based on [the concept of one layer providing services to the layers above it](#). TCP/IP covers many layers of the OSI model, and so it collectively provides services of this sort as well in many ways. Conceptually, we can divide TCP/IP services into two groups: services provided to other protocols and services provided to end users directly.

#### **Services Provided to Other Protocols**

The first group of services consists of the core functions implemented by the main TCP/IP protocols such as [IP](#), [TCP](#) and [UDP](#). These services are designed to actually accomplish the internetworking functions of the protocol suite. For example, at the network layer, [IP provides functions](#) such as addressing, delivery, and datagram packaging, fragmentation and reassembly. At the transport layer, TCP and UDP are concerned with encapsulating user data and managing connections between devices. Other protocols provide routing and management functionality. Higher-layer protocols use these services, allowing them to concentrate on what they are intended to accomplish.

#### **End-User Services**

The other general types of service provided by TCP/IP are end-user services. These facilitate the operation of the applications that users run to make use of the power of the Internet and other TCP/IP networks. For example, the [World Wide Web \(WWW\)](#) is arguably the most important Internet application. WWW services are provided through the [Hypertext](#)

---

[Transfer Protocol \(HTTP\)](#), a TCP/IP application layer protocol. HTTP in turn uses services provided by lower-level protocols. All of these details are of course hidden from the end users, which is entirely on purpose!

### ***The TCP/IP Client/Server Structural Model***

An important defining characteristic of TCP/IP services is that they primarily operate in the *client/server* structural model. This term refers to a system where a relatively small number of (usually powerful) server machines is dedicated to providing services to a much larger number of client hosts; I describe the concept more in [the topic on network structural models](#) in the [networking fundamentals](#) chapter. Just as client/server networking applies to hardware, this same concept can be applied to software and protocols, and this is exactly what was done in the design of TCP/IP protocols and applications.

TCP/IP protocols are not set up so that two machines that want to communicate use identical software. Instead, a conscious decision was made to make communication function using matched, complementary pairs of client and server software. The client initiates communication by sending a request to a server for data or other information. The server then responds with a reply to the client, giving the client what it requested, or else an alternative response such as an error message or information about where else it might find the data. Most (but not all) TCP/IP functions work in this manner, which is illustrated in [Figure 19](#).

There are numerous advantages to client/server operation in TCP/IP. Just as client hardware and server hardware can be tailored to their very different jobs, client software and the server software can also be optimized to perform their jobs as efficiently as possible. Let's take again the WWW as another example. To get information from the Web, a Web client software (usually called a *browser*) sends requests to a Web server. The Web server then responds with the requested content. (There's more to it than that, of course, but that's how it appears to the user.) The Web browser is created to provide the interface to the user and to talk to Web servers; the Web server software is very different, generally consisting only of high-powered software that receives and responds to requests.

**Key Concept:** The TCP/IP protocol suite is strongly oriented around the notion of *client/server* network communication. Rather than all devices and protocol software elements being designed as peers, they are constructed as matched sets. Clients normally initiate communications by sending requests, and servers respond to such requests, providing the client with the desired data or an informative reply.

---

### ***Understanding TCP/IP Client and Server Roles***

The terms “client” and “server” can be confusing in TCP/IP because they are used in several different ways, sometimes simultaneously:

**Figure 19: TCP/IP Client/Server Operation**

Most TCP/IP protocols involve communication between two devices, but the two rarely act as peers in the communication; one acts as the *client* and the other as the *server*. This simplified illustration shows a common example—a [World Wide Web](#) transaction using the [Hypertext Transfer Protocol \(HTTP\)](#). The Web browser is an HTTP client and initiates the communication with a request for a file or other resource sent over the Internet to a Web site, which is an HTTP server. The server then responds to the client with the information requested. Servers will generally respond to many clients simultaneously.

- ☉ **Hardware Roles:** The terms “client” and “server” usually refer to the primary roles played by networked hardware. A “client” computer is usually something like a PC or Macintosh computer used by an individual, and primarily initiates conversations by sending requests. A “server” is usually a very high-powered machine dedicated to responding to client requests, sitting in a computer room somewhere that nobody but its administrator ever sees.
- ☉ **Software Roles:** As mentioned earlier, TCP/IP uses different pieces of software for many protocols to implement “client” and “server” roles. A Web browser is a piece of client software, while Web server software is completely different. Client software is usually found on client hardware and server software on server hardware, but **not always**. Some devices may run both client and server software.
- ☉ **Transactional Roles:** In any exchange of information, the client is normally the device that initiates communication or sends a query; the server responds, usually providing information. Again, usually the client software on a client device initiates the transaction, but this is not always the case.

---

So, in a typical organization there will be many smaller individual computers designated “clients”, and a few larger ones that are “servers”. The servers normally run server software, and the clients run client software. But servers can also be set up with client software, and clients with server software.

For example, suppose you are an administrator working in the computer room on server #1 and need to transfer a file to server #2. You fire up FTP to initiate a file-transfer session with server #2. In this transaction, server #1 is playing the role of the client, since it is initiating communication using an FTP client program. Theoretically, you could even start an FTP transfer from server #1 to a particular client, if that client had FTP server software to answer the server's request. (This is less common, because server software is often not installed on client machines.)

Transactional roles come into play when communication occurs between servers in certain protocols. For example, when two [SMTP](#) servers communicate to exchange electronic mail, even though they are both server programs running on server hardware, during any transaction one device acts as the client while the other acts as the server. In some cases, devices can even swap client and server roles in the middle of a session!

I should conclude by making clear that the client and server roles I have discussed above are the *traditional* ones. The rise of powerful personal computers and widespread Internet access (especially “always-on” broadband connectivity) has led to a significant blurring of client and server hardware and software. Many client machines now include server software to allow them to, for example, respond to World Wide Web queries from other clients. There are also many file sharing programs around that allow clients to communicate using the [peer-to-peer structural model](#). However, most TCP/IP communication is still client/server in nature, so it's important to keep these roles in mind.

**Key Concept:** Understanding client/server computing concepts in TCP/IP is made more complex due to the very different meanings that the terms “client” and “server” can have in various contexts. The two terms can refer to *hardware roles*—designations given to hardware devices based on whether they usually function as clients or as servers. The terms can also refer to *software roles*, meaning whether protocol software components function as clients or servers. Finally, they can refer to *transactional roles*, meaning whether a device and program functions as a client or server in any given exchange of data.

---

## TCP/IP Architecture and the TCP/IP Model

The [OSI reference model](#) consists of seven layers that represent a functional division of the tasks required to implement a network. It is a conceptual tool that I often use to show how various protocols and technologies fit together to implement networks. However, it's not the only networking model that attempts to divide tasks into layers and components. The TCP/

---

IP protocol suite was in fact created before the OSI Reference Model; as such, its inventors didn't use the OSI model to explain TCP/IP architecture (even though the OSI model is often used in TCP/IP discussions today, as you will see in this Guide, believe me.)

## ***The TCP/IP Model***

The developers of the TCP/IP protocol suite created their own architectural model to help describe its components and functions. This model goes by different names, including the *TCP/IP model*, the *DARPA model* (after [the agency that was largely responsible for developing TCP/IP](#)) and the *DOD model* (after the United States Department of Defense, the “D” in “DARPA”). I just call it the TCP/IP model since this seems the simplest designation for modern times.

Regardless of the model you use to represent the function of a network—and regardless of what you call that model!—the functions that the model represents are pretty much the same. This means that the TCP/IP and the OSI models are really quite similar in nature even if they don't carve up the network functionality pie in precisely the same way. There is a fairly natural correspondence between the TCP/IP and OSI layers, it just isn't always a “one-to-one” relationship. Since the OSI model is used so widely, it is common to explain the TCP/IP architecture both in terms of the TCP/IP layers and the corresponding OSI layers, and that's what I will now do.

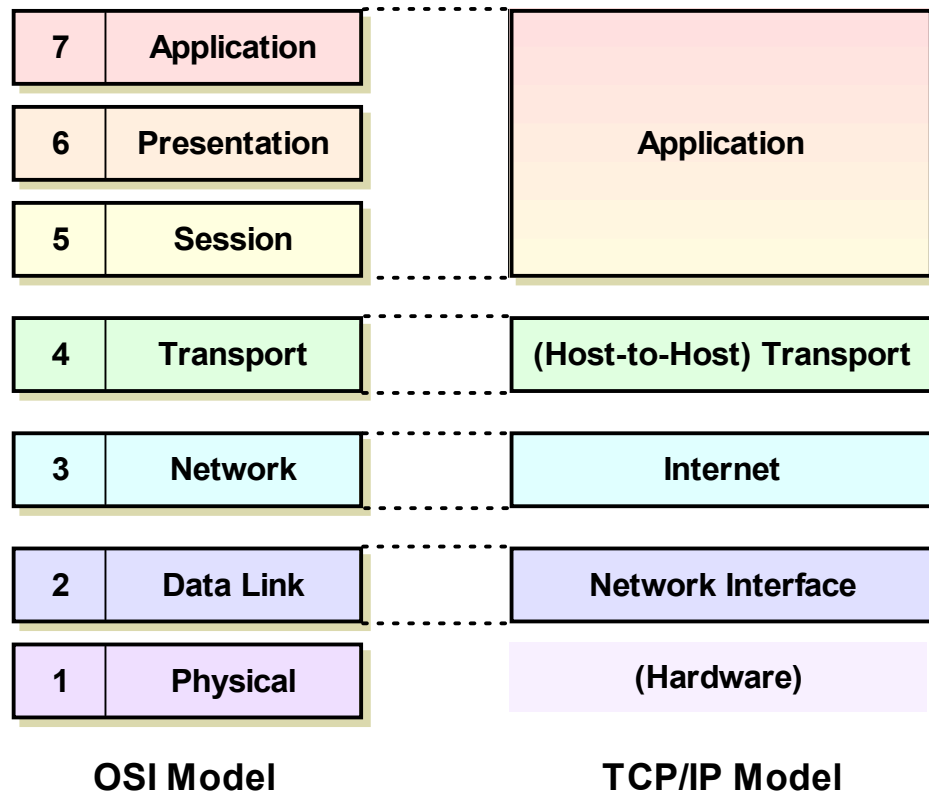

## ***TCP/IP Model Layers***

The TCP/IP model uses four layers that logically span the equivalent of the top six layers of the OSI reference model; this is shown in [Figure 20](#). (The physical layer is not covered by the TCP/IP model because the data link layer is considered the point at which the interface occurs between the TCP/IP stack and the underlying networking hardware.) The following are the TCP/IP model layers, starting from the bottom.

### **Network Interface Layer**

As its name suggests, this layer represents the place where the actual TCP/IP protocols running at higher layers interface to the local network. This layer is somewhat “controversial” in that some people don't even consider it a “legitimate” part of TCP/IP. This is usually because none of the core IP protocols run at this layer. Despite this, the network interface layer is part of the architecture. It is equivalent to the [data link layer \(layer two\) in the OSI Reference Model](#) and is also sometimes called the *link layer*. You may also see the name *network access layer*.

On many TCP/IP networks, there is no TCP/IP protocol running at all on this layer, because it is simply not needed. For example, if you run TCP/IP over an Ethernet, then Ethernet handles layer two (and layer one) functions. However, the TCP/IP standards do define protocols for TCP/IP networks that do not have their own layer two implementation. These protocols, the [Serial Line Interface Protocol \(SLIP\)](#) and the [Point-to-Point Protocol \(PPP\)](#), serve to fill the gap between the network layer and the physical layer. They are commonly used to facilitate TCP/IP over direct serial line connections (such as dial-up telephone networking) and other technologies that operate directly at the physical layer.

**Figure 20: OSI Reference Model and TCP/IP Model Layers**

The TCP/IP architectural model has four layers that approximately match six of the seven layers in the OSI Reference Model. The TCP/IP model does not address the physical layer, which is where hardware devices reside. The next three layers—*network interface*, *internet* and *(host-to-host) transport*—correspond to layers 2, 3 and 4 of the OSI model. The TCP/IP *application* layer conceptually “blurs” the top three OSI layers. It’s also worth noting that some people consider certain aspects of the OSI session layer to be arguably part of the TCP/IP host-to-host transport layer.

### Internet Layer

This layer corresponds to the [network layer in the OSI Reference Model](#) (and for that reason is sometimes called the *network layer* even in TCP/IP model discussions). It is responsible for typical layer three jobs, such as logical device addressing, data packaging, manipulation and delivery, and last but not least, routing. At this layer we find the [Internet Protocol \(IP\)](#), arguably the heart of TCP/IP, as well as support protocols such as [ICMP](#) and the [routing protocols \(RIP, OSPF, BGP, etc.\)](#) The new version of IP, called [IP version 6](#), will be used for the Internet of the future and is of course also at this layer.

### (Host-to-Host) Transport Layer

This primary job of this layer is to facilitate end-to-end communication over an internetwork. It is in charge of allowing logical connections to be made between devices to allow data to be sent either unreliably (with no guarantee that it gets there) or reliably (where the protocol

---

keeps track of the data sent and received to make sure it arrives, and re-sends it if necessary). It is also here that identification of the specific source and destination application process is accomplished

The formal name of this layer is often shortened to just the *transport layer*; the key TCP/IP protocols at this layer are the [Transmission Control Protocol \(TCP\)](#) and [User Datagram Protocol \(UDP\)](#). The TCP/IP transport layer corresponds to the layer of the same name in the OSI model ([layer four](#)) but includes certain elements that are arguably part of the OSI [session layer](#). For example, TCP establishes a connection that can persist for a long period of time, which some people say makes a TCP connection more like a session.

## Application Layer

This is the highest layer in the TCP/IP model. It is a rather broad layer, encompassing layers five through seven in the OSI model. While this seems to represent a loss of detail compared to the OSI model, I think this is probably a good thing! The TCP/IP model better reflects the “blurry” nature of the divisions between the functions of the higher layers in the OSI model, which in practical terms often seem rather arbitrary. It really is hard to separate some protocols in terms of which of layers five, six or seven they encompass. (I didn't even bother to try in this Guide which is why [the higher-level protocols are all in the same chapter](#), while layers one through four have their protocols listed separately.)

Numerous protocols reside at the application layer. These include application protocols such as [HTTP](#), [FTP](#) and [SMTP](#) for providing end-user services, as well as administrative protocols like [SNMP](#), [DHCP](#) and [DNS](#).

**Note:** The internet and host-to-host transport layers are usually considered the “core” of TCP/IP architecture, since they contain most of the key protocols that implement TCP/IP internetworks.

---

In the topic that follows I provide a brief look at each of the TCP/IP protocols covered in detail in this Guide and more detail on where they all fit into the TCP/IP architecture. There I will also cover a couple of protocols that don't really fit into the TCP/IP layer model at all.

**Key Concept:** The architecture of the TCP/IP protocol suite is often described in terms of a layered reference model called the *TCP/IP model*, *DARPA model* or *DOD model*. The TCP/IP model includes four layers: the *network interface layer* (responsible for interfacing the suite to the physical hardware on which it runs), the *internet layer* (where device addressing, basic datagram communication and routing take place), the *host-to-host transport layer* (where connections are managed and reliable communication is ensured) and the *application layer* (where end-user applications and services reside.) The first three layers correspond to layers two through four of the OSI Reference Model respectively; the application layer is equivalent to OSI layers five to seven.

---

---

## TCP/IP Protocols

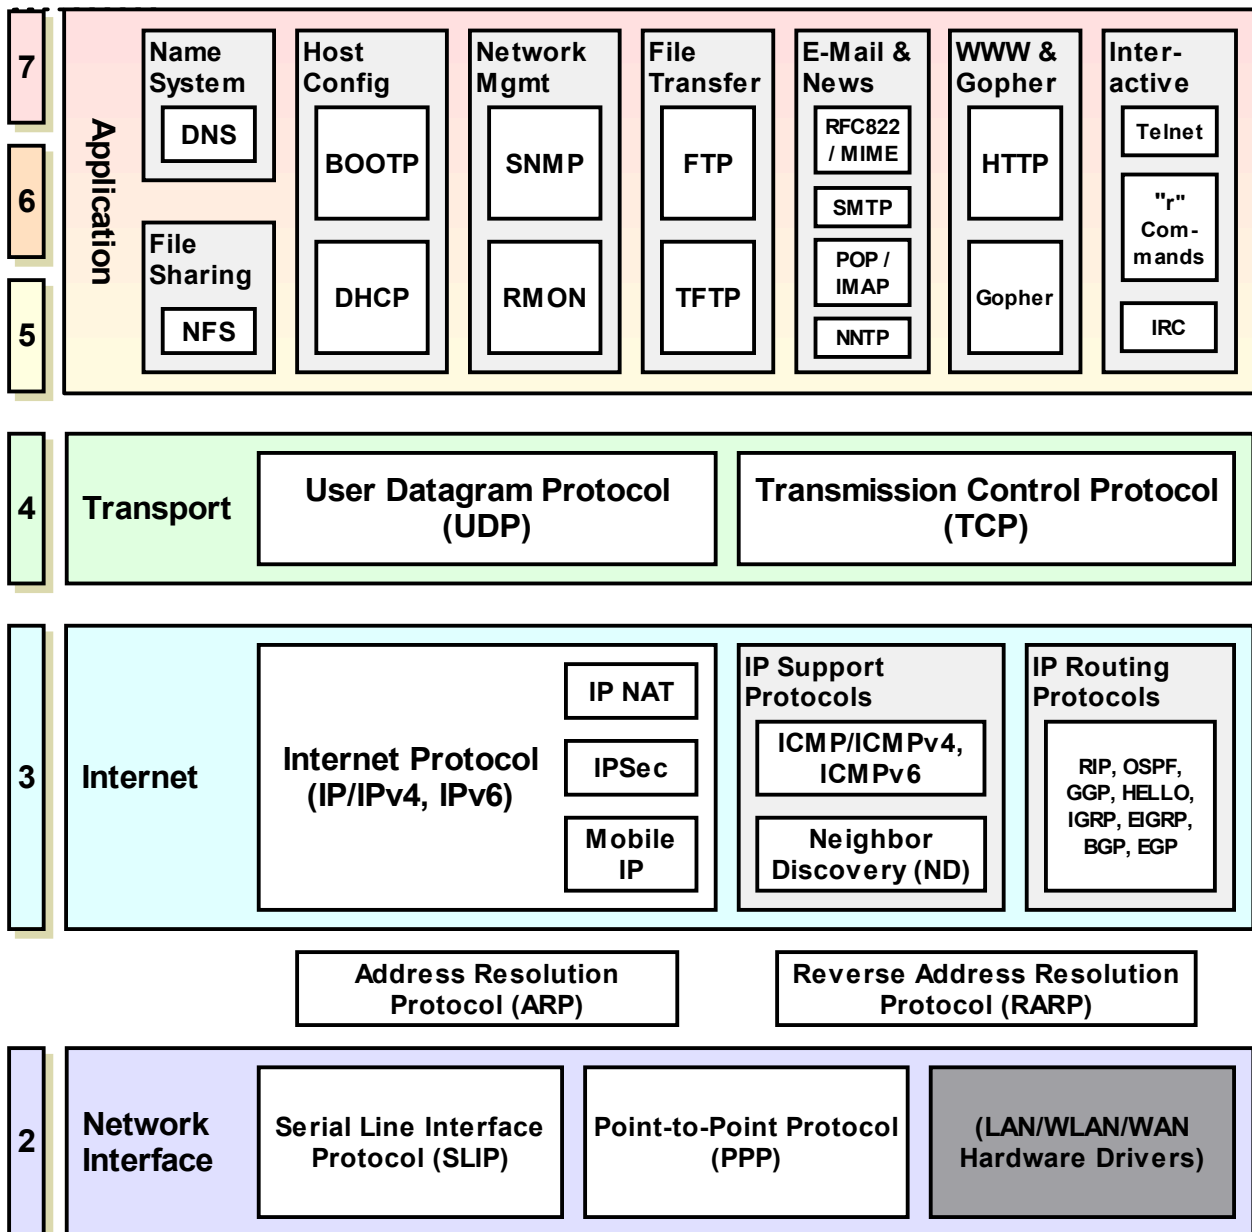

Since TCP/IP is a protocol suite, it is most often discussed in terms of the protocols that comprise it. Each protocol “resides” in a particular layer of the [TCP/IP architectural model](#) we saw earlier in this section. Every TCP/IP protocol is charged with performing a certain subset of the total functionality required to implement a TCP/IP network or application. They work together to allow TCP/IP as a whole to operate.

First, a quick word on the word “protocol”. You will sometimes hear TCP/IP called just a “protocol” instead of a “protocol suite”. This is a simplification that while technically incorrect, is widely used. I believe it arises in large part due to Microsoft referring to protocol suites as “protocols” in their operating systems. I discuss this issue in more detail in a [topic devoted to protocols](#) in the [networking fundamentals chapter](#).

As I mentioned earlier in this section, there are a few TCP/IP protocols that are usually called the “core” of the suite, because they are responsible for its basic operation. Which protocols to include in this category is a matter of some conjecture, but most people would definitely include here the main protocols at the internet and transport layers: the [Internet Protocol \(IP\)](#), [Transmission Control Protocol \(TCP\)](#) and [User Datagram Protocol \(UDP\)](#). These core protocols support many other protocols, to perform a variety of functions at each of the TCP/IP model layers. Still others enable user applications to function.

On the whole, there are many hundreds of TCP/IP protocols and applications, and I could not begin to cover each and every one in this Guide. I do include sections discussing several dozen of the protocols that I consider important for one reason or another. Full coverage of each of these protocols (to varying levels of detail) can be found in the other chapters of this Guide.

Below I have included a number of tables that provide a summary of each of the TCP/IP protocols discussed in this Guide. Each table covers one of the TCP/IP model layers, in order from lowest to highest, and I have provided links to the sections or topics where each is discussed. The organization of protocols in the TCP/IP suite can also be seen at a glance in [Figure 21](#).

**Figure 21: TCP/IP Protocols**

This diagram shows all the TCP/IP protocols covered by this guide, arranged by TCP/IP and OSI Reference Model layer (with the exception of the administration utilities; there are so many and I ran out of space! ☺) I have also shown in the network interface layer where TCP/IP hardware drivers conceptually reside; these are used at layer two when TCP/IP is implemented on a LAN or WAN technology, rather than using SLIP or PPP.

---

## Network Interface Layer (OSI Layer 2) Protocols

TCP/IP includes two protocols at the network interface layer, SLIP and PPP, which are described in [Table 20](#)..

**Table 20: TCP/IP Protocols: Network Interface Layer (OSI Layer 2)**

Protocol Name	Protocol Abbr.	Description
<a href="#">Serial Line Interface Protocol (SLIP)</a>	SLIP	Provides basic TCP/IP functionality by creating a layer-two connection between two devices over a serial line.
<a href="#">Point-to-Point Protocol</a>	PPP	Provides layer-two connectivity like SLIP, but is much more sophisticated and capable. PPP is itself a suite of protocols (“sub-protocols” if you will) that allow for functions such as authentication, data encapsulation, encryption and aggregation, facilitating TCP/IP operation over WAN links.

## Network Interface / Network Layer (“OSI Layer 2/3”) Protocols

[Table 21](#) describes ARP and RARP, the “oddballs” of the TCP/IP suite. In some ways they belong in both layer two and layer three, and in other ways neither. They really serve to link together the network interface layer and the internet layer. For this reason, I really believe they belong *between* these two and call them “layer connection” protocols. [See the section devoted to these protocols and their unique layer for more on this issue.](#)

**Table 21: TCP/IP Protocols: Network Interface / Network Layer (“OSI Layer 2/3”)**

Protocol Name	Protocol Abbr.	Description
<a href="#">Address Resolution Protocol</a>	ARP	Used to map layer three IP addresses to layer two physical network addresses.
<a href="#">Reverse Address Resolution Protocol</a>	RARP	Determines the layer three address of a machine from its layer two address. Now mostly superseded by BOOTP and DHCP.

---

## Network Layer (OSI Layer 3) Protocols

The very important network layer contains the Internet Protocol and several related and support protocols, as shown in [Table 22](#).

**Table 22: TCP/IP Protocols: Network Layer (OSI Layer 3)**

Protocol Name	Protocol Abbr.	Description
<b>Internet Protocol, Internet Protocol Version 6</b>	IP, IPv6	Provides encapsulation and connectionless delivery of transport layer messages over a TCP/IP network. Also responsible for addressing and routing functions.
<b>IP Network Address Translation</b>	IP NAT	Allows addresses on a private network to be automatically translated to different addresses on a public network, providing address sharing and security benefits. (Note that some people don't consider IP NAT to be a protocol in the strict sense of that word.)
<b>IP Security</b>	IPSec	A set of IP-related protocols that improve the security of IP transmissions.
<b>Internet Protocol Mobility Support</b>	Mobile IP	Resolves certain problems with IP associated with mobile devices.
<b>Internet Control Message Protocol</b>	ICMP/ ICMPv4, ICMPv6	A "support protocol" for IP and IPv6 that provides error-reporting and information request-and-reply capabilities to hosts.
<b>Neighbor Discovery Protocol</b>	ND	A new "support protocol" for IPv6 that includes several functions performed by ARP and ICMP in conventional IP.
<b>Routing Information Protocol, Open Shortest Path First, Gateway-to-Gateway Protocol, HELLO Protocol, Interior Gateway Routing Protocol, Enhanced Interior Gateway Routing Protocol, Border Gateway Protocol, Exterior Gateway Protocol</b>	RIP, OSPF, GGP, HELLO, IGRP, EIGRP, BGP, EGP	Protocols used to support the routing of IP datagrams and the exchange of routing information.

---

## Host-to-Host Transport Layer (OSI Layer 4) Protocols

The transport layer contains the essential protocols TCP and UDP, as shown in [Table 23](#).

**Table 23: TCP/IP Protocols: Host-to-Host Transport Layer (OSI Layer 4)**

Protocol Name	Protocol Abbr.	Description
<a href="#">Transmission Control Protocol</a>	TCP	The main transport layer protocol for TCP/IP. Establishes and manages connections between devices and ensures reliable and flow-controlled delivery of data using IP.
<a href="#">User Datagram Protocol</a>	UDP	A transport protocol that can be considered a “severely stripped-down” version of TCP. It is used to send data in a simple way between application processes, without the many reliability and flow management features of TCP, but often with greater efficiency.

## Application Layer (OSI Layer 5/6/7) Protocols

As discussed in the topic on the [TCP/IP model](#), in TCP/IP the single application layer covers the equivalent of OSI layers 5, 6 and 7. The application protocols covered in this Guide are shown in [Table 24](#).

**Table 24: TCP/IP Protocols: Application Layer (OSI Layer 5/6/7) (Page 1 of 2)**

Protocol Name	Protocol Abbr.	Description
<a href="#">Domain Name System</a>	DNS	Provides the ability to refer to IP devices using names instead of just numerical IP addresses. Allows machines to resolve these names into their corresponding IP addresses.
<a href="#">Network File System</a>	NFS	Allows files to be shared seamlessly across TCP/IP networks.
<a href="#">Bootstrap Protocol</a>	BOOTP	Developed to address some of the issues with RARP and used in a similar manner: to allow the configuration of a TCP/IP device at startup. Generally superseded by DHCP.
<a href="#">Dynamic Host Configuration Protocol</a>	DHCP	A complete protocol for configuring TCP/IP devices and managing IP addresses. The successor to RARP and BOOTP, it includes numerous features and capabilities.
<a href="#">Simple Network Management Protocol</a>	SNMP	A full-featured protocol for remote management of networks and devices.
<a href="#">Remote Monitoring</a>	RMON	A diagnostic “protocol” (really a part of SNMP) used for remote monitoring of network devices.
<a href="#">File Transfer Protocol, Trivial File Transfer Protocol</a>	FTP, TFTP	Protocols designed to permit the transfer of all types of files from one device to another.

---

**Table 24: TCP/IP Protocols: Application Layer (OSI Layer 5/6/7) (Page 2 of 2)**

Protocol Name	Protocol Abbr.	Description
<b>RFC 822, Multipurpose Internet Mail Extensions, Simple Mail Transfer Protocol, Post Office Protocol, Internet Message Access Protocol</b>	RFC 822, MIME, SMTP, POP, IMAP	Protocols that define the formatting, delivery and storage of electronic mail messages on TCP/IP networks.
<b>Network News Transfer Protocol</b>	NNTP	Enables the operation of the Usenet online community by transferring Usenet news messages between hosts.
<b>Hypertext Transfer Protocol</b>	HTTP	Transfers hypertext documents between hosts; implements the World Wide Web.
<b>Gopher Protocol</b>	Gopher	An older document retrieval protocol, now largely replaced by the World Wide Web.
<b>Telnet Protocol</b>	Telnet	Allows a user on one machine to establish a remote terminal session on another.
<b>Berkeley “r” Commands</b>	—	Permit commands and operations on one machine to be performed on another.
<b>Internet Relay Chat</b>	IRC	Allows real-time chat between TCP/IP users.
<b>Administration and Troubleshooting Utilities and Protocols</b>	—	A collection of software tools that allows administrators to manage, configure and troubleshoot TCP/IP internetworks.

---

# TCP/IP Lower-Layer (Interface, Internet and Transport) Protocols (OSI Layers 2, 3 and 4)

The TCP/IP protocol suite is largely defined in terms of the protocols that constitute it; several dozen are covered in this Guide. Most of the critical protocols of the suite function at the [lower layers](#) of the [OSI Reference Model](#): layers 2, 3 and 4, which correspond to the network interface, internet and transport layers in the [TCP/IP model architecture](#). Included here are the all-important Internet Protocol (IP) at layer 3 and Transmission Control Protocol (TCP) at layer 4, which combine to give TCP/IP its name.

Due to the importance of these and other TCP/IP protocols at the lower layers, this is the largest chapter of The TCP/IP Guide. It contains four subsections. The first describes the two TCP/IP protocols that reside at the network interface layer, layer 2 of the OSI model: PPP and SLIP. The second describes a couple of “special” protocols that reside architecturally between layers 2 and 3: ARP and RARP. The third covers the TCP/IP internet layer (OSI network layer, layer 3), including IP and several other related and support protocol. The fourth describes the TCP/IP transport layer protocols TCP and UDP.

**Background Information:** [The high-level section on the TCP/IP protocol suite](#) describes it in general terms and lays out its architecture and key protocols. If you have not already read through it, I strongly recommend that you consider doing so before proceeding here.

---

---

## TCP/IP Network Interface Layer (OSI Data Link Layer) Protocols

The lowest layer of the OSI Reference Model is the physical layer, which is responsible for the "nitty gritty" details of transmitting information from one place to another on a network. The layer just above the physical layer is the *data link layer*, called the *network interface layer* or just the *link layer* in the [TCP/IP architectural model](#). Its primary job is to implement networks at the local level, and to interface between the hardware-oriented physical layer, and the more abstract, software-oriented functions of the network layer and those above it.

In this section I provide a description of the two protocols that reside at the data link or network interface layer in the TCP/IP protocol suite. These are the Serial Line Interface Protocol (SLIP) and the Point-to-Point Protocol (PPP). They are both discussed in a single subsection below this one. (The reason why this section contains only one subsection is that the TCP/IP Guide is part of a larger networking reference that contains coverage for many more technologies and protocols at this layer.)

---

## TCP/IP Serial Line Internet Protocol (SLIP) and Point-to-Point Protocol (PPP)

The TCP/IP protocol suite is structured around the [Internet Protocol \(IP\)](#). IP operates at layer three of the [OSI Reference Model](#), and assumes that it will be layered on top of an existing layer two technology. However, certain types of connections exist that do not include a layer two protocol over which IP can run. To enable TCP/IP to operate on these kinds of links, two special TCP/IP data link layer protocols have been created.

In this section I describe the protocols used specifically to implement data link layer connectivity for TCP/IP internetworks. I begin with a brief overview of the two protocols used to connect devices at layer two and how they fit into the [TCP/IP protocol suite](#) as a whole. I then have a single topic that describes the operation of the rather simple Serial Line Internet Protocol (SLIP), and a comprehensive section on the much more capable Point-to-Point Protocol (PPP).

**Background Information:** I want to emphasize again that IP is really the foundation of the TCP/IP protocol suite, even though SLIP and PPP are at a lower architectural layer. For this reason, I strongly recommend at least a basic understanding of the Internet Protocol before proceeding with this section. If you are going to read about both IP and SLIP/PPP, [I recommend reading about IP first](#).

---

---

## **SLIP and PPP Overview and Role In TCP/IP**

The [TCP/IP protocol suite](#) was generally designed to provide implementation of the networking stack from the network layer (layer three) and above. The core protocols of TCP/IP operate at layers three and four of the OSI model, corresponding to the Internet layer and Host-to-Host Transport layer of the [TCP/IP architectural model](#). Other support protocols are defined at these two layers, and many application protocols run there too, as well as at the upper layers of the protocol stack.

However, the TCP/IP architectural model also defines the Network Interface layer, which corresponds to the data link layer (layer two) in the OSI scheme. In most classical networks, TCP/IP doesn't define any protocols operating at this layer. TCP/IP assumes that layer two functionality is provided by a WAN or LAN technology like Ethernet, Token Ring, or IEEE 802.11. These technologies are responsible for the classical layer two functions: physical layer addressing, media access control, and especially, layer two framing of datagrams received from layer three.

**Note:** I'm ignoring the protocols [ARP](#) and [RARP](#) for now, since they fall into a “gray area”, which I discuss in [the section that covers them](#).

---

### ***Why TCP/IP Needs Network Interface Layer Protocols***

There's a problem with the assumption that IP can run on top of an existing layer two protocol: sometimes there isn't one. There are certain technologies that establish only a basic, low-level connection at the physical layer. The most common example of this is a simple serial connection established between two devices. Years ago, it was fairly common for two computers to just be connected using serial ports instead of a full-fledged LAN protocol. Today, we see this much less, but there's another type of serial connection that is *very* popular: serial dial-up networking. When you use a modem to connect to a modem at your Internet Service Provider, the modems negotiate a connection that architecturally exists only at the physical layer.

Since the Internet Protocol assumes certain services will be provided at layer two, there is no way to make it operate directly over a serial line or other physical layer connection. The most important layer two function that is required at a minimum is some mechanism for framing the IP datagram for transmission—that is, providing the necessary data packaging to let datagrams be transmitted over the physical layer network. Without this, IP datagrams cannot be sent over the link.

### ***TCP/IP Network Interface Layer Protocols: SLIP and PPP***

We need something to “fill the gap” between IP at layer three and the physical connection at layer one. To this end, a pair of special protocols have been defined that operate at layer two and provide the services that IP requires to function. These are:

- 
- **Serial Line Internet Protocol (SLIP):** A very simple layer two protocol that provides only basic framing for IP.
  - **Point-to-Point Protocol (PPP):** A more complex, full-featured data link layer protocol that provides framing as well as many additional features that improve security and performance.

### ***Comparing SLIP and PPP***

Both SLIP and PPP are designed for connections that go between just two devices; thus the name “Point-to-Point” Protocol for PPP. They are used in point-to-point LAN or WAN connections, the simplest type. Since there are only two devices, A and B, communication is straight-forward: A sends to B and B sends to A. Since they only deal with simple two-device connections, they do not have to worry about complexities like media access control, or collisions, or unique addressing schemes, the way technologies like Ethernet must. As mentioned earlier, the primary focus of these protocols is providing framing services to layer three, as well as extra features as needed.

Why have two protocols? They both get the job done; the difference is in how they do it. SLIP is extremely simple and easy to implement but lacks the features of PPP, like authentication, compression, error detection and more. PPP is full-featured but much more complicated.

To draw an analogy, SLIP is a mostly-sturdy, ten-year old compact sedan, while PPP is a shiny new luxury SUV. Both will get you from here to Grandma's house, but the SUV is going to be safer, more comfortable and better able to deal with problems that might crop up on the road. If they cost the same to buy and operate, you'd probably choose the SUV. Both SLIP and PPP cost about the same, and unlike an SUV, PPP causes no air pollution and doesn't guzzle gas. For this reason, PPP is the choice of most serial line connections today, and has all but replaced SLIP.

**Key Concept:** *SLIP* and *PPP* provide layer two connectivity for TCP/IP implementations that run directly over a physical layer link without a layer two technology. SLIP is simple and was more commonly used years ago, but today PPP is favored due to its many features and capabilities.

---

### ***Are SLIP and PPP “Really” Part of TCP/IP?***

Incidentally, I should mention that there are some people who don't even consider SLIP and PPP to be part of the “true” TCP/IP protocol suite. They argue that TCP/IP really is defined at layers three and up on the OSI model, and IP itself is the basis of TCP/IP at layer three. Thus, SLIP and PPP are just “extra” protocols that can be used under TCP/IP. To support their argument they point to the fact that PPP can be used for protocols other than IP (which is true). For its part, SLIP is so simple it could carry any layer-three protocol, but I don't believe it has been implemented for network layer protocols other than IP.

---

Frankly, I consider these to be “how many angels fit on the head of a pin” type arguments. As far as I am concerned, SLIP and PPP are part of TCP/IP because they were originally designed for the specific purpose of letting TCP/IP run on layer one links. They were defined using the normal Internet RFC process as well. Regardless, whether they are part of TCP/IP or not, they are used by millions of people every day to enable TCP/IP networks to operate, and thus are deserving of a place in this Guide.

---

## Serial Line Internet Protocol (SLIP)

The need for a data link layer protocol to let IP operate over serial links was identified very early on in the development of TCP/IP. Engineers working on the Internet Protocol needed a way to send IP datagrams over serial connections linking computers together. To solve the problem they created a very simple protocol that would frame IP datagrams for transmission across the serial line. This protocol is called the *Serial Line Internet Protocol*, or *SLIP* for short.

### ***SLIP Overview and History***

SLIP is different from most TCP/IP protocols in that it has never been defined as a formalized standard. It was created informally in the early 1980s and its use spread as a [de facto standard](#) before it was ever described in an RFC document. Even when it was eventually published, in 1988, the decision was specifically made that SLIP would **not** be designated an official Internet standard. The authors of the paper that describes it, RFC 1055, made sure nobody would miss this point, by naming it *A Nonstandard For Transmission Of IP Datagrams Over Serial Lines: SLIP*.

**On The Web:** This is but one of several places where the IETF engineers let their sense of humor shine through. For another interesting example, see [RFC 1313](#). ☺

---

Why was SLIP designated as a “nonstandard” instead of a standard? Well, it was developed as a very rudimentary “stopgap” measure to provide layer two framing when needed. It's so simple that there really isn't much to standardize. Also, the protocol has so many deficiencies that the IETF apparently didn't want it given the status of a formalized standard. RFC 1055 makes specific mention of the problems with SLIP (which we'll see below) and the fact that work was already underway at that time to define a more capable successor to SLIP ([PPP](#)).

How simple is SLIP? So simple that it is one of the very few technologies in this Guide that I can describe almost completely without complaining that it's complicated, or resorting to telling you to “see the defining document for details”. SLIP performs only one function: framing of data for transmission. It does nothing else.

**Key Concept:** SLIP provides a *layer two framing service* for IP datagrams—and no other features or capabilities.

---

---

## SLIP Basic Data Framing Method and General Operation

Here's how SLIP framing works. An IP datagram is passed down to SLIP, which breaks it into bytes and sends them one at a time over the link. After the last byte of the datagram, a special byte value is sent that tells the receiving device that the datagram has ended. This is called the SLIP *END character*, and has a byte value of 192 decimal (C0 hexadecimal, 11000000 binary). And that's basically it: take the whole datagram, send it one byte at a time, and then send the byte 192 to delimit the end of the datagram.

A minor enhancement to this basic operation is to **precede** the datagram by an *END* character as well. The benefit of this is that it clearly separates the start of the datagram from anything that preceded it. To see why this might be needed, suppose at a particular time we have only one datagram to send, datagram #1. So, we send #1, and then send the *END* character to delimit it. Now, suppose there is a pause before the next datagram shows up. During that time we aren't transmitting, but if there is line noise, the other device might pick up spurious bytes here and there. If we later receive datagram #2 and just start sending it, the receiving device might think the noise bytes were part of datagram #2.

Starting datagram #2 off with an *END* character tells the recipient that anything received between this *END* character and the previous one is a separate datagram. If that's just noise, then this "noise datagram" is just gibberish that will be rejected at the IP layer. Meanwhile, it doesn't corrupt the real datagram we wish to send. If no noise occurred on the line between datagrams then the recipient will just see the *END* at the start of datagram #2 right after the one at the end of #1, and will ignore the "null datagram" between the two.

### Escaping Special Characters

There is only one other issue SLIP deals with. If the *END* character is 192 decimal, what happens if the byte value 192 appears in the datagram itself? Transmitting it "as is" would fool the recipient into thinking the datagram ended prematurely. To avoid this, a special *Escape character* (ESC) is defined, which has a decimal value of 219 (DB in hex, 11011011 in binary). The term "escape" means that this symbol conveys the meaning "this byte and the next one have a special meaning". When a value of 192 appears in the datagram, the sending device replaces it by the ESC character (219 decimal) followed by the value 220 decimal. Thus, a single "192" becomes "219 220" (or "DB DC" in hexadecimal). The recipient translates back from "219 220" to "192".

**Note:** The SLIP *ESC* character is not the same as the ASCII *ESC* character. They both perform an "escaping" operation but are otherwise unrelated.

---

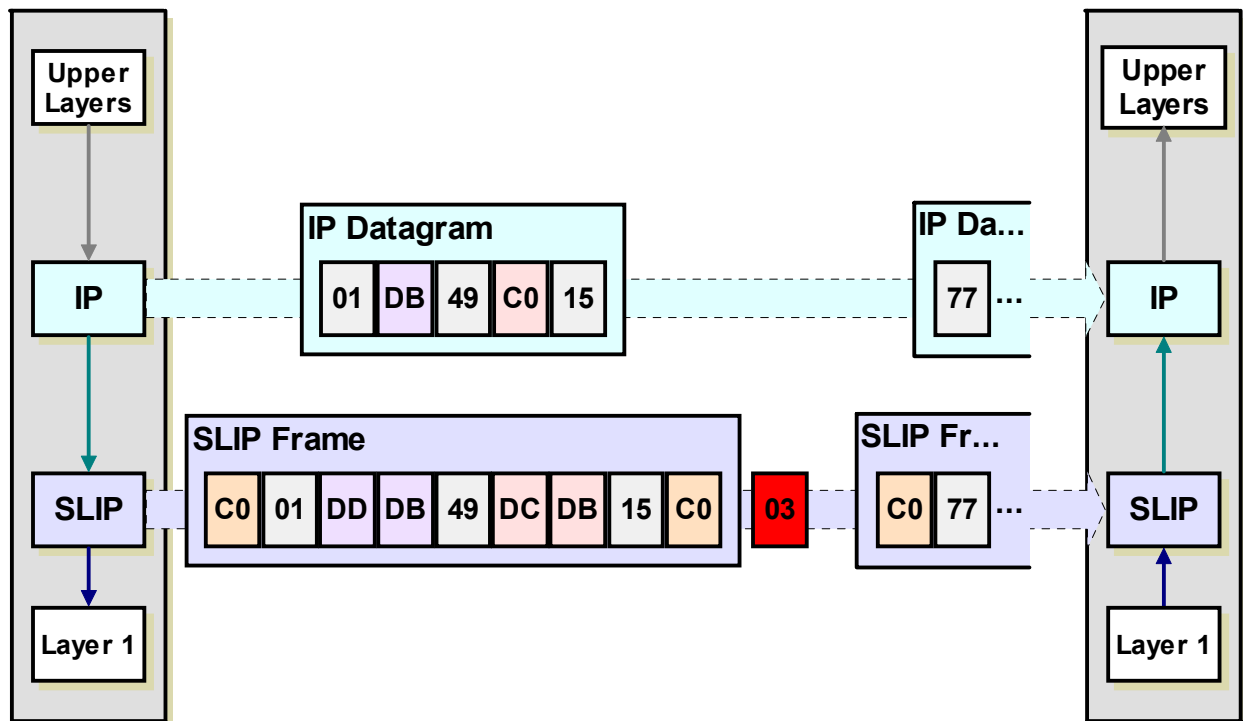

This leaves one final problem: what happens if the **escape character itself** is in the original datagram? That is, what if there's a byte value of 219 in the IP datagram to be sent? This is handled by a similar substitution: instead of "219" we put "219 221".

So in summary, this is basically everything SLIP does:

- ☉ Break an IP datagram into bytes.
- ☉ Send the *END* character (value “192”) after the last byte of the datagram; in better implementations, send the *END* character before the first byte as well.
- ☉ If any byte to be sent in the datagram is “192”, replace it with “219 220”.
- ☉ If any byte to be sent is “219”, replace it with “219 221”.

Figure 22 shows an example of how SLIP works, including the escaping of special characters, using a mock IP datagram.

**Figure 22: Operation of the Serial Line Internet Protocol (SLIP)**

IP datagrams are passed down to the SLIP software at layer two (a simplified one with only five bytes is shown here). There, they are framed by surrounding them with *END* characters (hexadecimal value C0h, shown in orange). Special characters with hexadecimal values DBh and C0h are replaced by two-byte sequences. Note that the presence of the bracketing *END* characters forces the receiving device to see the noise byte (03h, in red) as a separate IP datagram, rather than part of either of the real ones. It will be rejected when passed up to the IP layer.

### **Problems and Limitations of SLIP**

SLIP sounds great, right—nice and simple? Unfortunately, the cost of this simplicity is that SLIP just doesn't provide many of the features and capabilities we really need on modern serial links. Some of the most significant problems with SLIP include the fact that it is deficient in all of the following areas:

- 
- ☉ **Standardized Datagram Size Specification:** SLIP's maximum datagram size supported is not standardized and depends on the implementation. The usual default is 1006 bytes, which becomes the [maximum transmission unit \(MTU\)](#) for the link. If a different size is used this must be programmed into the IP layer.
  - ☉ **Error Detection/Correction Mechanism:** SLIP doesn't provide any way of detecting or correcting errors in transmissions. While such protection is provided at higher layers through [IP header checksums](#) and other mechanisms, it is a job “traditionally” also done at layer two. The reason is that relying on those higher layers means that errors are only detected after an entire datagram has been sent and passed back up the stack at the recipient. Error correction can only come in the form of re-sending any datagrams that were corrupted. This is inefficient, especially considering that serial links are generally much slower than normal LAN links.
  - ☉ **Control Messaging:** SLIP provides no way for the two devices to communicate control information between them to manage the link.
  - ☉ **Type Identification:** Since SLIP includes no headers of its own, it is not possible to identify the protocol it is sending. While developed for IP, you can see that there is no reason other layer three protocols could not be sent using SLIP. However, without type identification there is no way to mix datagrams from two or more layer three protocols on the same link.
  - ☉ **Address Discovery Method:** Addressing isn't needed at layer two due to the point-to-point nature of the connection—there are only two devices so the intended recipient of each message is obvious. However, devices do need some way of learning each other's IP addresses for routing at layer three. SLIP provides no method for this.
  - ☉ **Support For Compression:** Compression would improve performance over serial lines that are, again, slow compared to other technologies. SLIP provides no compression features. Note, however, that modems usually do support compression at layer one, for serial connections that use them. There was also a variant on SLIP called *Compressed SLIP* or *CSLIP* that was created in the late 1980s, but it was not as widely deployed as regular SLIP.
  - ☉ **Security Features:** SLIP provides no methods for authentication of connections or encryption of data, which means even the basics of security are not provided.

Sounds pretty bad, doesn't it? The many shortcomings of SLIP have led most implementations to move from SLIP over to the newer Point-to-Point Protocol (PPP), which is a much richer data link protocol for direct connections that resolves the problems listed above. SLIP is now outdated, and some even consider it a historical protocol. Despite that, SLIP is still used in many places. Simplicity is attractive, and computer people are famous for their inertia: if something is implemented and is working well, many will refuse to change unless they are forced to do so.

---

## Point-to-Point Protocol (PPP)

Even as SLIP was being documented as a “nonstandard” in RFC 1055, work was underway for a newer protocol to provide full-featured IP transmission over direct links between pairs of devices. The result is the *Point-to-Point Protocol (PPP)*, which defines a complete method for robust data link connectivity between units using serial lines or other physical layers. It includes numerous capabilities and features, including error detection, compression, authentication, encryption and much more.

Even though PPP is called a “protocol”, and even though it is considered part of TCP/IP—depending on whom you ask—it is really more a protocol **suite** than a particular protocol. The operation of PPP is based on procedures defined in many individual protocols, as we will see in this section. Thus, PPP can be considered a “protocol suite within a protocol suite”. Alternately, its components can be viewed as “subprotocols” within PPP.

In this section I provide a comprehensive look at the operation of the Point-to-Point Protocol, in four subsections. The first describes the fundamentals of PPP, including its history, standards and an overview of its general operation. The second explains the “core” protocols that are responsible for setting up PPP links and basic operation. The third covers the protocols used to implement various special features in PPP, such as compression and encryption. The last subsection provides detailed information on the various frame formats used by PPP protocols.

**Note:** The component protocols of PPP are normally just called “protocols” and not “subprotocols”. This is confusing, so watch out for it in networking literature. I try to be consistent in this section in referring to PPP as a suite, but remember that it really is often just collectively called a “protocol”.

**Note:** As we will see in this section, PPP can be used to carry the frames of many protocols operating at layers three and above. It is, however, best known for its use with IP, and that is the assumption for the descriptions in this section, unless otherwise specified.

**Related Information:** PPP is related to the High-Level Data Link Control (HDLC) protocol, which is in turn part of the Synchronous Data Link Control (SDLC) family of protocols. I have avoided reliance on the SDLC protocols in explaining PPP since PPP is important and widely used enough that I think it warrants independent description.

---

## **PPP Fundamentals and Operation**

The problem with the Serial Line Internet Protocol was that it was too simple and didn't include enough features. As the saying goes, “be careful what you wish for”, especially when the complaint is too much ***simplicity***. ☺ The Point-to-Point Protocol (PPP) corrects the lack of features in SLIP, but you could figure out, without really trying, what the cost is: significantly more complexity. Where the operation of SLIP can be explained in a few paragraphs, PPP is much more involved, including a number of specific processes that need to be explained.

Before discussing the individual protocols that comprise PPP, I want to take a high-level look at the protocol suite. I start with an overview, history and discussion of the benefits of PPP. I provide a high-level breakdown of the main components of the PPP suite, and a general description of how PPP operates. I then describe the steps involved in setting up and configuring a link, and the phases a PPP link passes through during its “lifetime”. Finally, I categorize and list the standards that define different aspects of PPP's functionality.

**Note:** I describe the operation of PPP before the standards that define it, which is different than the order used in most other sections in this Guide. I felt that in this case, the groupings used to list the standards would make more sense coming after the description of the PPP suite components and its overall operation.

---

### **PPP Overview, History and Benefits**

Albert Einstein is credited with the following quote: “Everything should be made as simple as possible — but no simpler”. The Serial Line Internet Protocol (SLIP) is a good example of this maxim. It provides basic layer two framing for IP, but it is just ***too*** simple for many uses. Since all it does is frame the end of each datagram, it doesn't provide many of the features that we really need for reliable, secure and high-performance operation over serial links. This is especially true today when most serial connections are not short LAN cables but dial-up WAN connections over relatively long distances.

### ***PPP Development and Standardization***

**SLIP** was basically a “hack” to fill a specific need: bridging the gap between IP at layer three and a serial link at layer one. It “gets the job done” but doesn't provide any of the features we really want in a robust protocol for direct links between devices. PPP was developed to be a complete protocol suite that would enable fully-functional layer two connectivity to support not just IP but the transmission of other network layer protocols as well.

The history of PPP goes back to the late 1980s, when SLIP was the de facto standard for serial IP implementations. The first formal IETF document related to PPP was RFC 1134, published in 1989. This RFC is not the standard itself but a proposal for what would eventually be defined as the first main PPP standard, RFC 1171, in 1990. This early

---

document has been revised several times and several other documents added that define the various protocols that comprise the entire PPP suite. [PPP standards are described later in this section.](#)

The IETF is always smart about not reinventing the wheel. Rather than try to develop PPP from scratch, the decision was made to base it on the ISO High-Level Data Link Control (HDLC) protocol, which was initially developed by IBM. HDLC is a derivative of the Synchronous Data Link Control (SDLC) protocol. PPP's developers adapted its framing structure and some of its general operation from the HDLC protocol.

### ***PPP General Function and Architecture***

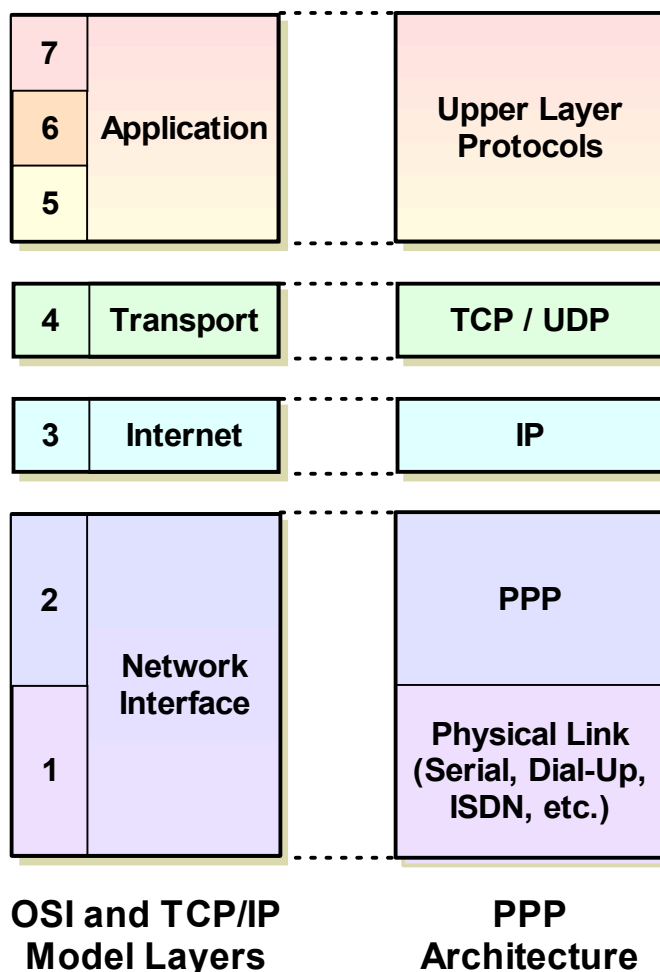

PPP is a [connection-oriented protocol](#) that enables layer two links over a variety of different physical layer connections. It is supported on both synchronous and asynchronous lines, and can operate in half-duplex or full-duplex mode. It was designed to carry IP traffic but is general enough to allow any type of network layer datagram to be sent over a PPP connection. As its name implies, it is for point-to-point connections between exactly two devices, and assumes that frames are sent and received in the same order.

PPP fits into the *Network Interface* layer (Link Layer) in the TCP/IP model, as shown in [Figure 23](#). The operation of PPP follows a specific sequence described in the [general operation topic](#), including a multi-step link establishment phase that may include optional authentication.

### ***PPP Advantages and Benefits***

A list of PPP's strengths reads very much like a list of SLIP's weaknesses, which I explained in detail in [the topic on SLIP](#). Some of the specific benefits of PPP compared to SLIP include:

- ☉ A more comprehensive framing mechanism, compared to the single *END* character in SLIP.
- ☉ Specification of the encapsulated protocol, to allow multiple layer three protocols to be multiplexed on a single link.
- ☉ Error detection for each transmitted frame through the use of a CRC code in each frame header.
- ☉ A robust mechanism for negotiating link parameters, including the maximum frame size permitted.
- ☉ A method for testing links before datagram transmission takes place, and monitoring link quality.
- ☉ Support for authentication of the connection using multiple authentication protocols.
- ☉ Support for additional optional features, including compression, encryption and link aggregation (allowing two devices to use multiple physical links as if they were a single, higher-performance link).

**Figure 23: PPP Location in TCP/IP Architecture**

PPP acts as the interface between the Internet Protocol and a physical link such as a serial line or dial-up networking connection. This corresponds to layer two in the OSI Reference Model.

The proliferation of serial links, especially for dial-up Internet access, has led to widespread use of PPP. It is now one of the most popular layer two WAN technologies in the networking world, and has replaced SLIP as the standard for serial connections on all but legacy implementations. While most often associated with dial-up modem use, PPP can run across any similar type of physical layer link. For example, it is often used to provide layer two functionality on ISDN B channels.

**Key Concept:** PPP is a complete link layer protocol suite for devices using TCP/IP, which provides framing, encapsulation, authentication, quality monitoring and other features to enable robust operation of TCP/IP over a variety of physical layer connections.

---

## ***PPP's Extensibility***

A key advantage of PPP is that it is an **extensible** protocol suite. Over the years new protocols have been added to the suite, to provide additional features or capabilities. For example, PPP is designed not to use just a single authentication protocol, but to allow a choice of which protocol is used for this purpose.

PPP's success has even led to the development of derivative protocols like PPP over Ethernet (PPPoE) and PPP over ATM (PPPoA). These actually layer PPP over existing data link layer technologies, which shows you how valued PPP's features are—even when a layer two technology is already in use, applying PPP on top provides authentication and management benefits for services like DSL.

## **PPP Components and General Operation**

PPP stands for the Point-to-Point **Protocol**, but even the standard that defines PPP immediately starts describing protocols that comprise it, which is why I consider it a protocol suite. At the highest level, the functions of PPP can be broken down into several components. Each of these encompasses a general class of PPP functionality, and is represented by either one protocol in the suite or a set of protocols.

### ***Main PPP Components***

The PPP standard itself describes three “main” components of PPP:

- ④ **PPP Encapsulation Method:** The primary job of PPP is to take higher-layer messages such as IP datagrams and encapsulate them for transmission over the underlying physical layer link. To this end, PPP defines a special frame format for encapsulating data for transmission, based on the framing used in the HDLC protocol. The PPP frame has been specially designed to be small in size and contain only simple fields, to maximize bandwidth efficiency and speed in processing.
- ④ **Link Control Protocol (LCP):** The PPP [Link Control Protocol \(LCP\)](#) is responsible for setting up, maintaining and terminating the link between devices. It is a flexible, extensible protocol that allows many configuration parameters to be exchanged to ensure that both devices agree on how the link will be used.
- ④ **Network Control Protocols (NCPs):** PPP supports the encapsulation of many different layer three datagram types. Some of these require additional setup before the link can be activated. After the general link setup is completed with LCP, control is passed to the PPP [Network Control Protocol \(NCP\)](#) specific to the layer three protocol being carried on the PPP link. For example, when IP is carried over PPP the NCP used is the PPP Internet Protocol Control Protocol (IPCP). Other NCPs are defined for supporting the IPX protocol, the NetBIOS Frames (NBF) protocol, and so forth.

The PPP encapsulation method and LCP are defined in the main PPP standard and some support standards; the NCPs are described in separate standard documents, one per NCP.

---

## Additional PPP Functional Groups

While the three components above do constitute much of the total package of PPP, I would add to the list of components in the standard two additional functional groups. These represent some of the many extra protocols that have been added over time to the suite to support or enhance the basic operation of PPP:

- ☛ **LCP Support Protocols:** Several protocols are included in the PPP suite that are used during the link negotiation process, either to manage it or to configure options. Examples include the [authentication protocols CHAP and PAP](#), which are used by LCP during the optional authentication phase.
- ☛ **LCP Optional Feature Protocols:** A number of protocols have been added to the basic PPP suite over the years to enhance its operation after a link has been set up and datagrams are being passed between devices. For example, the [PPP Compression Control Protocol \(CCP\)](#) allows compression of PPP data, the [PPP Encryption Control Protocol \(ECP\)](#) enables datagrams to be encrypted for security, and the [PPP Multilink Protocol \(PPP MP\)](#) allows a single PPP link to be operated over multiple physical links. The use of these features often also requires additional setup during link negotiation, so several define extensions (such as extra configuration options) that are negotiated as part of LCP.

Each of these additional protocols is generally defined by a different standards document. You can find a list of some of these in the topic on PPP standards.

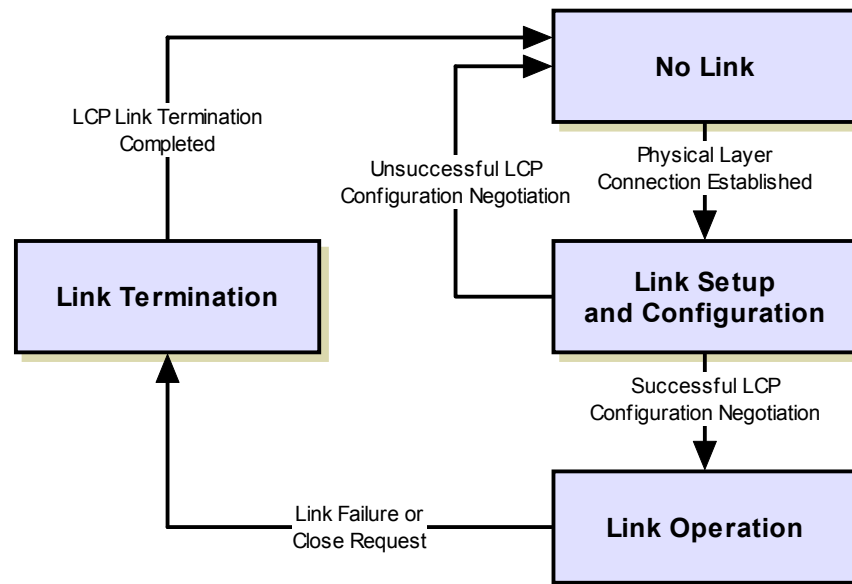

## PPP General Operation

The fact that the PPP suite includes literally dozens of protocols often makes it seem like it must be a really complex technology. In fact, the general operation of PPP is really quite straight-forward. The existence of all those PPP protocols allows PPP to be flexible and extensible, supporting many higher layer datagram types and various features.

The bottom line, however, is that PPP operation involves just three basic steps. Beginning in a state where there is no PPP link between the devices, these are the operations that occur in PPP (also illustrated in [Figure 24](#)):

1. **Link Setup and Configuration:** Before the two devices can exchange information, they must make contact and set up a link between them. During link setup, all the parameters needed to manage the operation of the link are agreed upon by the two devices. The LCP begins this process, and invokes the help of support protocols as they are needed, for options like authentication. After the link is set up in general terms, the appropriate NCP is called for whatever layer three technology is being carried on the link to complete link setup.
2. **Link Operation:** The devices on the link use it to send datagrams. Each device transmits by taking layer three datagrams, encapsulating them and sending them down to layer one to be transmitted. Each device receives by taking PPP frames sent up from its own physical layer, stripping off the PPP header and passing the datagram up to layer three. Where appropriate, optional feature protocols are used here, such as CCP for compression.

3. **Link Termination:** When either device decides it no longer wants to communicate, it terminates the link. The link can of course be re-established if desired.

**Figure 24: Overview of PPP Operation**

In simplest terms, PPP consists of only three basic steps: link setup, link operation and link termination.

Link setup is by far the most complicated of these general steps, as it involves several substeps used to negotiate link parameters and options. The next topic describes the steps in link setup, and discusses the phases that a link passes through as it is set up, used, and eventually terminated.

## **PPP Link Setup and Phases**

Before data can be exchanged on a PPP connection, a link must be set up between the two devices. As part of this setup task, a configuration process is undertaken whereby the two configure the link and agree on the parameters for how data should be passed between them. Only after this is completed can frames actually pass over the link.

The [PPP Link Configuration Protocol \(LCP\)](#) is generally in charge of setting up and maintaining PPP links. LCP may invoke an [authentication protocol](#) (PAP or CHAP) when PPP is configured to use authentication. After an LCP link has been opened, PPP invokes one or more [Network Control Protocols \(NCPs\)](#) for the layer three protocol being carried on the link. These perform any network-layer-specific configuration needed before the link can carry that particular network layer protocol.

The operation of a PPP link can be described as having a “life” of sort. Just as humans are born, grow, have an adult life span and then die, a PPP link is established, configured, used and eventually terminated. The process of setting up, using and closing a PPP link is described in the PPP standard as a series of *phases* or *states*. This is a type of *finite state machine (FSM)*, a tool used to explain the operation of protocols.

**Background Information:** The general concept behind an FSM is described in [the topic on the finite state machine of the Transmission Control Protocol \(TCP\)](#).

---

## **PPP Link Phases**

When we talk about a PPP link overall, we are talking about the status of the LCP connection between the two devices; again, LCP governs the overall state of PPP as a whole. Once an LCP link has been opened, each of the NCPs used on the link can be opened or closed independently of the overall PPP (LCP) link. We'll see how this works momentarily.

An excellent way of understanding how PPP works is to look at these phases, and the process by which transition is made from one to the next during the lifetime of the link. For purposes of clarity, this description is based on an example where device *A* is a PC performing a dial-up networking connection to a remote host *B* (see [Figure 25](#)).

### **Link Dead Phase**

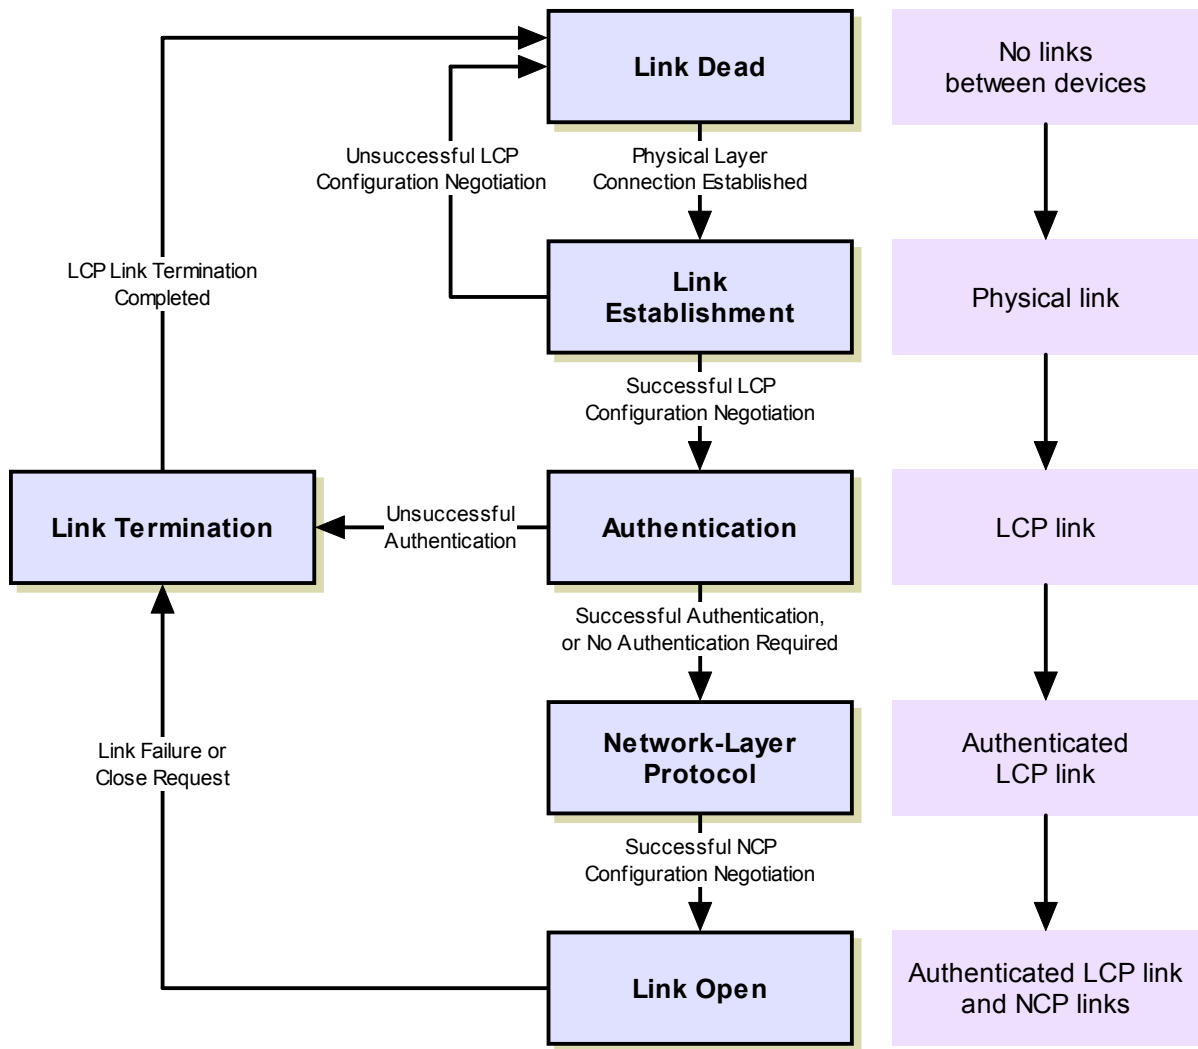

By design, the PPP link always begins and ends in this phase. This phase represents the situation where there is no physical layer link established between the two devices. It remains here until the physical layer link is set up, at which point the link proceeds to the *Link Establishment* phase.

In our example, when *A* is first turned on, there is no physical layer connection (modem connection) between it and *B*. Once the connection is made, the link can proceed to phase 2. (Note that in a direct connection, such as a serial cable linking two PCs, the link may only stay in the *Link Dead* phase for a fraction of a second, until the physical layer connection is detected.)

### **Link Establishment Phase**

The physical layer is now connected and LCP performs the basic setup of the link. Device *A* sends an LCP configuration request message to device *B* over the physical link, specifying the parameters it wishes to use. If Device *B* agrees, it replies with an acknowledgement. If *B* doesn't agree, it sends back a negative acknowledgment or rejection, telling device *A* what it won't accept. Device *A* can then try a different configuration request with new parameters that device *B* will hopefully accept. This process is described in more detail in [the topic covering LCP](#).

Hopefully, *A* and *B* will eventually come to agreement. If so, the status of the link is considered *LCP open*, and will proceed to the *Authentication* phase. If they cannot come to an agreement, the physical link is terminated, and we go back to the *Link Dead* phase.

**Figure 25: PPP Phases**

The PPP connection between the two devices begins in the *Link Dead* state and proceeds through three intermediate phases until the link is fully opened, as shown in the flow chart on the left. It remains in the stable *Link Open* phase until terminated. The purple boxes show the corresponding change in the status of the PPP link as transitions are made between phases.

### **Authentication Phase**

In many cases, a device may require authentication before it will permit connection of another device. (This is certainly usually the case when PPP is used for dial-up.) Authentication is not considered mandatory in PPP, however. When it is used, the appropriate authentication protocol (CHAP or PAP) is employed.

After successful authentication, the link proceeds to the *Network-Layer Protocol* phase. If authentication is not successful, the link fails and transitions to the *Link Termination* phase.

---

## Network-Layer Protocol Phase

Once the basic link has been configured and authentication completed, the general setup of the LCP link is complete. Now, the specific configuration of the appropriate network layer protocol is performed by invoking the appropriate NCP, such as IPCP, IPXCP and so forth.

Each particular network layer protocol whose NCP is successfully configured is considered to be open on the LCP link. More than one NCP can be open on a particular PPP link, and each can be closed independently when it is no longer needed. After all necessary NCPs have been invoked, the link proceeds to the *Link Open* state, even if none were successfully opened.

**Note:** Some PPP features require the negotiation of additional options between the two devices just as the various network layer protocols do. These may perform their own link establishment process during the Network-Layer Protocol phase. For example, the PPP [Compression Control Protocol \(CCP\)](#) sets up data compression in this manner.

---

## Link Open Phase

In this state, the LCP link and one or more NCP links are open and operational. Data can be passed for each NCP that has been successfully set up.

The link can be terminated at any time by either device for a variety of reasons. These may include user request (you hit the “disconnect” button when you want to log off your dial-up session); link quality problems (the modem hangs up on you due to line noise); or some other cause (you spend too much time in the bathroom and your ISP's idle timer logs you out ☺). When any of these occur the LCP link is broken and the link transitions to the *Link Termination* phase.

## Link Termination Phase

The device terminating the link sends a special LCP termination frame, and the other device acknowledges it. The link then goes back to the *Link Dead* phase. In the case where the termination was by request and the physical layer connection is still active, the PPP implementation is supposed to specifically signal the physical layer to terminate the layer one connection.

## Differentiating LCP and NCP Links

Remember that the basic link is established by LCP, and NCP links are set up within the LCP link. Closing an NCP link does not cause the LCP link to be closed. Even if all NCPs are closed, the LCP link remains open. (Of course, no data can be passed until an appropriate NCP link is re-established; a device is required to discard frames received containing

any layer three protocol that does not have an opened NCP.) To terminate a PPP connection, only the LCP link needs to be terminated in the *Link Termination* phase; the NCPs do not need to be explicitly closed.

### **PPP Link Setup and Phase Summary**

A summary of PPP phases can be found in [Table 25](#). In the table, the *LCP Link Status* and *NCP Link Status* columns show the status of the link as the phase starts.

**Table 25: PPP Phases**

Phase/ State	Phase Summary	LCP Link Status Upon Entry To Phase	NCP Link Status Upon Entry To Phase	Transition Requirement	Transition To Phase
<b>Link Dead</b>	Default state; physical layer not connected.	Closed	Closed	Successful physical layer connection	<i>Link Establishment</i>
<b>Link Establishment</b>	Physical layer connected, basic configuration of link performed by LCP.	Closed	Closed	Successful negotiation	<i>Authentication</i>
				Unsuccessful negotiation	<i>Link Dead</i>
<b>Authenti- cation</b>	Basic link is now opened, and optional authentication of device is performed.	Open	Closed	Successful authentication or no authentication required	<i>Network-Layer Protocol</i>
				Unsuccessful authentication	<i>Link Termination</i>
<b>Network-Layer Protocol</b>	One or more NCPs open an NCP link within the LCP link.	Open	Closed	All NCPs opened	<i>Link Open</i>
<b>Link Open</b>	Link is open and operating normally.	Open	Open	Link failure or close request	<i>Link Termination</i>
<b>Link Termination</b>	LCP link is shut down.	Open	Open		<i>Link Dead</i>

### **PPP Standards**

PPP is not a single protocol but rather a suite of many. The basic architecture of PPP was also designed to allow it to be easily extended through the addition of protocols to the suite. For both of these reasons, it makes sense that PPP's operation is defined not in a single standard but in many different standards. Like all TCP/IP standards, the PPP protocols are described in a series of [RFCs](#). These are regularly updated as changes are needed to the different components of PPP, and as new technologies are added to it.

---

While it makes sense to have different parts of PPP covered in different standards, this does make it much harder to learn about how PPP works than if everything were in one specification. Worse, there aren't just a few PPP standards; there are literally *dozens* of RFCs that cover PPP's main operation, its various protocols and other issues related to it. You can find most of them by consulting a master list of RFCs and searching for the string “PPP”, but this way you will find them in numerical (RFC number) order, which isn't very meaningful in terms of how the protocols are used. You also have to differentiate between ones that are current and those that have been obsoleted.

Below I have described the most important and/or interesting of the RFCs that are related to PPP. To make it easier to see what the RFCs are about, I have organized them into groups. These groups roughly correspond to the component groups I discussed in the general operation topic. Within each group the RFCs are listed in numerical order, which is also date order. Only the most recent RFC is listed, not earlier ones that were obsoleted (with the exception of RFC 1334; see the note below in that entry).

Despite the collective size of these tables, I haven't even come close to listing all the standards defined that relate to PPP. Incidentally, to keep it from being even larger (and more confusing) I didn't list the individual compression and encryption algorithms here; you can find them in the topics on [compression](#) and [encryption](#).

You can find more information on most of the protocols in the preceding table in the next two sections.

### **Base PPP Standards**

[Table 26](#) shows the “main” documents that describe PPP in general terms. They cover the basic operation of PPP including the [PPP Link Control Protocol \(LCP\)](#) and encapsulation of datagrams.

**Table 26: PPP Base Standards**

RFC Number	Standard Name	Description
1570	<u><i>PPP LCP Extensions</i></u>	Defines two new features for LCP that allow devices to identify each other to the other device and also tell the other device how much time remains in the current session.
1661	<u><i>The Point-to-Point Protocol (PPP)</i></u>	Base standard for the Point-to-Point protocol. Describes PPP architecture, general operation (including the process of link establishment, maintenance and termination) and details of the LCP protocol.
1662	<u><i>PPP in HDLC-like Framing</i></u>	Defines the specific framing method for PPP frames, based on that used in HDLC. This standard can be considered a “companion” to the main PPP standard, RFC 1661.

---

## LCP Support Protocols

These protocols, shown in [Table 27](#), support the basic operation of LCP. At this time the only protocols I put in this group are those that provide [authentication services](#) during link startup.

**Table 27: PPP LCP Support Protocol Standards**

RFC Number	Standard Name	Description
1334	<u><i>PPP Authentication Protocols</i></u>	Defines the two PPP authentication protocols: Password Authentication Protocol (PAP) and Challenge Handshake Authentication Protocol (CHAP).  Note that RFC 1994 obsoletes RFC 1334, but does not discuss the PAP protocol. This basically tells you what the IETF thinks about PAP. ☺ <a href="#">See the topic on PAP and CHAP</a> for more on this.
1994	<u><i>PPP Challenge Handshake Authentication Protocol (CHAP)</i></u>	Updates the information about CHAP provided in RFC 1334.

## Network Control Protocols (NCPs)

These are protocols that negotiate parameters specific to various layer three protocols carried over PPP. They are described in [Table 28](#).

**Table 28: PPP Network Control Protocol Standards**

RFC Number	Standard Name	Description
1332	<u><i>The PPP Internet Protocol Control Protocol (IPCP)</i></u>	The NCP for the Internet Protocol (IP).
1377	<u><i>The PPP OSI Network Layer Control Protocol (OSINLCP)</i></u>	The NCP for OSI protocol suite network layer protocols, such as CNLP, ES-IS, and IS-IS.
1378	<u><i>The PPP AppleTalk Control Protocol (ATCP)</i></u>	The NCP for the AppleTalk protocol.
1552	<u><i>The PPP Internetworking Packet Exchange Control Protocol (IPXCP)</i></u>	The NCP for the Novell Internetworking Packet Exchange (IPX) protocol.
2043	<u><i>The PPP SNA Control Protocol (SNACP)</i></u>	The NCP for IBM's Systems Network Architecture (SNA).
2097	<u><i>The PPP NetBIOS Frames Control Protocol (NBFCP)</i></u>	The NCP for NetBIOS Frames (NBF, also commonly called NetBEUI).
2472	<u><i>IP Version 6 over PPP</i></u>	Describes the NCP for IPv6: the IPv6 Control Protocol (IPv6CP).

---

## Feature Protocols

These protocols define optional features used with PPP, such as compression and encryption ([Table 29](#)).

**Table 29: PPP Feature Protocol Standards**

RFC Number	Standard Name	Description
1962	<u><i>The PPP Compression Control Protocol (CCP)</i></u>	Defines a mechanism for compressing data sent over PPP links to improve performance. This standard describes how compression is negotiated between two devices on a PPP link. It is used in conjunction with several compression algorithms that actually do the compression of data.
1968	<u><i>The PPP Encryption Control Protocol (ECP)</i></u>	Defines a mechanism for encrypting data sent over PPP links to improve performance. This standard describes how encryption is negotiated between two devices. It is used with several encryption algorithms.
1989	<u><i>PPP Link Quality Monitoring</i></u>	Defines a protocol that lets PPP devices generate reports to each other about the quality of the link.
1990	<u><i>The PPP Multilink Protocol (MP)</i></u>	Defines a method for running PPP over a set of aggregated links, allowing two devices to use multiple low-bandwidth links as a single, high-bandwidth virtual link.
2125	<u><i>The PPP Bandwidth Allocation Protocol (BAP) / The PPP Bandwidth Allocation Control Protocol (BACP)</i></u>	Defines two support protocols that manage the allocation of bandwidth in links aggregated using the PPP Multilink Protocol (MP).

## Applications and Miscellaneous

These protocols describe how PPP can be adapted to run over particular types of links, or that don't really fit into any of the other groups above. They are shown in [Table 30](#).

**Table 30: PPP Application and Miscellaneous Standards (Page 1 of 2)**

RFC Number	Standard Name	Description
1618	<u><i>PPP over ISDN</i></u>	Describes application particulars for running PPP over ISDN links.
1973	<u><i>PPP in Frame Relay</i></u>	Describes how PPP may be modified to run over Frame Relay at layer two.
2290	<u><i>Mobile-IPv4 Configuration Option for PPP IPCP</i></u>	Defines changes to the PPP Internet Protocol Control Protocol (IPCP) to support Mobile IP.
2364	<u><i>PPP Over AAL5</i></u>	Defines a method for sending PPP frames over AAL5 (ATM); commonly called PPPoA.

---

**Table 30: PPP Application and Miscellaneous Standards (Page 2 of 2)**

RFC Number	Standard Name	Description
2516	<u><i>A Method for Transmitting PPP Over Ethernet (PPPoE)</i></u>	Defines a technique for encapsulating PPP frames over Ethernet (PPPoE).
2615	<u><i>PPP over SONET/SDH</i></u>	Discusses how to encapsulate PPP frames over SONET/SDH links.

---

## PPP Core Protocols: Link Control, Network Control and Authentication

The PPP protocol suite consists of several dozen protocols that cover various aspects of its operation. Of these, a few protocols can be considered the most important or “core” of the suite. It's not that the others are *not* important, mind you. But this small group is responsible for the basic operation of PPP. In particular, they work together to implement the relatively complex link negotiation process, which is a big part of what PPP is all about.

In this section I describe the protocols that are responsible for PPP link setup and basic operation. I begin with a description of the key Link Control Protocol (LCP). I then describe the different Network Control Protocols (NCPs) used to configure PPP for different layer three protocols. Finally, I discuss the two PPP authentication protocols, PAP and CHAP, used to provide authentication during link setup.

**Related Information:** The frame formats for these protocols are detailed in the separate [section on PPP frames and frame formats](#).

---

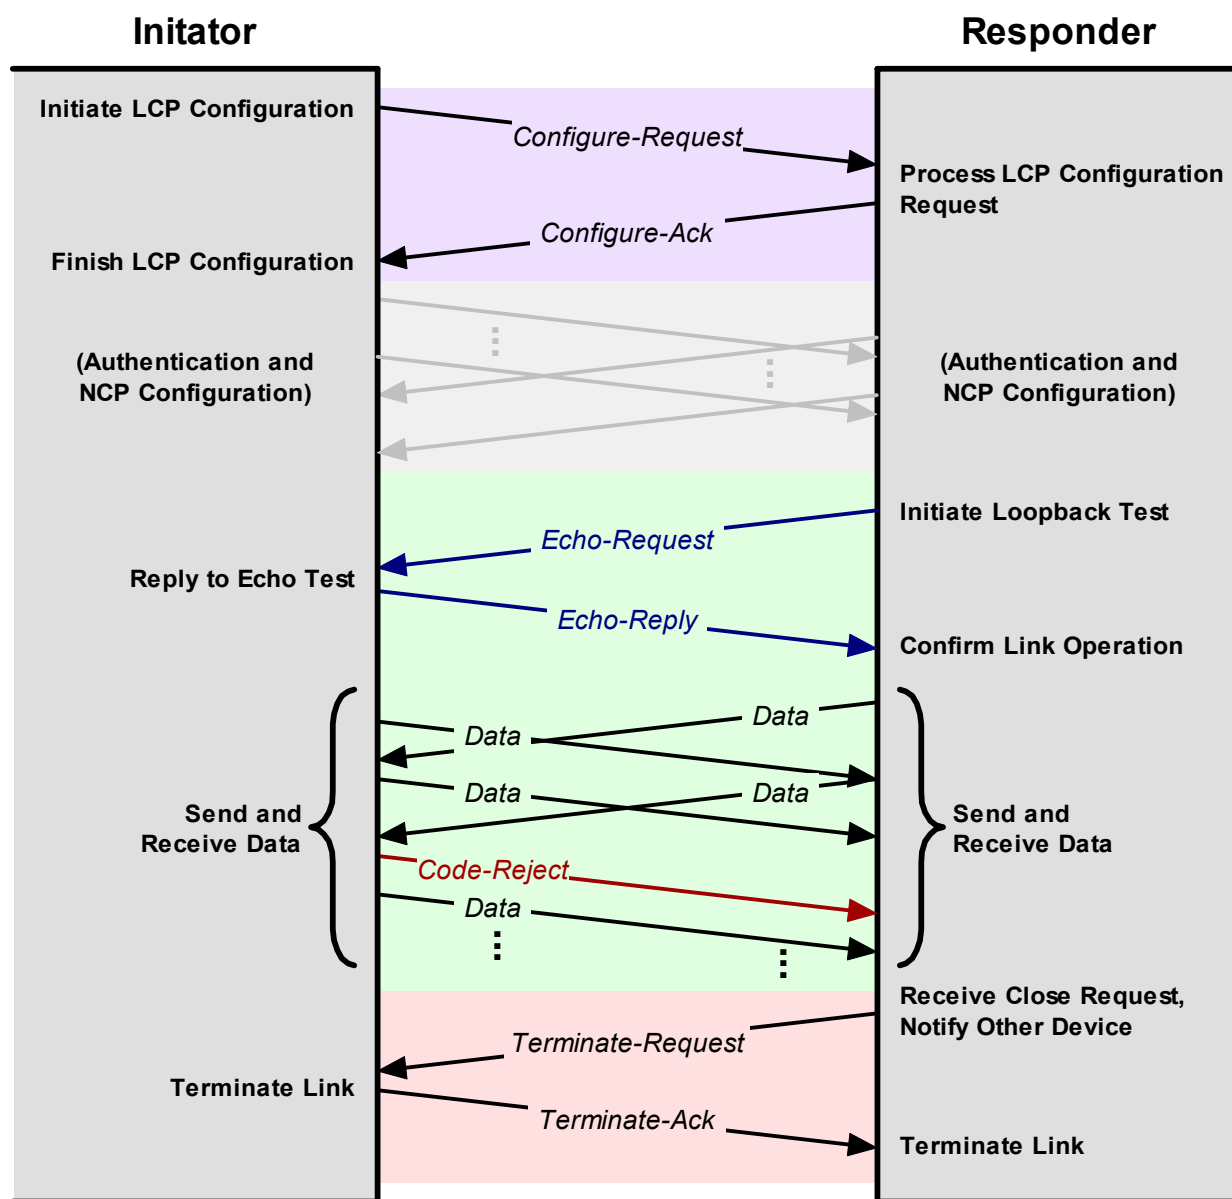

### PPP Link Control Protocol (LCP)

Of all the different PPP suite protocols, the single most important protocol is the PPP *Link Control Protocol (LCP)*. LCP is the “boss” of PPP; it is responsible for its overall successful operation, and for “supervising” (in a way) the actions of other protocols.

PPP is about links, and LCP is about controlling those links. As I discussed in the PPP fundamentals section, the operation of a PPP link can be thought of as proceeding through various “life stages” just as a biological organism does. There are three main stages of “link life” and LCP plays a key role in each one:

- ☉ **Link Configuration:** The process of setting up and negotiating the parameters of a link.
- ☉ **Link Maintenance:** The process of managing an opened link.
- ☉ **Link Termination:** The process of closing an existing link when it is no longer needed (or when the underlying physical layer connection closes).

Each of these functions corresponds to one of the “[life phases](#)” of a PPP link. Link configuration is performed during the initial *Link Establishment* phase of a link; link maintenance occurs while the link is open, and of course, link termination happens in the *Link Termination* phase. [Figure 26](#) represents a summary of the LCP link, showing the different message exchanges performed by LCP during these different life phases of a PPP connection.

**Figure 26: PPP Link Control Protocol (LCP) Message Exchanges**

This diagram provides an overview of many of the message exchanges performed by LCP during different phases of a PPP connection. Link Configuration is here shown as a simple exchange of a *Configure-Request* and *Configure-Ack*. After subsequent exchanges using other PPP protocols to authenticate and configure one or more NCPs, the link enters the *Link Open* phase. In this example, an *Echo-Request* and *Echo-Reply* message are first used to test the link, followed by the sending and receiving of data by both devices. One *Data* message is shown being rejected due to an invalid *Code* field. Finally, the link is terminated using *Terminate-Request* and *Terminate-Ack* messages.

## LCP Frames

Devices use LCP to control the PPP link by sending special LCP messages across the physical link between them. These messages are called both LCP packets and LCP frames; while the standard uses "packet", the term "frame" is preferred because layer two

---

messages are normally called frames. There are eleven different LCP frame types defined in the main PPP document, which are divided into three groups that correspond to the three link “life stages” above. Four LCP frame types are used for link configuration, five for maintenance and two for termination. The frame formats themselves are described in [the topic on LCP frames](#). Below I will discuss each of the three major functions of LCP and how the frames are used in each.

**Key Concept:** The *PPP Link Control Protocol (LCP)* is the most important protocol in the PPP suite. It is responsible for configuring, maintaining and terminating the overall PPP link. The two devices using PPP employ a set of LCP frames to conduct LCP operations.

---

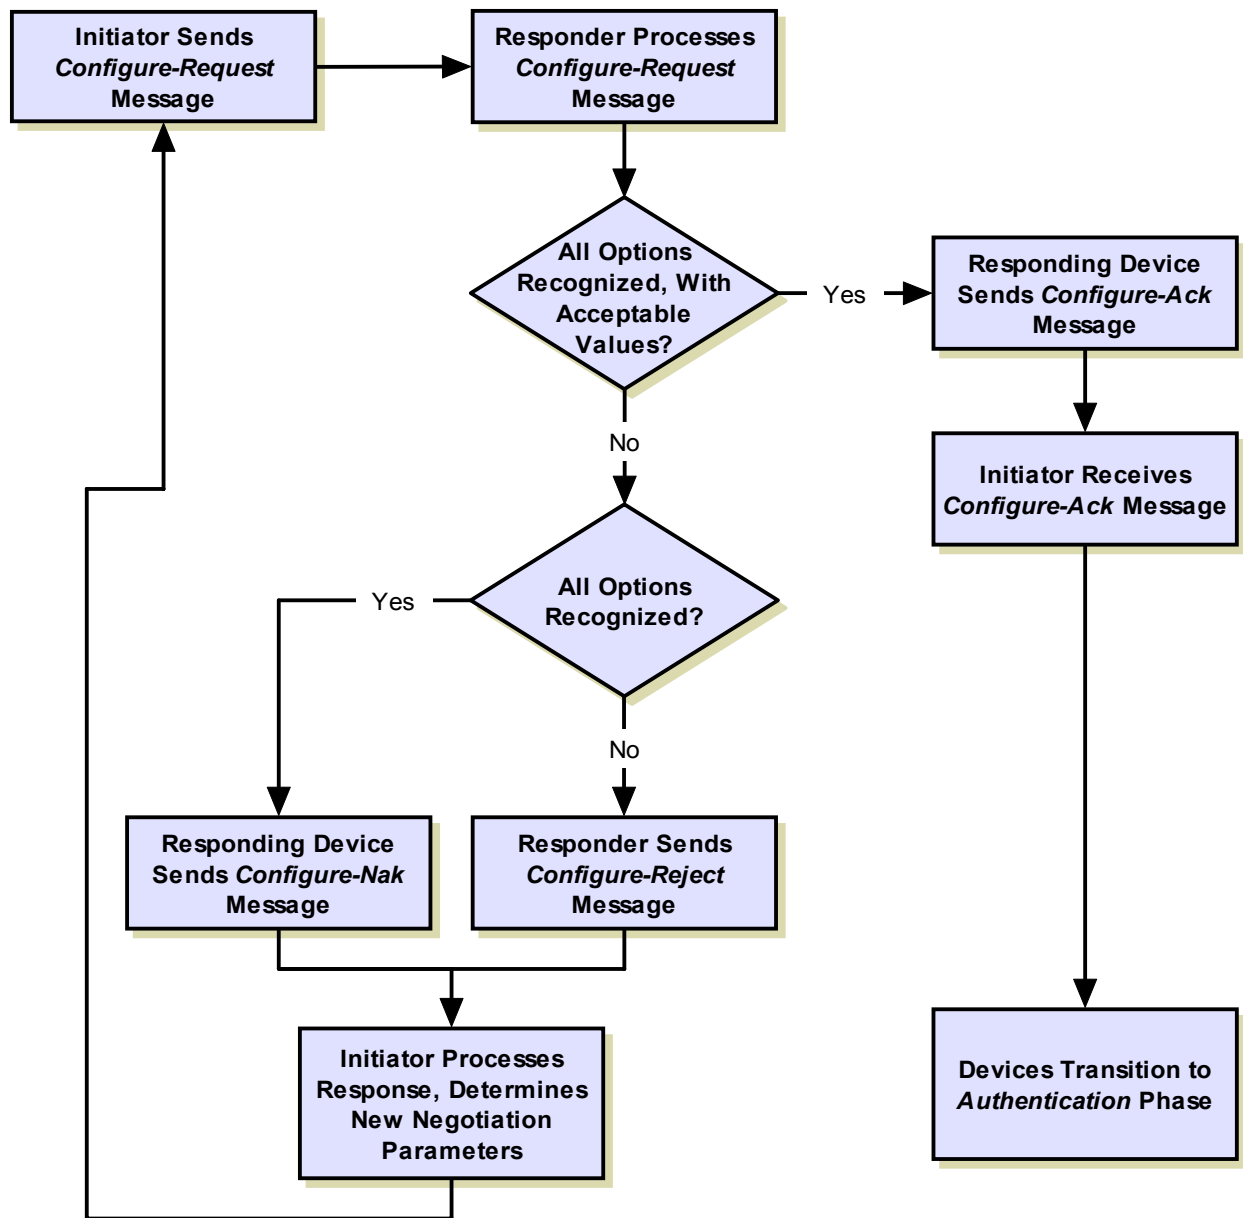

### ***LCP Link Configuration***

Link configuration is arguably the most important job that LCP does in PPP. During the *Link Establishment* phase, LCP frames are exchanged that enable the two physically-connected devices to negotiate the conditions under which the link will operate. [Figure 27](#) shows the entire procedure, which we will now examine in detail.

The process starts with the initiating device (let's call it device *A*, yeah, isn't that original) creating a *Configure-Request* frame that contains a variable number of configuration options that it wants to see set up on the link. This is basically device *A*'s “wish list” for how it wants the link created.

The main PPP document (RFC 1661) defines a number of different configuration options that the initiator can specify in this request. Any one of these can be included and if so, filled in with the value corresponding to what device *A* wants for that option. If absent, this means device *A* is neither requesting nor specifying that option. The six options are:

- ☉ ***Maximum-Receive-Unit (MRU):*** Lets device *A* specify the maximum size datagram it wants the link to be able to carry.
- ☉ ***Authentication-Protocol:*** Device *A* can indicate the type of authentication protocol it wishes to use (if any).
- ☉ ***Quality-Protocol:*** If device *A* wants to enable quality monitoring on the link, what protocol to use (though there is only one currently defined: LQR).
- ☉ ***Magic-Number:*** Used to detect looped back links or other anomalies in the connection.
- ☉ ***Protocol-Field-Compression:*** Allows device *A* to specify that it wants to use “compressed” (8 bit) *Protocol* fields in PPP data frames instead of the normal 16 bit *Protocol* field. This provides a small but free savings (one byte) on each PPP frame. Note that this has nothing to do with the compression feature offered by CCP. See the PPP general frame format topic for more on this feature.
- ☉ ***Address-and-Control-Field-Compression (ACFC):*** The same as the option just above but used to compress the *Address* and *Control* fields, again for small bandwidth savings. Again, see [the PPP general frame format topic](#) for more.

**Figure 27: PPP LCP Link Configuration Process**

This flowchart shows in more detail the negotiation process undertaken to configure the link by LCP. This process begins when the PPP link enters the *Link Establishment* phase. After successful configuration, the connection transitions to the *Authentication* phase.

Other options may also be added to this list by optional feature protocols. For example, [Multilink PPP](#) adds several options that must be negotiated during link setup.

The other device (let's call it say... device *B* ☺) receives the *Configure-Request* and processes it. It then has three choices of how to respond:

1. If every option in it is acceptable in every way, device *B* sends back a *Configure-Ack* ("acknowledge"). The negotiation is complete.

- 
2. If all the options that device *A* sent are valid ones that device *B* recognizes and is capable of negotiating, but it doesn't accept the values device *A* sent, then device *B* returns a *Configure-Nak* ("negative acknowledge") frame. This message includes a copy of each configuration option that *B* found unacceptable.
  3. If any of the options that *A* sent were either unrecognized by *B*, or represent ways of using the link that *B* considers not only unacceptable but not even subject to negotiation, it returns a *Configure-Reject* containing each of the objectionable options.

The difference between a *Configure-Nak* and a *Configure-Reject* is that the former is like device *B* saying "I don't accept your terms, but I'm willing to haggle", while the latter is device *B* basically saying "No way Jose". For example, if device *A* tries to request PAP as the authentication protocol but device *B* wants to use CHAP, it will send a *Configure-Nak*. If device *B* doesn't support authentication at all, it will send a *Configure-Reject*.

**Note:** Even after receiving a reject, device *A* can retry the negotiation with a new *Configure-Request*.

---

## **LCP Link Maintenance**

Once the link has been negotiated, LCP passes control to the appropriate authentication and/or NCP protocols as discussed in [the PPP Link Setup and Phases topic](#). Eventually the link setup will complete and go into the open state. LCP messages can then be used by either device to manage or debug the link:

- ☉ **Code-Reject and Protocol-Reject:** These frame types are used to provide feedback when one device receives an invalid frame due to either an unrecognized LCP *Code* (LCP frame type) or a bad *Protocol* identifier.
- ☉ **Echo-Request, Echo-Reply and Discard-Request:** These frames can be used for testing the link.

## **LCP Link Termination**

Finally, when the link is ready to be shut down, LCP terminates it. The device initiating the shutdown (which may not be the one that initiated the link in the first place) sends a *Terminate-Request* message. The other device replies back with a *Terminate-Ack*. A termination request indicates that the device sending it needs to close the link. Like a four-year-old who tells you he "needs to go now, **bad!**", this is a request that cannot be denied. ☺

## **Other LCP Messages**

The standard RFC 1570, *PPP LCP Extensions*, also defines two new LCP message types. The *Identification* message is used to allow a device to identify itself to its peer on the link. The *Time-Remaining* message lets one device tell the other how much time remains in the current session.

---

## ***Relationship Between LCP and Other PPP Protocols***

Note that many of the other protocols used in PPP are modeled after LCP. They use the same basic techniques for establishing protocol connections, and send and receive a subset of LCP message types. They also exchange configuration options in a similar manner. The next topic shows how the Network Control Protocols (NCPs) are based on LCP. You will see the same thing in looking at feature protocols such as CCP, ECP and others.

## **PPP Network Control Protocols (IPCP, IPXCP, NBFCP and others)**

One of the reasons why PPP is such a powerful technology is that it is flexible and expandable. Even though it was originally created with the idea of carrying IP datagrams, PPP's designers recognized that it would be short-sighted to think so narrowly. PPP could easily carry data from many types of network layer protocols, and on some networks, it might even be advantageous to let it carry datagrams from different layer three protocols simultaneously.

Allowing PPP to support multiple network layer protocols would require it to have knowledge of each one's idiosyncrasies. If we used only LCP for link configuration, it would need to know all the unique requirements of each layer three protocol. This would also require that LCP be constantly updated as new layer three protocols were defined and as new parameters were defined for existing ones.

Instead of this inflexible design, PPP takes a “modular” approach to link establishment. LCP performs the basic link setup, and after (optional) authentication, invokes a *Network Control Protocol (NCP)* that is specific to each layer three protocol that is to be carried over the link. The NCP conducts a negotiation of any parameters that are unique to the particular network layer protocol. More than one NCP can be run for each LCP link; the process of how this is done and the relationship between the NCP links and LCP link can be seen in [the topic on PPP link setup and phases](#).

Each of the common network layer technologies has a PPP NCP defined for it in a separate RFC. These documents are usually named in this pattern: “The PPP <layer three protocol name> Control Protocol”. The most common ones are *The PPP Internet Protocol Control Protocol (IPCP)*, *The PPP Internetworking Packet Exchange Control Protocol (IPXCP)*, and *The PPP NetBIOS Frames Control Protocol (NBFCP)*. These are the NCPs for IP, IPX and NBF (also called NetBEUI), respectively. A separate NCP is also defined for [IP version 6](#), the *PPP IP Version 6 Control Protocol (IPv6CP)*.

## ***Operation of PPP Network Control Protocols***

Each NCP operates very much like a “lite” version of LCP, as you can see by examining [Figure 28](#) (and comparing it to [Figure 26](#), which shows the messaging for LCP). Like LCP, each NCP performs functions for link setup, maintenance and termination—only it deals with its particular type of NCP link and not the “overall” LCP link. Each NCP uses a subset of seven of the message types defined in LCP, and uses them in very much the same way as the message type of the same name is used in LCP:

- 
- ☉ **Link Configuration:** The process of setting up and negotiating the parameters of the particular NCP link (once an LCP link is established) is accomplished using *Configure-Request*, *Configure-Ack*, *Configure-Nak* and *Configure-Reject* messages just as described in the LCP topic, except these ones are particular to the NCP. The configuration options are of course different; they are the network layer protocol parameters being negotiated.
  - ☉ **Link Maintenance:** *Code-Reject* messages can be sent to indicate invalid code values (NCP frame types).
  - ☉ **Link Termination:** An NCP link can be terminated using *Terminate-Request* and *Terminate-Ack*. (Remember that NCP links are set up within an LCP link; there can be more than one NCP link open, and closing NCP links doesn't terminate the LCP link. Also, NCP links do not need to be closed when an LCP link is terminated.)

**Key Concept:** After the primary PPP link is established using LCP, each network layer protocol to be carried over the link requires the establishment of the appropriate NCP link. The most important of these is the *PPP Internet Protocol Control Protocol (IPCP)*, which allows IP datagrams to be carried over PPP.

---

### **An Example NCP: The Internet Protocol Control Protocol (IPCP)**

Let's look at the NCP for IP, IPCP. When PPP is set up to carry IP datagrams, IPCP is invoked in the *Network-Layer Protocol* phase (one of the [PPP phases](#)) to set up an IP NCP link between the two devices. The setup is carried out using the four “*Configure-*” messages. For IP, there are two configuration options that can be specified in an IPCP *Configure-Request*:

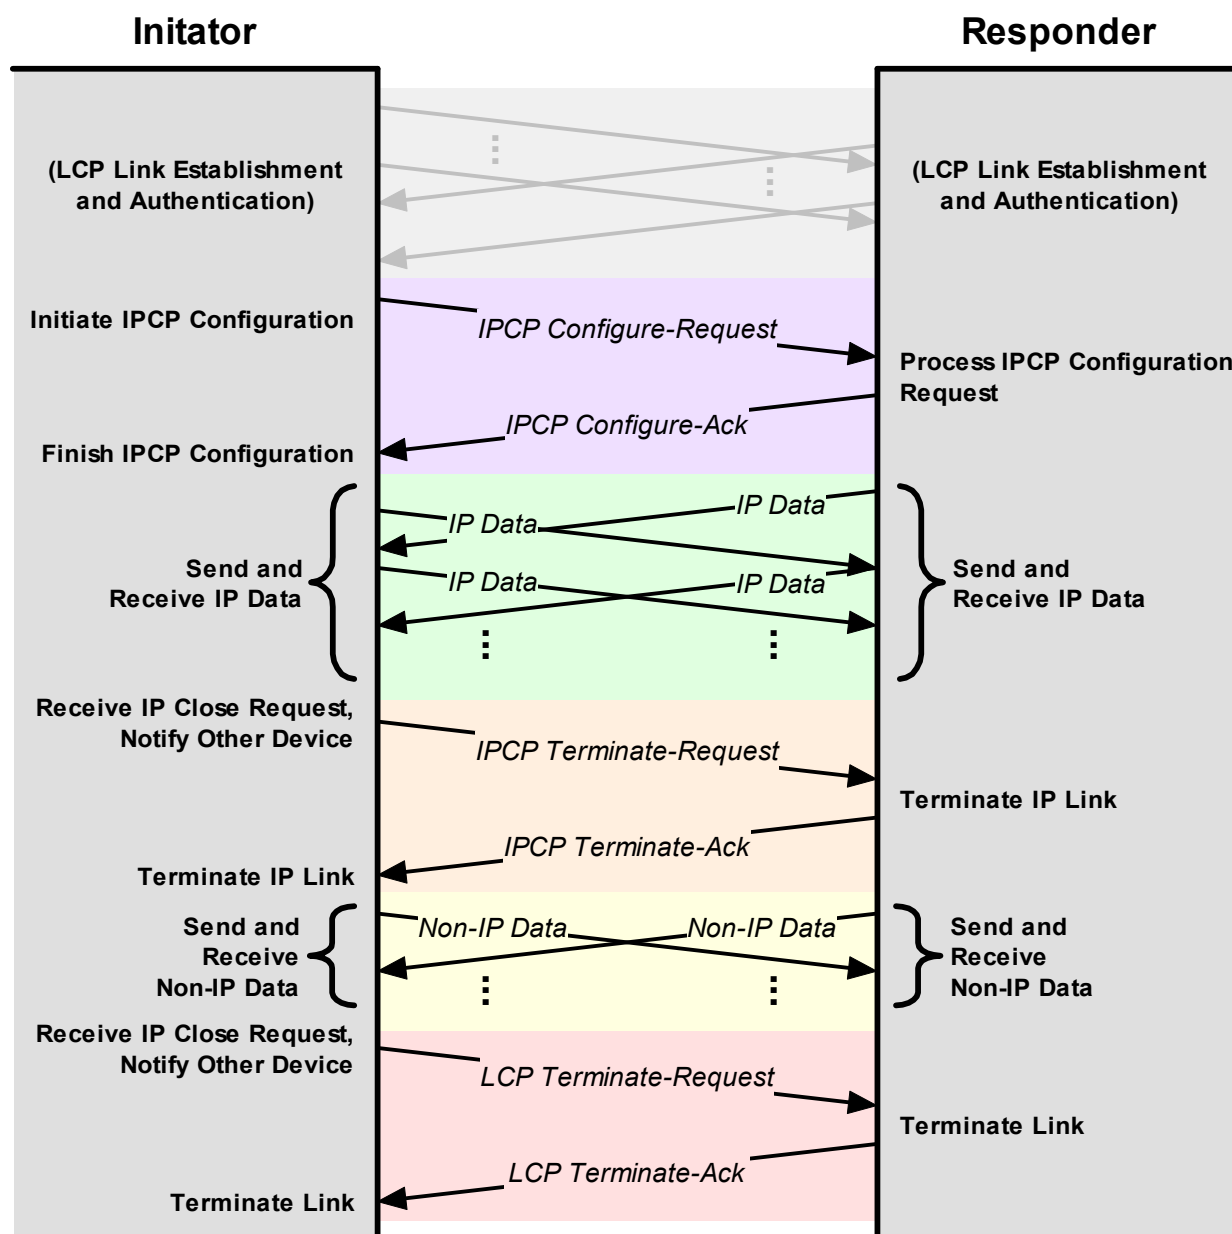

- ☉ **IP-Compression-Protocol:** Allows devices to negotiate the use of something called “Van Jacobson TCP/IP header compression”. This compresses the size of TCP and IP headers to save bandwidth. Thus, this is similar in concept to the *Protocol-Field-Compression* and *Address-and-Control-Field-Compression (ACFC)* options in LCP.
- ☉ **IP-Address:** Allows the device sending the *Configure-Request* to either specify an IP address it wants to use for routing IP over the PPP link, or to request that the other device supply it with one. This is most commonly used for dial-up networking links.

Again, the receiving device can send back an IPCP *Configure-Ack*, an IPCP *Configure-Nak*, or an IPCP *Configure-Reject*, just as they work in LCP. The other NCPs are similar, but use different configuration options. After configuration is complete, data can be sent for the layer three protocol corresponding to the NCP negotiated. This is indicated by using the appropriate value for the *Protocol* field in PPP data frames containing that layer three data.

**Note:** As an aside, the full expanded name of the NCP for IP is “The Point-to-Point Protocol Internet Protocol Control Protocol”. Three “protocols” in one name. That has to be some sort of a record. ☺

---

**Figure 28: PPP IP Control Protocol (IPCP) Message Exchanges**

The overall operation of the NCPs, such as IPCP, is very similar to that of LCP. After LCP configuration (including authentication) is complete, *IPCP Configure-Request* and *Configure-Ack* messages are used to establish an IPCP link. IP Data can then be sent over the link. If the IPCP connection is no longer needed it may be terminated, after which the LCP link remains open for other types of data to be transmitted. It is not necessary, however, to explicitly terminate the IPCP link before terminating the LCP connection.

---

## **PPP Authentication Protocols: Password Authentication Protocol (PAP) and Challenge Handshake Authentication Protocol (CHAP)**

PPP was designed to provide layer two connectivity over a variety of serial links and other physical layer technologies, some of which have much more of a concern about security than others. For example, suppose you hook two machines in your computer lab together with a serial cable and want to run PPP between them. When one of these initiates a PPP link with the other, you don't really need to worry about "who's calling". On the other hand, consider an Internet Service Provider using PPP for remote dial-in users. They generally want to allow only their customers to connect, not just anyone.

The PPP protocol suite was designed to include the use of an optional authentication protocol for links where authentication is important. During basic link setup by LCP, devices can negotiate the use of an authentication protocol. If they agree, after the LCP link is set up a series of authentication messages are sent to verify the identity of the device initiating the link. Only if authentication is successful can the link configuration proceed.

The PPP suite initially defined two different authentication protocols: the *Password Authentication Protocol (PAP)* and *Challenge Handshake Authentication Protocol (CHAP)*.

**Note:** Incidentally, in addition to PAP and CHAP, it is possible to use proprietary authentication schemes. This requires that the appropriate configuration option values be programmed into LCP for placement in the *Authentication-Protocol* configuration option.

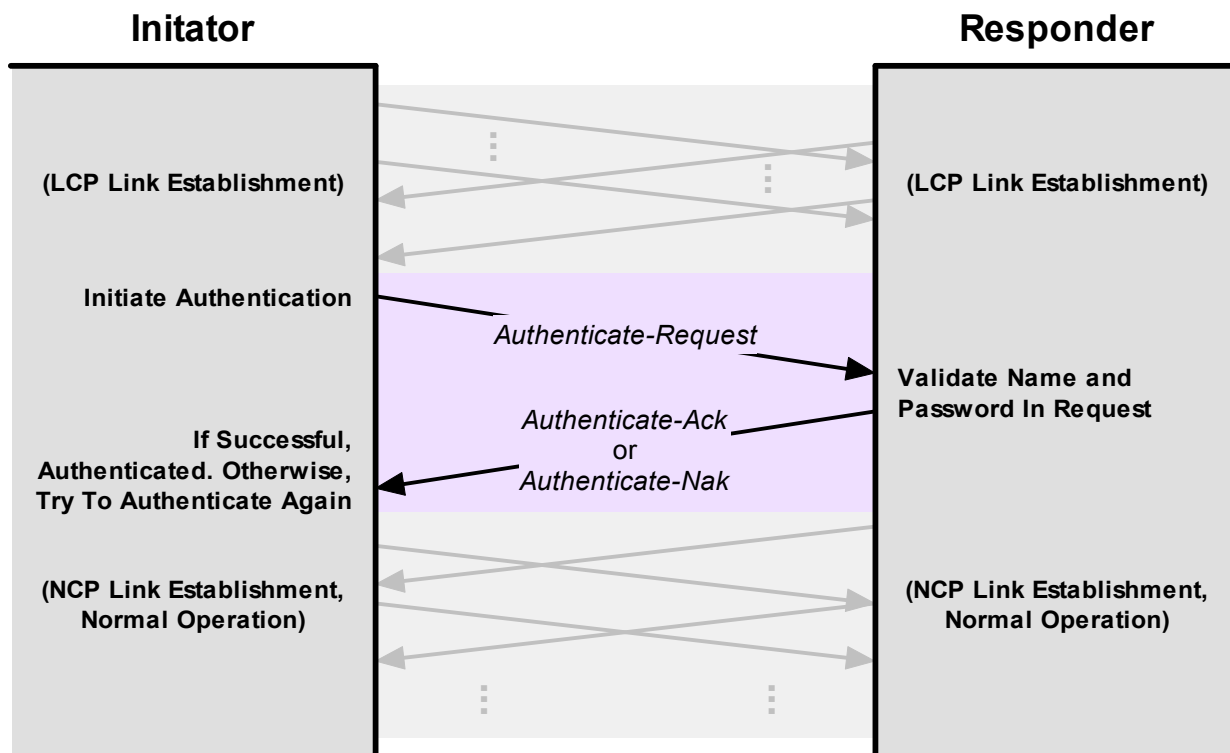

---

### ***Password Authentication Protocol (PAP).***

PAP is a very straight-forward authentication scheme, consisting of only two basic steps, as shown in [Figure 29](#):

1. **Authentication Request:** The initiating device sends an *Authenticate-Request* message that contains a name and a password.
2. **Authentication Reply:** The responding device looks at the name and password and decides whether to accept the initiating device and continue in setting up the link. If so, it sends back an *Authenticate-Ack*. Otherwise, it sends an *Authenticate-Nak*.

Simple. Now, [remember what Einstein said about simplicity](#)? PAP is another example of something that is just too simple for its own good. Chief amongst its flaws is that it transmits the user name and password in clear text across the link. This is a big "no-no" in security protocols, as it means any eavesdropper can get the password and use it in the future. PAP also provides no protection against various security attacks. For example, an unauthorized user could simply try different passwords indefinitely and hope he or she eventually found one that worked. PAP also puts control of the authentication squarely on the shoulders of the initiating device (usually a client machine) which is not considered desirable.

**Figure 29: PPP Password Authentication Protocol (PAP) Authentication**

PAP works using a simple exchange of a request containing name and password information, and a reply indicating whether or not authentication was successful.

### **Challenge Handshake Authentication Protocol (CHAP)**

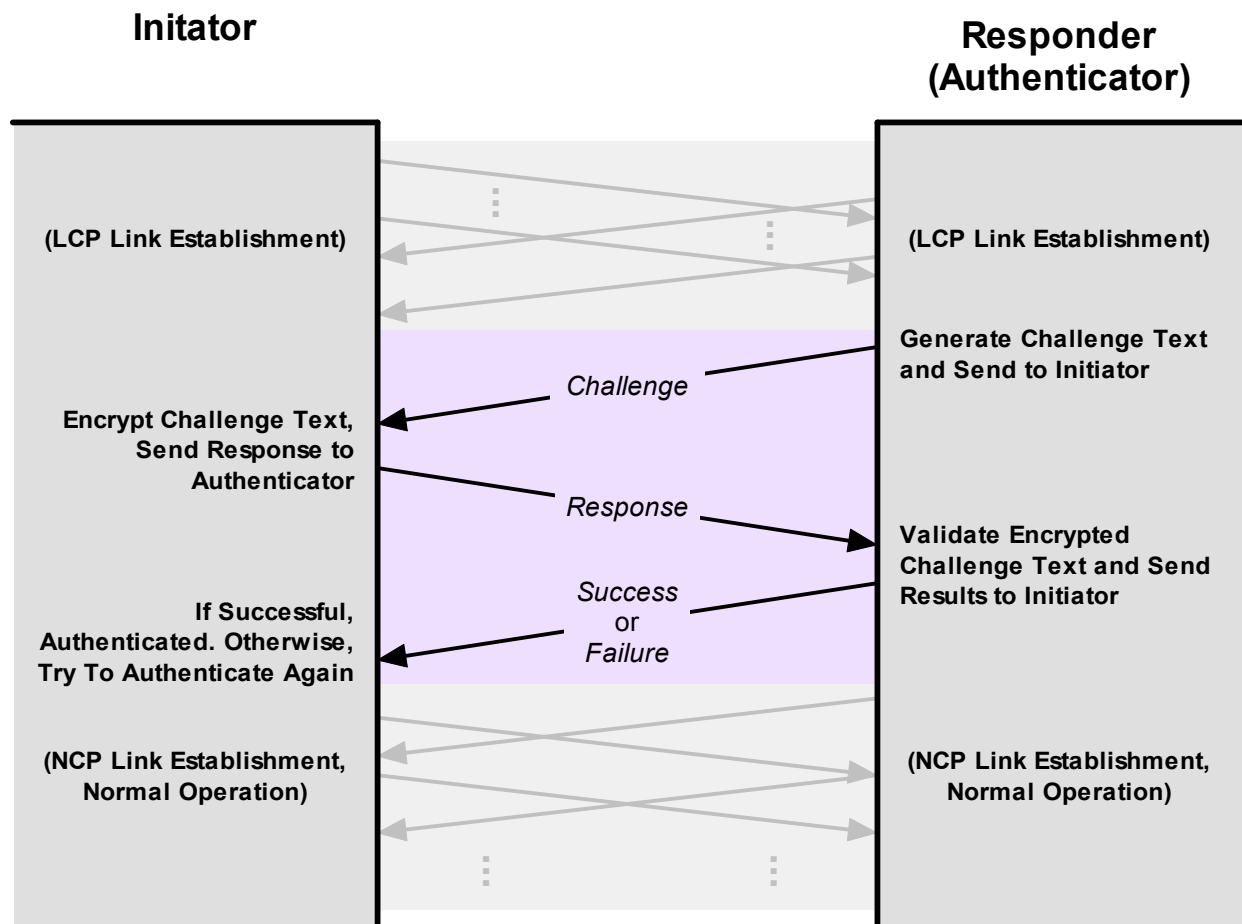

The most important difference between PAP and CHAP is that CHAP doesn't transmit the password across the link. Now you may be wondering—if that's the case, how is the password verified? Well, think of it this way. PAP works by the initiator telling the authenticator “here's the password I know, see if it matches yours”. CHAP does this by having each of the devices use the password to perform a cryptographic computation and then check if they each get the same result. If they do, they know they have the same password.

#### **CHAP Authentication Procedure**

In CHAP, a basic LCP link is set up between the initiator (calling client) and authenticator (generally the server that is deciding whether to grant authentication). The authenticator then takes charge of the authentication process, using a technique called a *three-way handshake*. This is a fairly common general authentication procedure; the same basic technique is used, for example, in IEEE 802.11 Shared Key Authentication.

The three-way handshake steps are as follows (and as illustrated in [Figure 30](#)):

1. **Challenge:** The authenticator generates a frame called a *Challenge* and sends it to the initiator. This frame contains a simple text message (sometimes called the *challenge text*). The message has no inherent special meaning so it doesn't matter if anyone intercepts it. The important thing is that after receipt of the *Challenge* both devices have the same challenge message.
2. **Response:** The initiator uses its password (or some other shared “secret” that the authenticators also knows) to encrypt the challenge text. It then sends the encrypted challenge text as a *Response* back to the authenticator.
3. **Success or Failure:** The authenticator performs the same encryption on the challenge text that the initiator did. If the authenticator gets the same result that the initiator sent it in the *Response*, the authenticator knows that the initiator had the right password when it did its encryption, so the authenticator sends back a *Success* message. Otherwise, it sends a *Failure* message.

**Figure 30: PPP Challenge Handshake Authentication Protocol (CHAP) Authentication**

CHAP uses a three-way handshake beginning with a *Challenge* from the authenticating device (usually the remote server accessed by a host). This message is encrypted and returned to the authenticating device, which checks to see if the device trying to authenticate used the correct password (or other “shared secret”).

---

## Benefits of CHAP

You can see the beauty of this: it verifies that the two devices have the same “shared secret” but doesn't require that the secret be sent over the link. The *Response* is calculated based on the password, but the content of the *Response* is encrypted and thus, much harder to derive the password from. CHAP also provides protection against replay attacks, where an unauthorized user captures a message and tries to send it again later on. This is done by changing an identifier in each message and varying the challenge text. Also, in CHAP the server controls the authentication process, not the client that is initiating the link.

**Key Concept:** PPP supports two authentication protocols: *PAP* and *CHAP*. *PAP* is a simple request/reply authentication protocol that is widely considered to be inadequate since it sends the user name and password in clear text and provides little protection against many security concerns. *CHAP* uses a three-way handshake procedure and is preferred over *PAP* in most implementations.

---

CHAP itself is not perfect, but it's a heck of a lot closer to perfection than *PAP* is. In fact, the IETF made a rather strong statement in this regard when it revised the original RFC describing *PAP* and *CHAP*, and [included only CHAP in the new standard](#). Despite this, *PAP* is still used in some applications, because it is simple. And well, some folks think they are smarter than Einstein. ☺ Seriously though, *PAP* can be fine in situations where security is not a big deal, but *CHAP* is much better and still not really that complicated.

---

## **PPP Feature Protocols**

PPP is the standard for data link layer connectivity over serial links because its core protocols provide a solid operational foundation, as we saw in [the previous section](#). However, PPP's popularity is based not just on its highly capable link establishment and management features. It also has a number of very useful features that provide important security and performance benefits to network users.

In this section I describe the protocols that implement several of the most common "extra" features in PPP. I begin with a discussion of PPP link quality monitoring. I describe the sets of protocols used to configure and implement data compression and data encryption. I then discuss the PPP Multilink Protocol (MP, MLPPP), which allows PPP to bundle multiple low-speed links into a single high-speed link. I also cover the BAP and BACP protocols, which are used to manage the operation of Multilink PPP.

### **PPP Link Quality Monitoring/Reporting (LQM/LQR)**

PPP includes optional authentication in recognition of the varying **security** needs of the many different kinds of links over which PPP may operate. These links also differ greatly in terms of their **quality**. Just as we don't need to worry about authentication much when two machines are linked with a short cable, we also can feel pretty confident that data sent between them is going to arrive intact. Now, contrast that to a PPP session established over a long-distance telephone call. For that matter, how about PPP over a dial-up call using an analog cellular phone?

PPP includes in its basic package a provision for detecting errors in sent frames (a CRC field), and higher-layer protocols like TCP also include methods of providing robustness on noisy lines. These techniques allow a link to **tolerate** problems, but provide little in the way of useful information about what the status of the link is. In some situations, devices may want to be able to keep track of how well the link is working, and perhaps take action on it. For example, a device experiencing too many errors on a dial-up connection might want to cut off and retry a new call. In some cases a device might want to try an alternate method of attachment if the current physical link is not working well.

Recognizing this need, the PPP suite includes a feature that allows devices to analyze the quality of the link between them. This is called *PPP Link Quality Monitoring* or *LQM*. PPP is set up generically to allow any number of different monitoring functions to be used, but at present there is only one, called *Link Quality Reporting (LQR)*. LQR works by having a device request that its peer (the other device on the link) keep track of statistics about the link and send them in reports on a regular basis.

#### ***LQR Setup***

Before LQR can be used it must be set up, which is done by LCP as part of the negotiation of basic link parameters in the *Link Establishment* phase. The device opening the link requests link monitoring by including the *Quality-Protocol* configuration option in its

---

*Configure-Request* frame. Again, LQR is the only quality protocol presently defined. The configuration option also specifies a *reporting period* that indicates the longest period of time the requesting device wants to go between receiving reports.

### **LQR Counters**

Assuming that the negotiation is successful, LQR will be enabled. A number of counters are set up that keep track of various link statistics, and a timer used to regulate the sending of quality reports over the link. Each time the timer expires a special link quality report is generated and sent in a PPP frame over the link. These are sent using the special PPP *Protocol* field [hexadecimal value 0xC025](#).

Each counter holds information about a different statistic regarding the use of the link. Each of these counters is reset to zero when LQR is set up and then incremented each time a transmission is made or an event occurs that is relevant to the counter. The statistics tracked include the following:

- ☉ The number of frames sent/received.
- ☉ The number of octets (bytes) in all frames sent/received.
- ☉ The number of errors that have occurred.
- ☉ The number of frames that had to be discarded.
- ☉ The number of link quality reports generated.

These counters are only reset at the start of the link, so they contain figures kept cumulatively over the life of the connection. The counters can be used in the absolute sense, meaning that the counter value itself is reported. Alternately, they can be expressed as relative (or delta) values, which represent the change since the last report. This is done when a report is received simply by subtracting the previous report's numbers from those in the current report.

### **Using Link Quality Reports**

LQR specifies the quality reporting mechanism, but not specific standards for link quality, since these are so implementation-dependent. Based on the numbers in these reports, a device can decide for itself what conclusions to draw about link quality, and in turn what action to take, if any. For example:

- ☉ Some devices might decide to shut down a link if the absolute number of errors seen in any report reaches a certain threshold.
- ☉ Some might look at the trend in successive reporting periods and take action if they detect certain trends, such as an increase in the rate of discarded frames.
- ☉ Some devices might just log the information and take no action at all.

Note that LQR aggregates its statistics for all higher-layer protocols transmitted over a particular link. It doesn't keep track of statistics for different higher-layer protocols separately (which makes sense, since the quality of the link shouldn't vary from one higher layer protocol to the next).

---

## **PPP Compression Control Protocol (CCP) and Compression Algorithms**

PPP is, of course, primarily used to provide data link layer connectivity to physical serial links. One of the biggest problems with serial links compared to many other types of layer one connections is that they are relatively slow. Consider that while 10 Mbps regular Ethernet is considered sluggish by modern LAN standards, it is actually much faster than most serial lines used for WAN connectivity, which can be 10, 100 or even 1000 times slower.

One way to improve performance over serial links is to use compression on the data sent over the line. Depending on the data transferred, this can double the performance compared to uncompressed transmissions, and can in some cases do even better than that. For this reason, many hardware devices include the ability to compress the data stream at the physical layer. The best example of this is probably the set of compression protocols used on analog modems.

Some physical links don't provide any compression capabilities, but could still benefit from it. To this end, an optional compression feature was created for PPP. It is implemented using two distinct protocol components:

- 🕒 **PPP Compression Control Protocol (CCP):** This protocol is responsible for negotiating and managing the use of compression on a PPP link.
- 🕒 **PPP Compression Algorithms:** A set of compression algorithms that perform the actual compression and decompression of data. Several of these are defined in Internet standards ([RFCs](#)). In addition, it is possible for two devices to negotiate the use of a proprietary compression method if they want to use one not defined by a public standard.

**Key Concept:** PPP includes an optional compression feature, which can improve performance over slow physical links. A variety of different compression algorithms are supported. To enable compression, both devices on a PPP link use the *PPP Compression Control Protocol (CCP)* to negotiate a compression algorithm to use. The compression algorithm is then used to compress and decompress PPP data frames.

---

### ***CCP Operation: Compression Setup***

When most people talk about compression in PPP they mention CCP, which is considered “the” compression protocol for PPP. However, CCP is actually used only to configure and control the use of compression; it is the algorithms that do the real work of compressing and decompressing. This “separation of powers” provides flexibility, since it allows each implementation to choose what type of compression they wish to use.

CCP is analogous to the [Network Control Protocols \(NCPs\)](#) that negotiate parameters specific to a network layer protocol sent on the link. An NCP lets two devices decide how they will carry layer three traffic, such as how IPCP lets the devices determine how to carry IP. CCP lets two devices decide how they will compress data, in the same basic way.

---

Similarly, just as each NCP is like a “lite” version of [LCP](#), CCP is also like a “lite” version of LCP. It is used to set up a compression connection called a *CCP link* within an LCP link between two devices. Once established, compressed frames can be sent between the two devices. CCP also provides messaging capabilities for managing and eventually terminating a CCP link, again very similar to how each network layer protocol sets up a NCP link within LCP. A CCP link is maintained independently of any NCP links.

CCP uses the same subset of seven LCP message types that the NCPs use, and adds two additional ones. The use of these messages for each of the “life stages” of a CCP link is as follows, which should look very familiar if you've already read about how the NCPs and LCP itself work:

- ☉ **Link Configuration:** Like the NCPs, compression configuration is done once CCP reaches the *Network-Layer Protocol* phase. The process of setting up compression and negotiating parameters is accomplished using *Configure-Request*, *Configure-Ack*, *Configure-Nak* and *Configure-Reject* messages [just as described in the LCP topic](#), except the configuration options are particular to CCP.
- ☉ **Link Maintenance:** *Code-Reject* messages can be sent to indicate invalid code values in CCP frames. The two new message types are *Reset-Request* and *Reset-Ack*, which are used to reset the compression (the CCP link) in the event of a detected failure in decompression.
- ☉ **Link Termination:** A CCP link can be terminated using *Terminate-Request* and *Terminate-Ack*. Again, remember that like the NCP links, the CCP link is set up within an LCP link, and closing it doesn't terminate the LCP link which controls PPP overall.

### **CCP Configuration Options and Compression Algorithms**

CCP configuration options are used for only one purpose: to negotiate the type of compression to be used by the two devices, and the specifics of how that algorithm is to be employed. The device initiating the negotiation sends a *Configure-Request* with one option for each of the compression algorithms it supports. The other device compares this list of options to the algorithms it understands. It also checks for any specific details relevant to the option to see if it agrees on how that algorithm should be used. It then sends back the appropriate reply (*Ack*, *Nak* or *Reject*) and a negotiation ensues until the two devices come up with a common algorithm both understand. If so, compression is turned on; otherwise, it is not enabled.

The CCP configuration options begin with a *Type* value that indicates the compression algorithm. When the *Type* value is 0, this indicates that the option contains information about a special, proprietary compression algorithm not covered by any RFC standards, which can be used if both devices understand it. Several values from 1 to 254 indicate

---

compression algorithms that have been defined for use with CCP. [Table 31](#) shows the most common values of the *Type* field, including the compression algorithm each corresponds to and the number of the RFC that defines it:

**Table 31: PPP Compression Control Protocol (CCP) Compression Algorithms**

CCP Option Type Value	Defining RFC	Compression Algorithm (As Given in RFC Title)
0	—	Proprietary
1 and 2	1978	<u><i>PPP Predictor Compression Protocol</i></u>
17	1974	<u><i>PPP Stac LZS Compression Protocol</i></u>
18	2118	<u><i>Microsoft Point-To-Point Compression (MPPC) Protocol</i></u>
19	1993	<u><i>PPP Gandalf FZA Compression Protocol</i></u>
21	1977	<u><i>PPP BSD Compression Protocol</i></u>
23	1967	<u><i>PPP LZS-DCP Compression Protocol (LZS-DCP)</i></u>
26	1979	<u><i>PPP Deflate Protocol</i></u>

### ***Compression Algorithm Operation: Compressing and Decompressing Data***

Once an algorithm has been successfully negotiated, the compression algorithm is used to compress data before transmission, and to decompress it once received. To compress, the transmitting device takes the data that would normally be put in the *Information* field of an uncompressed PPP frame and runs it through the compression algorithm. To indicate that a frame has been compressed, the special value 0x00FD (hexadecimal) is placed in the PPP *Protocol* field. When compression is used with multiple links and the links are compressed independently, a different value is used: 0x00FB. Recall that in a regular uncompressed frame, the *Protocol* field indicates what layer three protocol the data comes from; since we still need to know this, the original *Protocol* value is actually prepended to the data before compression. When the data is decompressed, this value is used to restore the original *Protocol* field, so the receiving device knows what higher layer the data belongs to.

For example, if we use IPCP to encapsulate IP data in PPP, the uncompressed frame would have a value of 0x8021 (hex) in the *Protocol* field. This value (0x8021) would be placed at the start of the data to be compressed. The compressed data would be put in a PPP frame with a *Protocol* value of 0x00FD. The receiving device would see the value 0x00FD in the *Protocol* field, recognize the frame as compressed, decompress it and restore the original frame with 0x8021 as the *Protocol* value. The [PPP general frame format topic](#) covers this in more detail.

In theory, a compression algorithm can put more than one PPP data frame into a compressed PPP data frame. Despite this, many if not most of the algorithms maintain a one-to-one correspondence, putting each PPP data frame into one compressed frame. Note that LCP frames are not compressed, nor are the control frames used for other protocols. For example, a data frame carrying IP traffic would be compressed, but a control frame for IPCP (the Network Control Protocol for IP) would not be.

---

Compression can be combined with encryption; in this case compression is done before encryption.

**Note:** The compression performed by CCP has nothing to do with the header compression options that can be negotiated as part of LCP. That type of “compression” doesn’t involve compressing a data stream using a compression algorithm, but rather a simple way of saving space in headers when both ends of a link agree to do so.

---

## **PPP Encryption Control Protocol (ECP) and Encryption Algorithms**

The [PPP authentication protocols PAP and CHAP](#) can be used to ensure that only authorized devices can establish a PPP connection. Once that is done, PPP normally provides no other security to the data being transmitted. In particular, all data is normally sent “in the clear” (unencrypted), making it easy for someone who intercepts it to read. For important data that must be kept secure, encryption prior to transmission is a good idea. This can be done at higher layers using something like [IPSec](#), but PPP also provides an optional feature that allows data to be encrypted and decrypted at the data link layer itself.

**Note:** This topic is very similar in structure and content to the [preceding one that covers PPP compression](#), because the features are implemented in a very similar way. For the benefit of those who may not be reading in sequence I have provided a standalone description in this topic, without assuming you have read the prior topic on compression. This means this topic may seem almost like “deja vu” if you just read the topic on CCP.

---

PPP data encryption is implemented using two protocol components:

- 🕒 **PPP Encryption Control Protocol (ECP):** This protocol is responsible for negotiating and managing the use of encryption on a PPP link.
- 🕒 **PPP Encryption Algorithms:** A family of encryption algorithms that perform the actual encryption and decryption of data. Several of these are defined in Internet standards (RFCs), and two devices can also negotiate a proprietary encryption method if they want to use one not defined by a public standard.

ECP is usually the only part mentioned when encryption in PPP is discussed. ECP is in fact used only to configure and control the use of encryption; it is the algorithms that do the real work. This technique allows each implementation to choose what type of encryption they wish to use. The original ECP defined only a single encryption method, and a couple of others have since been added.

**Key Concept:** PPP includes an optional encryption feature, which provides privacy for data transported over PPP. A number of encryption algorithms are supported. To enable encryption, both devices on a PPP link use the *PPP Encryption Control Protocol (ECP)* to negotiate which algorithm to use. The selected algorithm is then used to encrypt and decrypt PPP data frames.

---

### ***ECP Operation: Compression Setup***

Like CCP, ECP is analogous to the [Network Control Protocols \(NCPs\)](#) that negotiate parameters specific to a network layer protocol sent on the link, but deals with how devices encrypt data rather than how they transport layer three traffic. This also means that like the NCPs, ECP is a "lite" version of LCP and works in the same basic way. Once an ECP link is negotiated, encrypted frames can be sent between devices. When no longer needed, the ECP link can be terminated.

ECP uses the same subset of seven LCP message types that the NCPs use, and adds two more. The use of these messages for each of the "life stages" of an ECP link is as follows:

- ☉ **Link Configuration:** Like the NCPs (and also like CCP of course), encryption configuration is done once ECP reaches the *Network-Layer Protocol* phase. The process of setting up encryption and negotiating parameters is accomplished using *Configure-Request*, *Configure-Ack*, *Configure-Nak* and *Configure-Reject* messages just [as described in the LCP topic](#), except the configuration options are particular to ECP.
- ☉ **Link Maintenance:** *Code-Reject* messages can be sent to indicate invalid code values in ECP frames. The two new message types are *Reset-Request* and *Reset-Ack*, which are used to reset the encryption (the ECP link) in the event of a detected failure in decryption.
- ☉ **Link Termination:** An ECP link can be terminated using *Terminate-Request* and *Terminate-Ack*. Again, remember that like the NCP links, the ECP link is set up within an LCP link, so closing it doesn't terminate the LCP link.

### ***ECP Configuration Options and Encryption Algorithms***

ECP configuration options are used only to negotiate the type of encryption algorithm to be used by the two devices, and the specifics of how that algorithm is to be employed. The device initiating the negotiation sends a *Configure-Request* with one option for each of the encryption algorithms it supports. The other device compares this list of options to the algorithms it understands. It also checks for any details relevant to the option to see if it agrees on how that algorithm should be used. It then sends back the appropriate reply (*Ack*, *Nak* or *Reject*) and a negotiation ensues until the two devices come up with a common algorithm both understands. If so, encryption is enabled, and otherwise, it is left turned off.

The ECP configuration options begin with a *Type* value that indicates the encryption algorithm. When the *Type* value is 0, this indicates that the option contains information about a special, proprietary encryption method not covered by any RFC standards, which can be used if both devices understand it. Values in the range from 1 to 254 indicate

---

encryption algorithms that have been defined for use with ECP; at present, only two are defined. [Table 32](#) shows the values of the *Type* field, including the encryption algorithm each corresponds to and the number of the RFC that defines it:

**Table 32: PPP Encryption Control Protocol (ECP) Encryption Algorithms**

ECP Option Type Value	Defining RFC	Encryption Algorithm (As Given in RFC Title)
0	—	Proprietary
2	2420	<u><i>The PPP Triple-DES Encryption Protocol (3DESE)</i></u>
3	2419	<u><i>The PPP DES Encryption Protocol, Version 2 (DESE-bis)</i></u>

**Note:** *Type* value 1 was for the original DES algorithm, defined in RFC 1969, which was superseded by DES version 2 in RFC 2419.

---

### ***Encryption Algorithm Operation: Encrypting and Decrypting Data***

After an encryption algorithm has been successfully negotiated, it is used to encrypt data before transmission, and to decrypt data received. To encrypt, the transmitting device takes the data that would normally be put in the *Information* field of an unencrypted PPP frame and runs it through the encryption algorithm. To indicate that a frame has been encrypted, the special value 0x0053 (hexadecimal) is placed in the PPP *Protocol* field. When encryption is used with multiple links and the links are encrypted independently, a different value is used: 0x0055. Recall that in a regular unencrypted frame, the *Protocol* field indicates what layer three protocol the data comes from; since we still need to know this, the original *Protocol* value is actually prepended to the data before encryption. When the data is decrypted, this value is used to restore the original *Protocol* field, so the receiving device knows what higher layer the data belongs to.

For example, if we use IPCP to encapsulate IP data in PPP, the unencrypted frame would have a value of 0x8021 (hex) in the *Protocol* field. This value (0x8021) would be placed at the start of the data to be encrypted. The encrypted data would be put in a PPP frame with a *Protocol* value of 0x0053. The receiving device would see the value 0x0053 in the *Protocol* field, recognize the frame as encrypted, decrypt it and restore the original frame with 0x8021 as the *Protocol* value. The [discussion of the PPP general frame format](#) covers this more completely.

Each encrypted PPP data frame carries exactly one PPP data frame. Note that unlike what we saw in compression, LCP frames and the control frames used for other protocols **can** be encrypted. Compression can be combined with encryption; in this case compression is done before encryption.

---

## PPP Multilink Protocol (MP/MLP/MLPPP)

Most of the time, there is only a single physical layer link between two devices. There are some situations, however, when there may actually be two layer one connections between the same pair of devices. This may seem strange; why would there be more than one link between any pair of machines?

There are in fact a number of situations in which this can occur. One common one is when two links are intentionally placed between a pair of devices. This is often done to increase performance by “widening the pipe” between two devices, without going to a newer, more expensive technology. For example, if two machines are connected to each other using a regular analog modem and it is too slow, a relatively simple solution is to just use two analog modem pairs connecting the machines to double bandwidth.

A slightly different situation occurs when multiplexing creates the equivalent of several physical layer “channels” between two devices even if they only have one hardware link between them. Consider ISDN for example. The most common form of ISDN service (ISDN basic rate interface or BRI) creates two 64,000 bps *B channels* between a pair of devices. These B channels are time division multiplexed and carried along with a D channel on a single pair of copper wire, but to the devices they appear **as if** there were two physical layer links between devices, each of which carries 64 kbps of data. And the ISDN primary rate interface (PRI) actually creates 23 or even more channels, all between the same pair of hardware devices.

In a situation where we have multiple links, we could of course just establish PPP over each connection independently. However, this is far from an ideal solution, because we would then have to manually distribute our traffic over the two (or more) channels or links that connect them. If you wanted to connect to the Internet, you'd have to make separate connections and then choose which to use for each action. Not exactly a recipe for fun, and what's worse is that you could never use all the bandwidth for a single purpose, such as downloading the latest 100 megabyte Microsoft security patch.

What we really want is a solution that will let us combine multiple links and use them as if they were one high-performance link. Some hardware devices actually allow this to be done at the hardware level itself; in ISDN this technology is sometimes called *bonding* when done at layer one. For those hardware units that don't provide this capability, PPP makes it available in the form of the *PPP Multilink Protocol (MP)*. This protocol was originally described in RFC 1717, and was updated in RFC 1990.

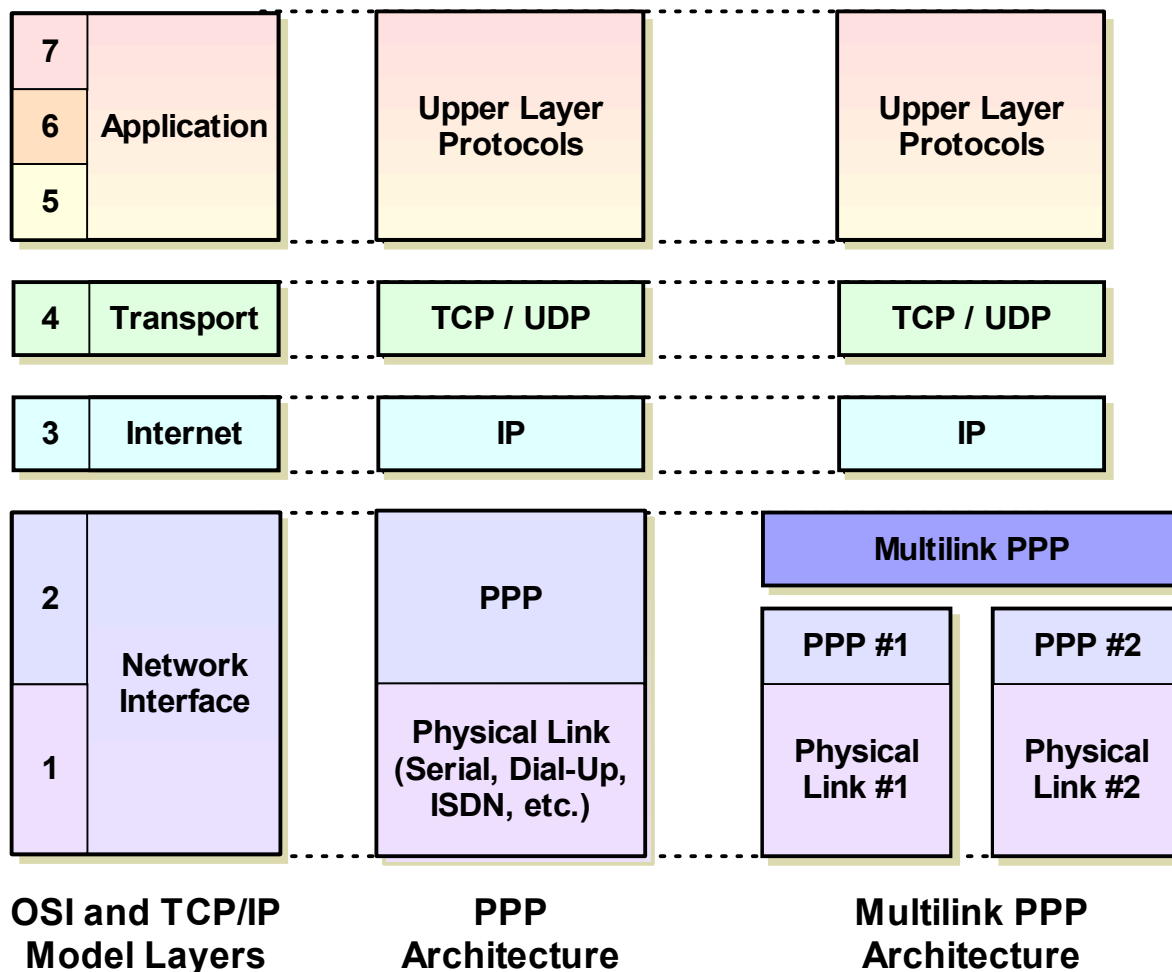

**Note:** The PPP Multilink Protocol is properly abbreviated “MP”, but it is common to see any of a multitude of other abbreviations used for it. Many of these are actually derived from changing the order of the words in the name into “Multilink PPP”, so you will frequently see this called “ML PPP”, “MLPPP”, “MPPP”, “MLP” and so forth. These are technically “incorrect” but widely used, especially “MLPPP”. I use the correct abbreviation in this Guide.

---

---

## PPP Multilink Protocol Architecture

MP is an optional feature of PPP, so it must be designed to integrate seamlessly into regular PPP operation. To accomplish this, MP is implemented as a new architectural “sublayer” within PPP. In essence, an MP sublayer is inserted between the “regular” PPP mechanism and any network layer protocols using PPP, as shown in [Figure 31](#). This allows MP to take all network layer data to be sent over the PPP link and spread it over multiple physical connections, without causing either the normal PPP mechanisms or the network layer protocol interfaces to PPP to “break”.

**Figure 31: Multilink PPP Architecture**

The column on the left shows the TCP/IP model architecture with corresponding [OSI Reference Model](#) layer numbers. The center column shows the normal PPP layer architecture. When Multilink PPP is used, there are separate PPP implementations running over each of two or more physical links. Multilink PPP sits, architecturally, between these links and any network layer protocols to be transported over those links. (In this diagram only IP is shown, since it is most common, but Multilink PPP can in fact work with multiple network layer protocols, each being sent over each physical link.)

**Key Concept:** The *PPP Multilink Protocol (MP)* allows PPP to bundle multiple physical links and use them like a single, high-capacity link. It must be enabled during link configuration. Once operational, it works by fragmenting whole PPP frames and sending the fragments over different physical links.

---

### ***PPP Multilink Protocol Setup and Configuration***

To use MP, both devices must have it implemented as part of their PPP software and must negotiate its use. This is done by LCP as part of the negotiation of basic link parameters in the *Link Establishment* phase (just like [Link Quality Reporting](#)). Three new configuration options are defined to be negotiated to enable MP:

- ☉ ***Multilink Maximum Received Reconstructed Unit:*** Provides the basic indication that the device starting the negotiation supports MP and wants to use it. The option contains a value specifying the maximum size of PPP frame it supports. If the device receiving this option does not support MP it must respond with a *Configure-Reject LCP* message.
- ☉ ***Multilink Short Sequence Number Header Format:*** Allows devices to negotiate use of a shorter sequence number field for MP frames, for efficiency. (See the [topic on MP frames](#) for more.)
- ☉ ***Endpoint Discriminator:*** Uniquely identifies the system; used to allow devices to determine which links go to which other devices.

Before MP can be used, a successful negotiation of at least the *Multilink Maximum Received Reconstructed Unit* option must be performed on each of the links between the two devices. Once this is done and an LCP link exists for each of the physical links, a virtual *bundle* is made of the LCP links and MP is enabled.

### ***PPP Multilink Protocol Operation***

As mentioned above, MP basically sits between the network layer and the regular PPP links and acts as a “middleman”. Here is what it does for each “direction” of communication:

- ☉ ***Transmission:*** MP accepts datagrams received from any of the network layer protocols configured using appropriate NCPs. It first encapsulates them into a modified version of the regular PPP frame. It then takes that frame and decides how to transmit it over the multiple physical links. Typically, this is done by dividing the frame into *fragments* that are evenly spread out over the set of links. These are then encapsulated and sent over the physical links. However, an alternate strategy can also be implemented as well, such as alternating full-sized frames between the links. Also, smaller frames are typically not fragmented, nor are control frames such as those used for link configuration.
- ☉ ***Reception:*** MP takes the fragments received from all physical links and reassembles them into the original PPP frame. That frame is then processed like any PPP frame, by looking at its *Protocol* field and passing it to the appropriate network layer protocol.

---

The fragments used in MP are similar in concept to IP fragments, but of course these are different protocols running at different layers. To PPP or MP, an IP fragment is just an IP datagram like any other.

The fragmenting of data in MP introduces a number of complexities that the protocol must handle. For example, since fragments are being sent roughly concurrently, we need to identify them with a sequence number to facilitate reassembly. We also need some control information to identify the first and last fragments. A [special frame format is used for MP fragments](#) to carry this extra information, which I describe in the [section on PPP frame formats](#). That topic also contains more information about how fragmenting is accomplished, as well as an illustration that demonstrates how it works.

**Related Information:** I also recommend reading the next topic, which describes two protocols defined after MP to better control how it works: BAP and BACP.

---

## **PPP Bandwidth Allocation Protocol (BAP) and Bandwidth Allocation Control Protocol (BACP)**

The [PPP Multilink Protocol \(MP\)](#) described in the previous topic allows multiple links between a pair of devices, whether physical or in the form of virtual channels, to be combined into a “fat pipe” (high-capacity channel). This offers tremendous advantages to many PPP users, as it lets them make optimal use of all their bandwidth, especially for applications such as Internet connectivity. It's no surprise, then, that MP has become one of the most popular features of PPP.

The original standard defining MP basically assumed that multiple links would be combined into a single bundle. For example, if you had two modem links they would both be connected and then combined, or two B channels in an ISDN link would be combined. After MP was set up the bundle would be available for either device to use in its entirety.

There's one drawback to this system: the “fat pipe” is always enabled, and in many cases, it is expensive to have this set up all the time. It often costs more to connect two or more layer one links than a single one, and it's not always needed. For example, some ISDN services charge per minute for calls on either of the B channels. In the case of modem dialup there are per-minute charges in some parts of the world. Even where regular phone calls are “free”, there is a cost in the form of tying up a phone line. Consider that in many applications, the amount of bandwidth needed varies over time.

It would be better if we could set up MP so that it could dynamically add links to the bundle when needed, such as when we decided to download some large files, and then automatically drop them when no longer required. This enhancement to the basic MP package was provided in the form of a pair of new protocols described in RFC 2125:

- 
- ☉ **Bandwidth Allocation Protocol (BAP):** Describes a mechanism where either device communicating over an MP bundle of layer one links may request that a link be added to the bundle or removed from it.
  - ☉ **Bandwidth Allocation Control Protocol (BACP):** Allows devices to configure how they want to use BAP.

**Key Concept:** *BAP* and *BACP* are used to provide dynamic control over how the PPP Multilink Protocol functions.

---

### ***BACP Operation: Configuring the Use of BAP***

Let's start with BACP, since it is the protocol used for initial setup of the feature. BACP is very similar in general concept to all those other PPP protocols with "Control" in their names, such as *LCP*, the *NCP family*, *CCP* and *ECP*, but is actually even simpler. It is used only during link configuration to set up BAP. This is done using *Configure-Request*, *Configure-Ack*, *Configure-Nak* and *Configure-Reject* messages just as described in the *LCP* topic. The only configuration option that is negotiated in BACP is one called *Favored-Peer*, which is used to ensure that the two devices on the link don't get "stuck" if each tries to send the same request at the same time.

If both devices support BAP then the BACP negotiation will succeed and BAP will be activated.

### ***BAP Operation: Adding and Removing Links***

BAP defines a special set of messages that can be sent between devices to add or drop links to/from the current PPP bundle. What's particularly interesting about BAP is that it includes the tools necessary to have a device actually initiate different types of physical layer connections (such as dialing a modem for bundled analog links or enabling an extra ISDN channel) when more bandwidth is required, and then shut them down when no longer needed.

A brief description of the BAP message types:

- ☉ ***Call-Request and Call-Response:*** When one device on the link wants to add a link to the bundle and initiate the new physical layer link itself, it sends a *Call-Request* frame to tell the other device, which replies with a *Call-Response*.
- ☉ ***Callback-Request and Callback-Response:*** These are just like the two message types above, but used when a device wants its peer (the other device on the link) to initiate the call to add a new link. So, if device A says "I need more bandwidth but I want you to call me, instead of me calling you", it sends device B a *Callback-Request*.
- ☉ ***Call-Status-Indication and Call-Status-Response:*** After a device attempts to add a new link to the bundle (after sending a *Call-Request* or receiving a *Callback-Request*) it reports the status of the new link using the *Call-Status-Indication* frame. The other device then replies with a *Call-Status-Response*.

- 
- ☉ ***Link-Drop-Query-Request* and *Link-Drop-Query-Response*:** These messages are used by one device to request that a link be dropped and the other to respond to that request.

I should also point out that the decision of when to add or remove links is not made by these protocols. It is left up to the particular implementation.

---

## PPP Protocol Frame Formats

The PPP protocol suite includes a number of different protocols used to send both data and control information in different ways. Each of these packages information into messages called *frames*, each of which follows a particular *frame format*. PPP starts with a general frame format that encompasses all frames sent on the link, and then includes more specific formats for different purposes. Understanding these formats not only makes diagnosing PPP issues easier, it also helps make more clear how the key PPP protocols function.

In this section I illustrate the most common frame formats used for sending both data and control information over PPP. I begin with an explanation of the overall format used for all PPP frames. I also describe the general format used for the various control protocols and the option format that most of them use. (One of the nice things about PPP is that so many of the protocols use control frames with a common format.)

I then specifically list the frames used for the Link Control Protocol (LCP) and the authentication protocols (PAP and CHAP). I also describe the special format used by the PPP Multilink Protocol (MP) to transport fragments of data over bundled links.

**Note:** Due to the sheer number of different protocols in PPP (dozens) and the fact that many have their own unique options, I cannot describe all the specific frame formats and option formats for every protocol in detail here. Please refer to the appropriate RFCs (shown in the topic on PPP standards) if you need more detail than provided in this section.

---

### PPP General Frame Format

All messages sent using PPP can be considered either *data* or *control information*. The word “data” describes the higher-layer datagrams we are trying to transport here at layer two; this is what our “customers” are giving us to send. Control information is used to manage the operation of the various protocols within PPP itself. Even though different protocols in the PPP suite use many types of frames, at the highest level they all fit into a single, *general frame format*.

In the overview of PPP I mentioned that the basic operation of the suite is based on the ISO High-Level Data Link Control (HDLC) protocol. This becomes very apparent when we look at the structure of PPP frames overall—they use the same basic format as HDLC, even to the point of including certain fields that aren't strictly necessary for PPP itself. The only major change is the addition of a new field to specify the protocol of the encapsulated data. The general structure of PPP frames is defined in RFC 1662, a “companion” to the main PPP standard RFC 1661.

The general frame format for PPP, showing how the HDLC framing is applied to PPP, is described in [Table 33](#) and illustrated in [Figure 32](#).

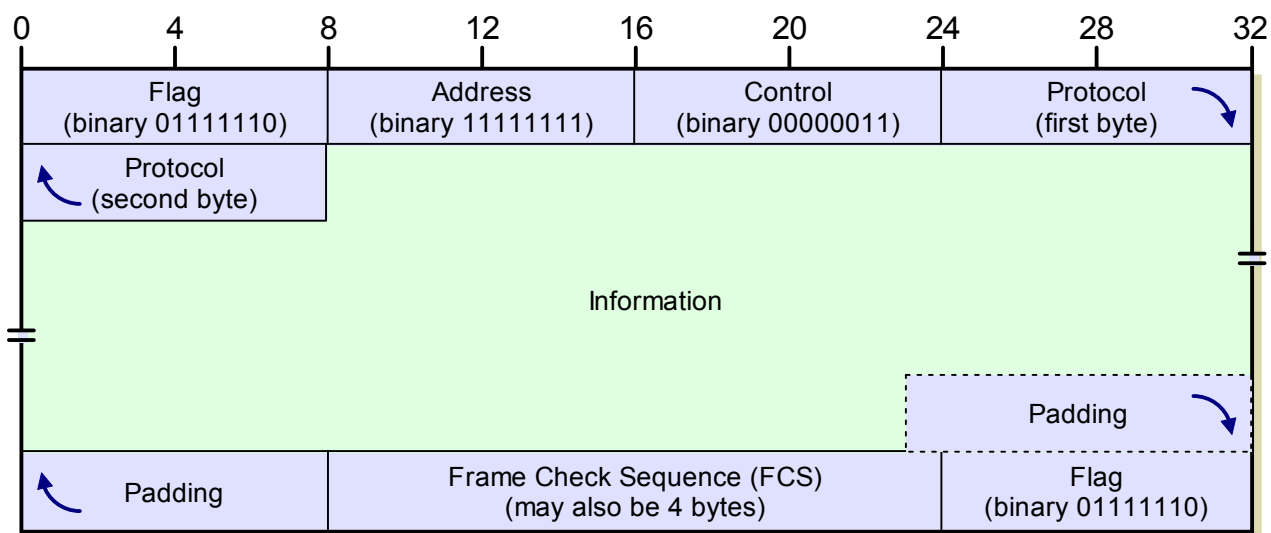

**Table 33: PPP General Frame Format**

Field Name	Size (bytes)	Description
<i>Flag</i>	1	<b>Flag:</b> Indicates the start of a PPP frame. Always has the value “01111110” binary (0x7E hexadecimal, or 126 decimal).
<i>Address</i>	1	<b>Address:</b> In HDLC this is the address of the destination of the frame. But in PPP we are dealing with a direct link between two devices, so this field has no real meaning. It is thus always set to “11111111” (0xFF or 255 decimal), which is equivalent to a broadcast (it means “all stations”).
<i>Control</i>	1	<b>Control:</b> This field is used in HDLC for various control purposes, but in PPP it is set to “00000011” (3 decimal).
<i>Protocol</i>	2	<b>Protocol:</b> Identifies the protocol of the datagram encapsulated in the Information field of the frame. See below for more information on the <i>Protocol</i> field.
<i>Information</i>	Variable	<b>Information:</b> Zero or more bytes of payload that contains either data or control information, depending on the frame type. For regular PPP data frames the network-layer datagram is encapsulated here. For control frames, the control information fields are placed here instead.
<i>Padding</i>	Variable	<b>Padding:</b> In some cases, additional dummy bytes may be added to pad out the size of the PPP frame.
<i>FCS</i>	2 (or 4)	<b>Frame Check Sequence (FCS):</b> A checksum computed over the frame to provide basic protection against errors in transmission. This is a CRC code similar to the one used for other layer two protocol error protection schemes such as the one used in Ethernet. It can be either 16 bits or 32 bits in size (default is 16 bits).  The FCS is calculated over the <i>Address</i> , <i>Control</i> , <i>Protocol</i> , <i>Information</i> and <i>Padding</i> fields.
<i>Flag</i>	1	<b>Flag:</b> Indicates the end of a PPP frame. Always has the value “01111110” binary (0x7E hexadecimal, or 126 decimal).

[Figure 33](#) shows one common application of the PPP general frame format: carrying data. The value 0x0021 in the *Protocol* field marks this as an IPv4 datagram. This sample has one byte of *Padding* and a 2-byte *FCS* as well. (Obviously real IP datagrams are longer than the 23 bytes shown here! These bytes are arbitrary and don’t represent a real datagram.) See [Figure 43](#) for an illustration of how this same data frame is formatted and then fragmented for transmission over multiple links using the [PPP Multilink Protocol](#).

### **Protocol Field Ranges**

The *Protocol* field is the main “frame type” indicator for the device receiving the frame. For data frames this is normally the network-layer protocol that created the datagram, and for control frames, the PPP protocol that created the control message. In the case of protocols

**Figure 32: PPP General Frame Format**

All PPP frames are built upon the general format shown above. The first three bytes are fixed in value, followed by a two-byte *Protocol* field that indicates the frame type. The variable-length *Information* field is formatted in a variety of ways, depending on the PPP frame type. *Padding* may be applied to the frame, which concludes with an *FCS* field of either 2 or 4 bytes (2 bytes shown here) and a trailing Flag value of 0x7E. See [Figure 33](#) for an example of how this format is applied.

0	4	8	12	16	20	24	28	32
Flag = 7E	Address = FF	Control = 03	Protocol (byte 1) = 00					
Protocol (byte 2) = 21	2A	00	1D					
47	9F	BC	19					
88	18	E5	01					
73	A3	69	AF					
1B	90	54	BA					
00	7C	D1	AA					
Padding = 00	Frame Check Sequence = ????		Flag = 7E					

**Figure 33: Sample PPP Data Frame**

This sample PPP data frame has a value of 0x0021 in the *Protocol* field, indicating it is an IP datagram (though the actual data is made up and not a real IP message.)

---

that modify data such as when [compression \(CCP\)](#) or [encryption \(ECP\)](#) are used, this field identifies the data as being either compressed or encrypted, and the original *Protocol* value is extracted after the *Information* field is decompressed/decrypted.

There are dozens of network-layer protocols and PPP control protocols, and a correspondingly large number of *Protocol* values. The main PPP standard defines four ranges for organizing these values, as shown in [Table 34](#).

**Table 34: PPP *Protocol* Field Ranges**

Protocol Field Range (hexadecimal)	Description
0000 - 3FFF	Encapsulated network layer datagrams that have an associated <a href="#">Network Control Protocol (NCP)</a> . In this case, control frames from the corresponding NCP use a <i>Protocol</i> field value that is computed by adding “8” to the first octet of the network layer <i>Protocol</i> value. For example, for IP the <i>Protocol</i> value is 0021, and control frames from the IP Control Protocol (IPCP) use <i>Protocol</i> value 8021.  This range also includes several values used for specially-processed encapsulated datagrams, such as when compression or encryption are employed.
4000 - 7FFF	Encapsulated datagrams from “low-volume” protocols. These are protocols that do not have an associated NCP.
8000 - BFFF	<a href="#">Network Control Protocol (NCP)</a> control frames that correspond to the network layer <i>Protocol</i> values in the 0000-3FFF range.
C000 - FFFF	Control frames used by <a href="#">LCP</a> and LCP support protocols such as <a href="#">PAP</a> and <a href="#">CHAP</a> . Some miscellaneous protocol values are included here as well.

The standard also specifies that the *Protocol* value must be assigned so that the first octet is even, and the second octet is odd. So, for example, 0x0021 is a valid value but 0x0121 and 0x0120 are not. (The reason for this will become apparent shortly). There are also certain blocks that are reserved and not used.

---

## Protocol Field Values

The full list of PPP *Protocol* values is maintained by the [Internet Assigned Numbers Authority \(IANA\)](#) along with all the other different reserved numbers for Internet standards. [Table 35](#) shows some of the more common values:

**Table 35: Common Protocols Carried In PPP Frames and *Protocol* Field Values (Page 1 of 2)**

Protocol Type	Protocol Field Value (hex)	Protocol
Encapsulated Network Layer Datagrams	0021	Internet Protocol version 4 (IPv4)
	0023	OSI Network Layer
	0029	Appletalk
	002B	Novell Internetworking Packet Exchange (IPX)
	003D	PPP Multilink Protocol (MP) Fragment
	003F	NetBIOS Frames (NBF/NetBEUI)
	004D	IBM Systems Network Architecture (SNA)
	0053	Encrypted Data (using ECP and a PPP encryption algorithm)
	0055	Individual-Link Encrypted Data under PPP Multilink
	0057	Internet Protocol version 6 (IPv6)
	00FB	Individual-Link Compressed Data under PPP Multilink
	00FD	Compressed Data (using CCP and a PPP compression algorithm)
Low-Volume Encapsulated Protocols	4003	CDPD Mobile Network Registration Protocol
	4025	Fibre Channel
Network Control Protocol (NCP) Control Frames	8021	PPP Internet Protocol Control Protocol
	8023	PPP OSI Network Layer Control Protocol
	8029	PPP Appletalk Control Protocol
	802B	PPP IPX Control Protocol
	803F	PPP NetBIOS Frames Control Protocol
	804D	PPP SNA Control Protocol
	8057	PPP IPv6 Control Protocol

**Table 35: Common Protocols Carried In PPP Frames and *Protocol* Field Values (Page 2 of 2)**

Protocol Type	Protocol Field Value (hex)	Protocol
LCP and Other Control Frames	C021	PPP Link Control Protocol (LCP)
	C023	PPP Password Authentication Protocol (PAP)
	C025	PPP Link Quality Report (LQR)
	C02B	PPP Bandwidth Allocation Control Protocol (BACP)
	C02D	PPP Bandwidth Allocation Protocol (BAP)
	C223	PPP Challenge Handshake Authentication Protocol (CHAP)

### ***PPP Field Compression***

PPP uses the HDLC basic framing structure, which includes two fields that are needed in HDLC but not in PPP due to how the latter operates: the *Address* and *Control* fields. Why bother sending two bytes that have the same value for every frame and aren't used for anything? Originally they were maintained for compatibility, but this reduces efficiency.

To avoid wasting two bytes in every frame, it is possible during initial link setup using LCP for the two devices on the link to negotiate a feature called *Address and Control Field Compression (ACFC)* using the LCP option by that same name. When enabled, this feature simply causes these two fields not to be sent for most PPP frames (but not LCP control frames.) In fact, the feature would be better named “Address and Control Field ***Suppression***” because the fields are just suppressed: compressed down to nothing.

Now, even when devices agree to use field compression, they must still be capable of receiving both “compressed” and “uncompressed” frames. They differentiate one from the other by looking at the first two bytes after the initial *Flag* field. If they contain the value 0xFF03, they must be the *Address* and *Control* fields; otherwise, those fields were suppressed. (The value 0xFF03 is not a valid *Protocol* field value, so there is no chance of ambiguity.)

Similarly, it is also possible for the two devices on the link to negotiate compression of the *Protocol* field, so it takes only one byte instead of two. This is done generally by dropping the first byte if it is zero, a process called *Protocol Field Compression (PFC)*. Recall that the first byte must be even and the second odd. Thus, a receiving device examines the evenness of the first byte of the *Protocol* field in each frame. If it is odd, this means that a leading byte of zeroes in the *Protocol* field has been suppressed, because the first byte of a full two-byte *Protocol* value must be even.

**Note:** This “field compression” (really suppression) has nothing to do with data compression using PPP's [Compression Control Protocol \(CCP\)](#) and [compression algorithms](#).

## **PPP General Control Protocol Frame Format and Option Format**

A general frame format is used for all of the many frame types defined in the PPP protocol suite. Within that format, the *Information* field carries either encapsulated layer-three user data, or encapsulated control messages. These control messages contain specific information that is used to configure, manage and discontinue PPP links, and to implement the various features that comprise PPP.

As we saw in previous sections, there are many different PPP control protocols, which usually can be distinguished by the word “Control” appearing their names. These include the main PPP [Link Control Protocol \(LCP\)](#), a family of [Network Control Protocols \(NCPs\)](#) such as IPCP, IPXCP and so forth, and also control protocols for implementing features, such as [CCP](#) and [ECP](#). The [authentication protocols PAP and CHAP](#) lack “Control” in the name but also fall into this category.

The control protocols each use control messages in a slightly different way, but there is also a great deal of commonality between the messages in many of them. This is because, as I explained in the topics describing the PPP protocols, most of the control protocols such as the NCP family, CCP and ECP are implemented as “subsets” of the functionality of the Link Control Protocol. They perform many of the same functions, so the PPP designers wisely “adapted” the LCP messaging system for these other control protocols.

This all means that control protocol frames have themselves a common format that fits within the overall general frame format in PPP. Even protocols like PAP and CHAP that aren't based on LCP use this general control frame format, which is described in [Table 36](#).

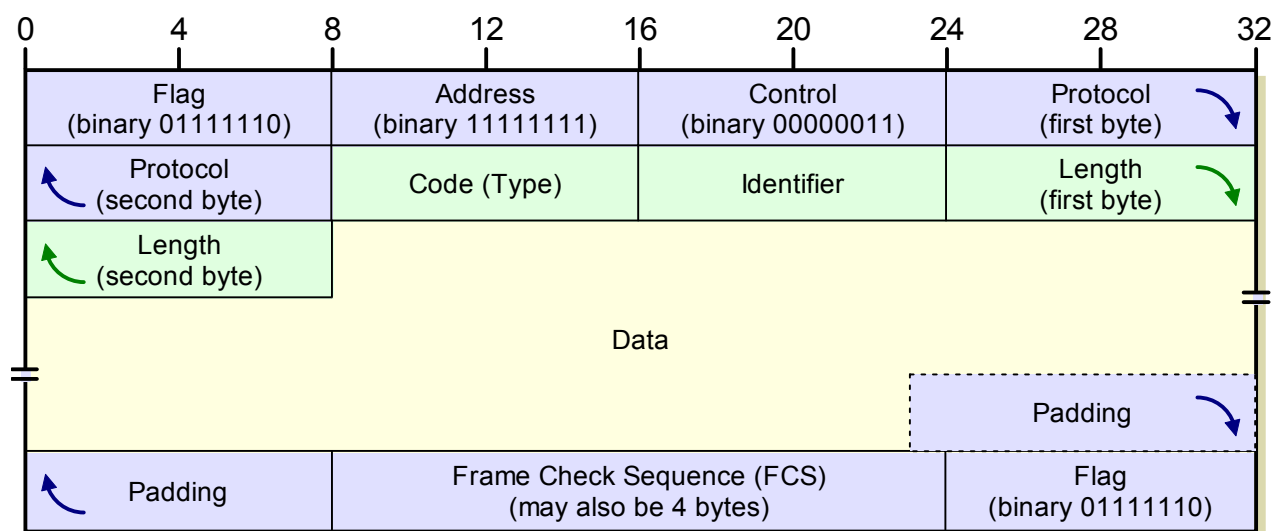

**Table 36: PPP Control Message Format (Page 1 of 2)**

Field Name	Size (bytes)	Description
<b>Code (Type)</b>	1	<b>Code:</b> A single byte value that indicates what type of control message is in this control frame. It is sometimes instead called “Type” in certain PPP standards.
<b>Identifier</b>	1	<b>Identifier:</b> This is a label field, used to match up requests with replies. When a request is sent a new <i>Identifier</i> is generated. When a reply is created, the value from the <i>Identifier</i> field in the request that prompted the reply is used for the reply's <i>Identifier</i> field.

**Table 36: PPP Control Message Format (Page 2 of 2)**

Field Name	Size (bytes)	Description
<b>Length</b>	2	<b>Length:</b> Specifies the length of the control frame; this is needed because the <i>Data</i> field is variable in length. The <i>Length</i> field is specified in bytes and includes all the fields in the control frame including the <i>Code</i> , <i>Identifier</i> , <i>Length</i> and <i>Data</i> fields.
<b>Data</b>	Variable	<b>Data:</b> Contains information specific to the message type. See below for more.

This entire structure becomes the payload of a PPP frame, meaning that it fits into the *Information* field of a PPP frame, as shown in [Figure 34](#). Thus, the *Length* field is equal in size to that of the *Information* field in the PPP frame. The *Protocol* field of a control frame is set to match the protocol that generated the control frame. For example, it would be 0xC021 for an LCP frame.

**Figure 34: PPP Control Message Format**

The four fields of the PPP control message format fit within the *Information* field of the PPP general frame format. The *Data* field is subsequently filled in with data specific to the control message type.

### PPP Control Messages and Code Values

The *Code* field indicates the type of control frame within the particular control protocol. Some protocols have a unique set of codes used only by that particular protocol; examples include the authentication protocols (PAP and CHAP) and the [Bandwidth Allocation Protocol \(BAP\)](#). Since the NCPs and many of the feature control protocols like CCP and

---

ECP are based on LCP, they use a common set of message codes and types. [Table 37](#) shows these common message codes, as well as a cross-reference table indicating which control protocols use them:

**Table 37: PPP Control Messages, Code Values and PPP Protocol Usage**

Code Value	Control Message	LCP	NCPs	CCP and ECP
1	<i>Configure-Request</i>	✓	✓	✓
2	<i>Configure-Ack</i>	✓	✓	✓
3	<i>Configure-Nak</i>	✓	✓	✓
4	<i>Configure-Reject</i>	✓	✓	✓
5	<i>Terminate-Request</i>	✓	✓	✓
6	<i>Terminate-Ack</i>	✓	✓	✓
7	<i>Code-Reject</i>	✓	✓	✓
8	<i>Protocol-Reject</i>	✓		
9	<i>Echo-Request</i>	✓		
10	<i>Echo-Reply</i>	✓		
11	<i>Discard-Request</i>	✓		
12	<i>Identification</i>	✓		
13	<i>Time-Remaining</i>	✓		
14	<i>Reset-Request</i>			✓
15	<i>Reset-Ack</i>			✓

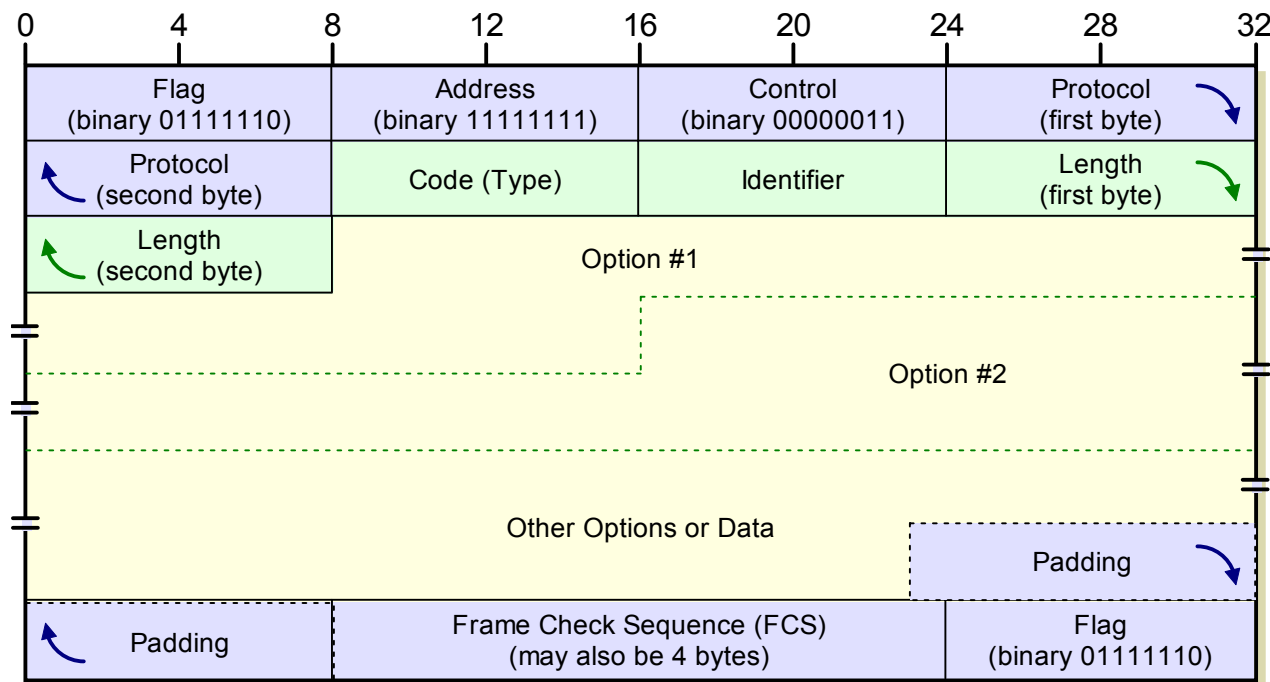

**Note:** I describe the specific ways these frame types are used in the individual topics on LCP, the NCPs, CCP and ECP.

The contents of the *Data* field depends entirely on the type of control message. In some cases, no extra data needs to be sent at all, in which case the *Data* field may be omitted. In other control messages it carries information relevant to the message type. For example, a *Code-Reject* message carries in the *Data* field a copy of the frame that was rejected.

### **PPP Control Message Option Format**

The various *Configure-* messages are used to negotiate configuration options in LCP and the other control protocols. In their *Data* fields they carry one or more options that are, again, specific to the protocol using them. For example, LCP uses one set of configuration options for the link as a whole; CCP uses options to negotiate a compression algorithm, MP

uses it to set up multilink bundles and so on. [Figure 35](#) shows how these options, which can vary in length, are placed in the *Data* field of a PPP control message (which is in turn nested inside the general PPP frame format).

**Figure 35: PPP Control Message Carrying Options**

This diagram shows a sample PPP control message carrying options in its *Data* field. Any number of options can be included, and/or mixed with other data, depending on the needs of the message.

Again, there is commonality here; while every option is different, they all use the same basic format, as described in [Table 38](#) and illustrated in [Figure 36](#):

**Table 38: PPP Control Message Option Format**

Field Name	Size (bytes)	Description
Type	1	<b>Type:</b> A type value that indicates the option type. The set of <i>Type</i> values is unique to each protocol. So, for example, LCP has one set of <i>Type</i> values corresponding to its configuration options, each NCP has a different set, CCP has its own set and so on.
Length	1	<b>Length:</b> Specifies the length of the option in bytes.
Data	Variable	<b>Data:</b> Contains the specific data for the configuration option.

The configuration options are described briefly in the individual protocol topics. I am not showing the specific contents of each option as there are just too many of them. These are in the RFCs.

**Figure 36: PPP Control Message Option Format**

Each option that appears in any of the many PPP control message types consists of this triplet of Type, Length and Data.

### ***Summary of PPP Control Message Formatting***

Well now... My intention in this topic was to show you the general format used for the different control protocols since they are so similar and I don't have the time or space to describe each protocol's frames individually. I concede that this may have ended up being more confusing than enlightening, since it may be difficult to see how PPP moves from the general to the specific in its formatting. If it will help, here's a quick summary:

1. The PPP general frame format is used for all frames, including all control frames. Its *Information* field contains the payload, which carries the entire control message within it for control frames.
2. The control frame is structured using the general format I gave at the start of this topic. The *Code* value indicates the type of control frame for each control protocol. The *Data* field is variable in length, and contains data for that control frame, which in some cases may include one or more configuration options.
3. For configuration control frames like *Configure-Request* and *Configure-Ack*, the *Data* field contains an encapsulated set of options using the general structure in the second table in this topic. Each option has its own *Data* subfield that contains data specific to that option.

To help make this more clear, the next two topics provide more specific examples of frame formats for LCP and the authentication protocols.

### **PPP Link Control Protocol (LCP) Frame Formats**

The previous topic described the general format used by the various protocols in PPP that exchange control messages. Of the many control protocols in PPP, the [Link Control Protocol \(LCP\)](#) is the most important, as it is responsible for basic PPP link setup and operation. It is also the protocol used as a "template" for many of the other control protocols.

Since it is so central to PPP, and since many of the other protocols use a similar messaging system, I want to make the general frame format seen in the previous page more "concrete" by showing the specific frame formats used for each of the LCP control frames. There are thirteen different ones, however, and since they have many fields in common, I didn't want to put here thirteen tables all of which look almost the same.

To save space and show how the messages differ, I have put them into a single large summary table instead of making thirteen smaller ones. [Table 39](#) shows the contents and meaning for each of the fields in the thirteen LCP frame types:

**Table 39: PPP Link Control Protocol (LCP) Frame Types and Fields (Page 1 of 2)**

Frame Type	Code Field	Identifier Field	Length Field	Data Field
<b>Configure-Request</b>	1	New value generated for each frame.	4 + Length of all included configuration options.	Configuration options to be negotiated by the two peers on a link. <a href="#">The previous topic</a> describes the general format of configuration options.
<b>Configure-Ack</b>	2	Copied from the <i>Identifier</i> field of the <i>Configure-Request</i> frame for which this <i>Configure-Ack</i> is a reply.	4 + Length of all included configuration options.	Configuration options being positively acknowledged (accepted during negotiation of the link).
<b>Configure-Nak</b>	3	Copied from the <i>Identifier</i> field of the <i>Configure-Request</i> frame for which this <i>Configure-Nak</i> is a reply.	4 + Length of all included configuration options.	Configuration options being negatively acknowledged (renegotiation requested).
<b>Configure-Reject</b>	4	Copied from the <i>Identifier</i> field of the <i>Configure-Request</i> frame for which this <i>Configure-Reject</i> is a reply.	4 + Length of all included configuration options.	Configuration options being rejected (since the device cannot negotiate them).
<b>Terminate-Request</b>	5	New value generated for each frame.	4 (or more if extra data is included).	Not required. See note below.
<b>Terminate-Ack</b>	6	Copied from the <i>Identifier</i> field of the matching <i>Terminate-Request</i> .	4 (or more if extra data is included).	Not required. See note below.
<b>Code-Reject</b>	7	New value generated for each frame.	4 + Length of rejected frame.	A copy of the LCP frame that was rejected. This is not the complete PPP frame, just the LCP control portion from its <i>Information</i> field.
<b>Protocol-Reject</b>	8	New value generated for each frame.	6 + Length of rejected frame.	The first two bytes contain the <i>Protocol</i> value of the frame rejected. The rest contains a copy of the <i>Information</i> field from the frame rejected.

**Table 39: PPP Link Control Protocol (LCP) Frame Types and Fields (Page 2 of 2)**

Frame Type	Code Field	Identifier Field	Length Field	Data Field
<b>Echo-Request</b>	9	New value generated for each frame.	8 (or more if extra data is included).	Contains a 4-byte “magic number” used to detect looped-back links, if the appropriate configuration option has been negotiated; otherwise, set to zero.  May also contain additional “uninterpreted data”; see note below.
<b>Echo-Reply</b>	10	Copied from the <i>Identifier</i> field of the matching <i>Echo-Request</i> .	8 (or more if extra data is included).	Contains a 4-byte “magic number” used to detect looped-back links, if the appropriate configuration option has been negotiated; otherwise, set to zero.  May also contain additional “uninterpreted data”; see note below.
<b>Discard-Request</b>	11	New value generated for each frame.	8 (or more if extra data is included).	Contains a 4-byte “magic number” used to detect looped-back links, if the appropriate configuration option has been negotiated; otherwise, set to zero.  May also contain additional “uninterpreted data”; see note below.
<b>Identification</b>	12	New value generated for each frame.	8 (or more if extra data is included).	Contains a 4-byte “magic number” used to detect looped-back links, if the appropriate configuration option has been negotiated; otherwise, set to zero.  May also contain additional “uninterpreted data”; see note below.
<b>Time-Remaining</b>	13	New value generated for each frame.	12 (or more if extra data is included).	Contains a 4-byte “magic number” used to detect looped-back links, if the appropriate configuration option has been negotiated; otherwise, set to zero.  Also contains a 4-byte value indicating the number of seconds remaining in the current session. A value of all ones in this field is interpreted as “forever”, meaning the session will not expire.  May also contain additional “uninterpreted data”; see note below.

**Note:** LCP frame types 5, 6, 9, 10, 11, 12 and 13 allow an additional amount of data to be included in the *Data* field whose use is not strictly described by the protocol. The PPP standard says that this may be zero or more octets that “contains uninterpreted data for use by the sender” and “may consist of any binary value”. The inclusion of this “uninterpreted data” is left as an implementation-dependent option.

---

All LCP control frames are encapsulated into a PPP frame by placing the frame structure into its *Information* field [as discussed in the previous topic](#). The *Protocol* field is set to 0xC021 for LCP. For an explanation of how the frames are used, see [the operational description of LCP](#).

### **PPP Authentication Protocol (PAP, CHAP) Frame Formats**

For links where security is important, PPP provides two optional authentication protocols. These are used during initial link setup by the Link Control Protocol (LCP) to deny PPP connections to unauthorized devices. The two authentication protocols are the [Password Authentication Protocol \(PAP\)](#) and [Challenge Handshake Authentication Protocol \(CHAP\)](#).

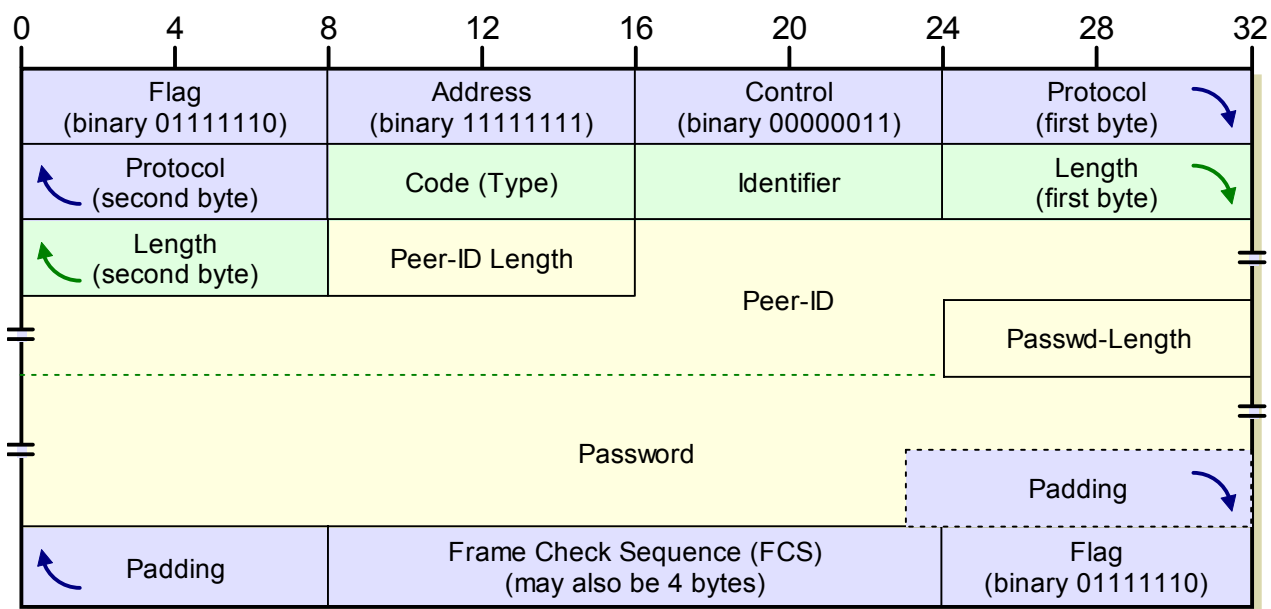

PAP and CHAP are control protocols and thus use the same basic control protocol frame format described earlier in this section. However, since they have a very different purpose than LCP and many of the other control protocols, they use a distinct set of frames, with their own unique set of *Code* values. I thought it might be useful to see how PAP and CHAP frames are constructed. PAP uses three different control frame types, and CHAP uses four. To save space and show how the frames compare to each other, I will show them in one table for each protocol instead of seven tables.

## PPP PAP Control Frame Formats

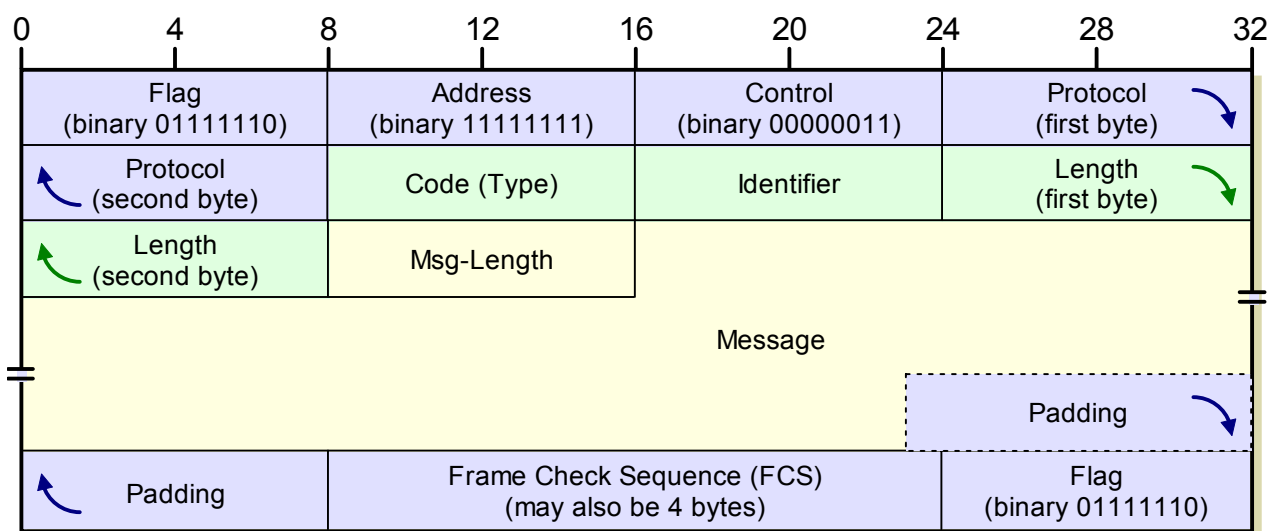

Let's start with PAP. Its three control frames are constructed as shown in [Table 40](#). The *Authenticate-Request* uses one format, illustrated in [Figure 37](#), while the other two frame types use a different format, shown in [Figure 38](#).

**Table 40: PPP Password Authentication Protocol (PAP) Frame Formats**

Frame Type	Code Field	Identifier Field	Length Field	Data Field															
<b><i>Authenticate-Request</i></b>	1	New value generated for each frame.	6 + Length of <i>Peer-ID</i> + Length of <i>Password</i>	<div>Contains the “user name” and password for authentication. This is carried in four subfields arranged as follows:</div> <table><tr><th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr><tr><td><b><i>Peer-ID Length</i></b></td><td>1</td><td><b><i>Peer-ID Length</i></b>: Length of the <i>Peer-ID</i> field, in bytes.</td></tr><tr><td><b><i>Peer-ID</i></b></td><td>Variable</td><td><b><i>Peer-ID</i></b>: The name of the device to be authenticated; equivalent in concept to a “user name”.</td></tr><tr><td><b><i>Passwd-Length</i></b></td><td>1</td><td><b><i>Password Length</i></b>: Length of the <i>Password</i> field, in bytes.</td></tr><tr><td><b><i>Password</i></b></td><td>Variable</td><td><b><i>Password</i></b>: The password corresponding to the name being authenticated.</td></tr></table>	Subfield Name	Size (bytes)	Description	<b><i>Peer-ID Length</i></b>	1	<b><i>Peer-ID Length</i></b> : Length of the <i>Peer-ID</i> field, in bytes.	<b><i>Peer-ID</i></b>	Variable	<b><i>Peer-ID</i></b> : The name of the device to be authenticated; equivalent in concept to a “user name”.	<b><i>Passwd-Length</i></b>	1	<b><i>Password Length</i></b> : Length of the <i>Password</i> field, in bytes.	<b><i>Password</i></b>	Variable	<b><i>Password</i></b> : The password corresponding to the name being authenticated.
Subfield Name	Size (bytes)	Description																	
<b><i>Peer-ID Length</i></b>	1	<b><i>Peer-ID Length</i></b> : Length of the <i>Peer-ID</i> field, in bytes.																	
<b><i>Peer-ID</i></b>	Variable	<b><i>Peer-ID</i></b> : The name of the device to be authenticated; equivalent in concept to a “user name”.																	
<b><i>Passwd-Length</i></b>	1	<b><i>Password Length</i></b> : Length of the <i>Password</i> field, in bytes.																	
<b><i>Password</i></b>	Variable	<b><i>Password</i></b> : The password corresponding to the name being authenticated.																	
<b><i>Authenticate-Ack</i></b>	2	Copied from the <i>Identifier</i> field of the <i>Authenticate-Request</i> frame for which this is a reply.	5 + Length of included <i>Message</i> .	Contains a one-byte <i>Msg-Length</i> subfield that specifies the length of the <i>Message</i> subfield that follows it. The <i>Message</i> subfield contains an arbitrary string of data whose use is implementation dependent. It may be used to provide an indication of authentication success or failure to the user. If not used, the <i>Msg-Length</i> field is still included, but its value is set to zero.															
<b><i>Authenticate-Nak</i></b>	3																		

**Figure 37: PPP PAP Authenticate-Request Frame Format**

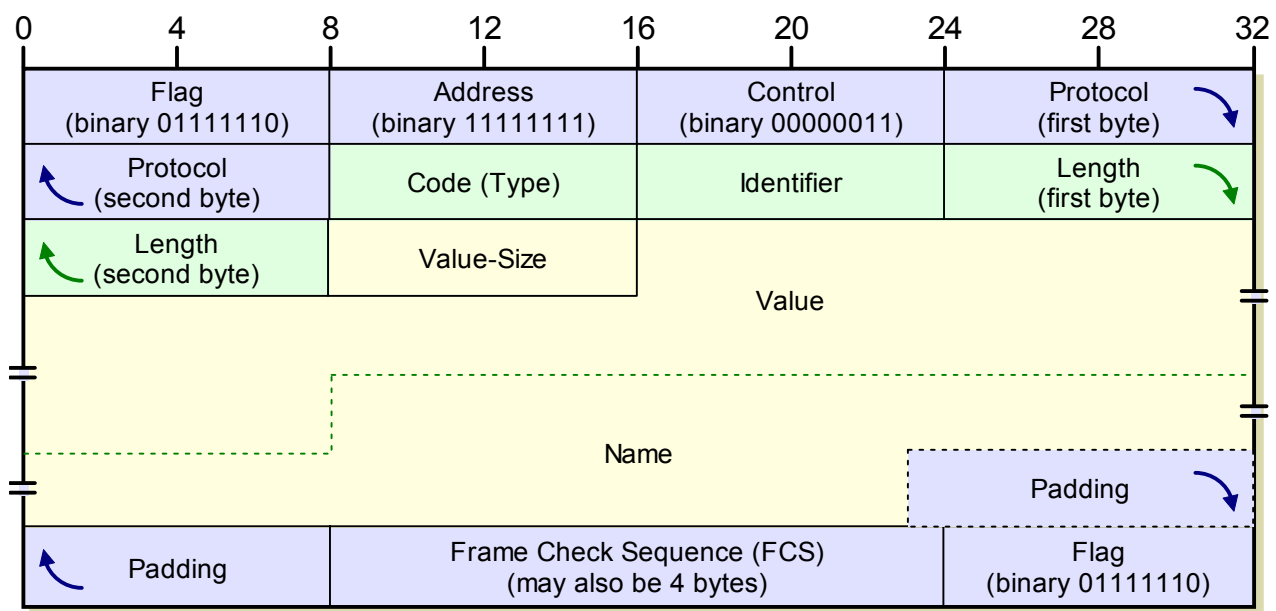

**Figure 38: PPP PAP Authenticate-Ack and Authenticate-Nak Frame Format**

## PPP CHAP Control Frame Formats

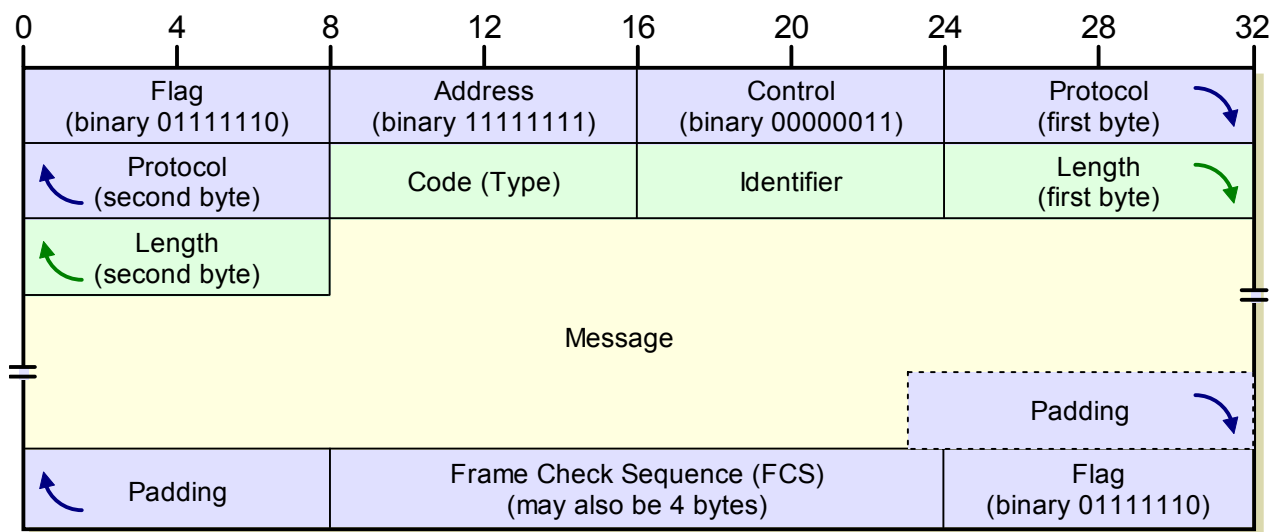

The four CHAP frame types are formatted as shown in [Table 41](#). As you can see in that table, the *Challenge* and *Response* frames use one message format, illustrated in [Figure 39](#), while *Success* and *Failure* frames use a different one, shown in [Figure 40](#).

**Table 41: PPP Challenge Handshake Authentication Protocol (CHAP) Formats**

Frame Type	Code Field	Identifier Field	Length Field	Data Field												
Challenge	1	New value generated for each frame.	5 + Length of challenge text + Length of name	Carries the challenge text or response text, and a system identifier. This information is carried in three subfields: <table><tr><th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr><tr><td>Value-Size</td><td>1</td><td><b>Value-Size:</b> Length of the <i>Value</i> subfield that follows, in bytes.</td></tr><tr><td>Value</td><td>Variable</td><td><b>Value:</b> For a Challenge frame, contains the challenge text used in the initial “challenge”. For a Response frame, the encrypted challenge text being returned to the authenticator.</td></tr><tr><td>Name</td><td>Variable</td><td><b>Name:</b> One or more bytes of text used to identify the device that sent the frame.</td></tr></table>	Subfield Name	Size (bytes)	Description	Value-Size	1	<b>Value-Size:</b> Length of the <i>Value</i> subfield that follows, in bytes.	Value	Variable	<b>Value:</b> For a Challenge frame, contains the challenge text used in the initial “challenge”. For a Response frame, the encrypted challenge text being returned to the authenticator.	Name	Variable	<b>Name:</b> One or more bytes of text used to identify the device that sent the frame.
Subfield Name	Size (bytes)	Description														
Value-Size	1	<b>Value-Size:</b> Length of the <i>Value</i> subfield that follows, in bytes.														
Value	Variable	<b>Value:</b> For a Challenge frame, contains the challenge text used in the initial “challenge”. For a Response frame, the encrypted challenge text being returned to the authenticator.														
Name	Variable	<b>Name:</b> One or more bytes of text used to identify the device that sent the frame.														
Response	2	Copied from the <i>Identifier</i> field of the <i>Challenge</i> frame for which this is a reply.	5 + Length of <i>Value</i> + Length of <i>Name</i>													
Success	3	Copied from the <i>Identifier</i> field of the <i>Response</i> frame for which this is a reply.	4 (or more if extra data is included).	May contain an arbitrary, implementation-dependent <i>Message</i> field to indicate to the user whether authentication was successful or failed.												
Failure	4

## PPP Multilink Protocol (MP) Frame Format

Some devices are connected not by a single physical layer link but by two or more. These may be either multiple physical connections such as two connected pairs of modems, or multiplexed virtual layer one connections like ISDN B channels. In either case, the PPP

---

Multilink Protocol (MP, which also goes by several aliases such as MLPPP and MLP) can be used to aggregate the bandwidth of these physical links to create a single, high-speed *bundle*. I describe how this is done in the [operational topic on MP](#).

**Table 42: PPP Multilink Protocol Fragment Frame Format**

Field Name	Size (bytes)	Description
<b>B</b>	1/8 (1 bit)	<b>Beginning Fragment Flag:</b> When set to 1, flags this fragment as the first of the split-up PPP frame. It is set to 0 for other fragments.
<b>E</b>	1/8 (1 bit)	<b>Ending Fragment Flag:</b> When set to 1, flags this fragment as the last of the split-up PPP frame. It is set to 0 for other fragments.
<b>Reserved</b>	2/8 (2 bits) <b>OR</b> 6/8 (6 bits)	<b>Reserved:</b> Not used, set to zero.
<b>Sequence Number</b>	1 1/2 (12 bits) <b>OR</b> 3 (24 bits)	<b>Sequence Number:</b> When a frame is split up, the fragments are given consecutive sequence numbers so the receiving device can properly reassemble them.
<b>Fragment Data</b>	Variable	<b>Fragment Data:</b> The actual fragment from the original PPP frame.

After MP is configured and starts working, it operates by employing a strategy for dividing up regular PPP frames amongst the many individual physical links that comprise the MP bundle. This is usually accomplished by chopping up the PPP frames into pieces called *fragments* and spreading these fragments across the physical links. This allows the traffic on the physical links to be easily balanced.

### **PPP Multilink Protocol Frame Fragmentation Process**

To accomplish this fragmentation process, a three step process is followed:

1. **Original PPP Frame Creation:** The data or other information to be sent is first formatted as a “whole” PPP frame, but in a modified form, as described below.
2. **Fragmentation:** The full-sized PPP frame is chopped into fragments by MP.
3. **Encapsulation:** Each fragment is encapsulated in the *Information* field of a new PPP MP fragment frame, along with control information to allow the fragments to be reassembled by the recipient.

Several of the fields that normally appear in a “whole” PPP frame aren’t needed if that frame is going to then be divided and placed into other PPP Multilink frames, so when fragmentation is to occur, they are omitted when the original PPP frame is constructed for efficiency’s sake. Specifically:

- ☉ The *Flag* fields at the start and end are used only for framing for transmission and aren’t needed in the logical frame being fragmented.
- ☉ The *FCS* field is not needed, because each fragment has its own *FCS* field.

- ☛ The special “compression” options that are possible for any PPP frame are used when creating this original frame: [Address and Control Field Compression \(ACFC\)](#) and [Protocol Field Compression \(PFC\)](#). This means that there are no *Address* or *Control* fields in the frame, and the *Protocol* field is only one byte in size. Note that this inherently restricts fragments to carrying only certain types of information.

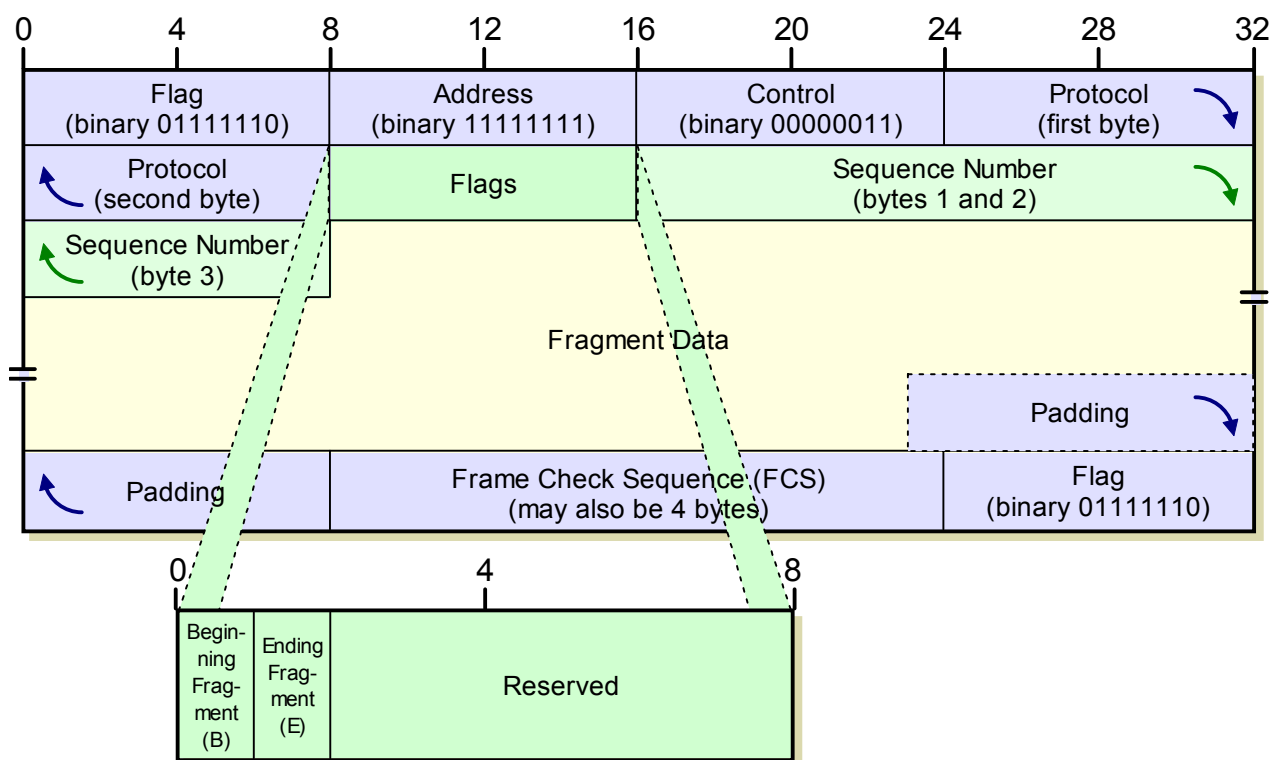

These changes save a full eight bytes on each PPP frame to be fragmented. As a result, the original PPP frame has a very small header, consisting of only a one-byte *Protocol* field. The *Protocol* value of each fragment is set to 0x003D to indicate a MP fragment, while the *Protocol* field of the original frame becomes the first byte of “data” in the first fragment.

**Key Concept:** The PPP Multilink Protocol normally divides data amongst physical links by creating an original PPP frame with unnecessary headers removed, and then dividing it into fragment frames. Each fragment includes special headers to allow reassembly of the original frame by the recipient device.

### PPP Multilink Protocol Fragment Frame Format

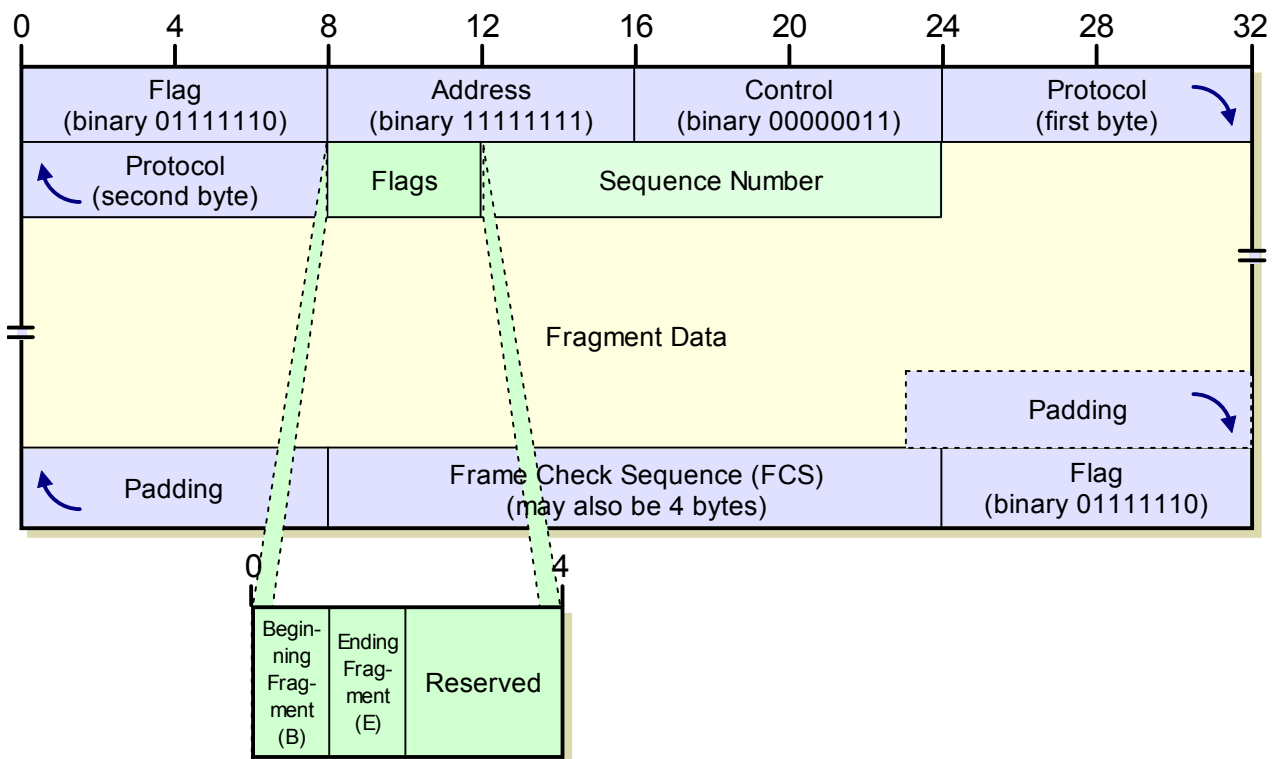

The *Information* field of each fragment uses a substructure that contains a four-field *MP* header along with one fragment of the original PPP frame, as shown in [Table 42](#).

**Figure 41: PPP Multilink Protocol Long Fragment Frame Format**

The long PPP Multilink Protocol frame format uses a full byte for flags and a 24-bit *Sequence Number*.

**Figure 42: PPP Multilink Protocol Short Fragment Frame Format**

The short version of the PPP Multilink Protocol format uses 4 bits for flags and a 12-bit *Sequence Number*.

As you can see, the MP frame format comes in two versions: the long format uses a 4-byte header, while the short format requires only 2 bytes. The default MP header format uses a 24-bit *Sequence Number* and has 6 reserved bits, as shown in [Figure 41](#). It is possible when MP is set up, for devices to negotiate the *Multilink Short Sequence Number Header Format* configuration option. If this is done successfully, shorter 12-bit *Sequence Numbers* are used instead. Four of the reserved bits are also truncated, to save 2 bytes on each frame, as illustrated in [Figure 42](#). (Considering that 12 bits still allows for over 4,000 fragments per PPP frame, this is usually more than enough!)

The *Fragment Data* field contains the actual fragment to be sent. Since the original PPP header (including the *Protocol* field) is at the start of the original PPP frame, this will appear at the start of the first fragment. The remaining fragments will have just portions of the *Information* field of the original PPP frame. The last fragment will end with the last bytes of the original PPP frame.

The receiving device will collect all the fragments for each PPP frame, extract the fragment data and MP headers from each. It will use the *Sequence Numbers* to reassemble the fragments and then process the resulting PPP frame.

---

## **PPP Multilink Protocol Fragmentation Demonstration**

A demonstration of fragmenting a PPP data frame can be seen in [Figure 43](#). At top is the same PPP data frame shown in [Figure 33](#). The eight bytes grayed out are the ones not used when a frame is to be fragmented. Thus, the PPP frame used for MP is 24 bytes long, as seen in the smaller table at left (note that the eight bytes are not created and removed, I just showed them in the upper table for illustration). This frame is split into 8-byte chunks, each carried in the *Fragment Data* fields of an MP fragment. Note the consecutive *Sequence Number* (“Seq”) values in the fragment frames. Also, note that the *Beginning Fragment* field is set only for the first fragment, and the *Ending Fragment* only for the last one.

Flag = 7E	Address = FF	Control = 03	Protocol (byte 1) = 00

---

## TCP/IP Network Interface / Internet "Layer Connection" Protocols

The second layer of the [OSI Reference Model](#) is the [data link layer](#); it corresponds to the [TCP/IP network interface layer](#). It is there that most LAN, WAN and WLAN technologies are defined, such as Ethernet and IEEE 802.11. The third layer is the [network layer](#), also called the internet layer in the TCP/IP model, where internetworking protocols are defined, the most notable being the [Internet Protocol](#). These two layers are intimately related, because messages sent at the network layer must be carried over individual physical networks at the data link layer. They perform different tasks but as neighbors in the protocol stack, must cooperate with each other.

There is a set of protocols that serves the important task of linking together these two layers and allowing them to work together. The problem with them is deciding where exactly they should live! They are sort of the “black sheep” of the networking world—nobody denies their importance, but they always think they belong in “the other guy's” layer. For example, since these protocols pass data on layer two networks, the folks who deal with layer two technologies say they belong at layer three. But those who work with layer three protocols consider these “low level” protocols that provide services to layer three, and hence put them as part of layer two.

So where do they go? Well, to some extent it doesn't really matter. Even if they are “black sheep” I consider them somewhat special, so I gave them their own home. Welcome to “networking layer limbo”, also known as “OSI layer two-and-a-half”. ☺ This is where a couple of protocols are described that serve as “glue” between the data link and network layers. The main job performed here is address resolution, or providing mappings between layer two and layer three addresses. This resolution can be done in either direction, and is represented by the two TCP/IP protocols ARP and RARP (which, despite their similitudes, are used for rather different purposes in practice.)

**Background Information:** I suggest familiarity with the basics of [layer two](#) and [layer three](#) before proceeding here. In particular, some understanding of [IP addressing](#) is helpful, though not strictly necessary. In general, if you are going to read about IP anyway, you would be better off covering that material before proceeding to this section.

---

---

## **Address Resolution and the TCP/IP Address Resolution Protocol (ARP)**

Communication on an internetwork is accomplished by sending data at layer three using a network layer address, but the actual transmission of that data occurs at layer two using a data link layer address. This means that every device with a fully-specified networking protocol stack will have both a layer two and a layer three address. It is necessary to define some way of being able to link these addresses together. Usually, this is done by taking a network layer address and determining what data link layer address goes with it. This process is called *address resolution*.

In this section I look at the problem of address resolution at both a conceptual and practical level, with a focus on how it is done in the important [TCP/IP protocol suite](#). I begin with a section that overviews address resolution in general terms and describes the issues involved in the process. I then describe the TCP/IP Address Resolution Protocol (ARP), probably the best-known and most commonly used address resolution technique. I also provide a brief overview of how address resolution is done for multicast addresses in IP, and the method used in the new IP version 6.

---

## **Address Resolution Concepts and Issues**

Due to the prominence of TCP/IP in the world of networking, most discussions of address resolution jump straight to the [TCP/IP Address Resolution Protocol \(ARP\)](#). This protocol is indeed important, and we will take a look at it in the next section. However, the basic problem of address resolution is not unique to any given implementation that deals with it, such as TCP/IP's ARP. To provide better understanding of resolving addresses between the data link layer and the network layer and to support for our examination of ARP, I think it's a good idea to start by looking at the matter in more general terms.

To that end, I provide here some background information on address resolution, exploring various concepts and issues related to the technique in general terms. I begin by discussing the need for address resolution in general terms. I then describe the two main methods for solving the address resolution problem: direct mapping and dynamic resolution. I also discuss some of the efficiency issues involved in practical dynamic address resolution, with a focus on the importance of caching.

### **The Need For Address Resolution**

I can imagine that some people might balk at the notion of address resolution and the need for protocols that perform this function. In my chapter on the [OSI Reference Model](#) I talked extensively about how the whole point of having conceptual layers was to separate logical functions and allow higher-layer protocols to be hidden from lower-layer details. Given this, why do we need address resolution protocols that tie protocols and layers together?

I did say that layers are distinct, true. However, I also tried to make the point that the OSI Reference Model is exactly that—a *model*. There are often practicalities that arise that require solutions that don't strictly fit the layer model. [When the model doesn't fit reality, the model must yield](#). And so it is in dealing with the problem of address resolution.

### ***Addressing at Layer Two and Layer Three***

When we consider the seven layers of the OSI Reference Model, there are two that deal with addressing: the data link layer and the network layer. The physical layer is not strictly concerned with addressing at all, only sending at the bit level. The layers above the network layer all work with network layer addresses.

So the next obvious question is: why is addressing done at two different layers? The answer is that they are very different types of addresses that are used for different purposes. Layer two addresses (such as IEEE 802 MAC addresses) are used for local transmissions between hardware devices that can communicate directly. They are used to implement basic LAN, WLAN and WAN technologies. In contrast, layer three addresses (most commonly [Internet Protocol or IP addresses](#)) are used in internetworking, to create the equivalent of a massive “virtual” network at the network layer.

---

The most important distinction between these types of addresses is the distinction between layers two and three themselves: layer two deals with directly-connected devices (on the same network) while layer three deals with **indirectly**-connected devices (as well as directly-connected). Say, for example, you want to connect to the Web server at <http://www.tcpipguide.com>. This is a web site that runs on a server that has an Ethernet card in it for connecting it to its Internet service provider site. However, even if you know its MAC address, you cannot use it to talk directly to this server using the Ethernet card in your home PC, because the devices are on different networks—in fact, they may be on different continents!

Instead, you communicate at layer three, using the [Internet Protocol](#) and higher layer protocols such as [TCP](#) and [HTTP](#). Your request is *routed* from your home machine, through a sequence of routers, to the server at The TCP/IP Guide, and the response is routed back to you. The communication is, logically, at layers three and above; you send the request not to the MAC address of the server's network card, but rather to the server's IP address.

However, while we can **virtually** connect devices at layer three, these connections are really conceptual only. When you send a request using IP, it is sent one *hop* at a time, from one physical network to the next. At each of these hops, an actual transmission occurs at the physical and data link layers. When your request is sent to your local router at layer three, the actual request is encapsulated in a frame using whatever method you physically connect to the router, and passed to it using the router's data link layer address. The same happens for each subsequent step, until finally, the router nearest the destination sends to the destination using its data link (MAC) address. This is illustrated in [Figure 44](#).

### ***Converting Layer Three Addresses to Layer Two: Address Resolution***

The basic problem is that IP addresses are **too high level** for the physical hardware on networks to deal with; they don't understand what they are. When your request shows up at the router that connects to The TCP/IP Guide, it can see the <http://www.tcpipguide.com> server's IP address, but that isn't helpful: it needs to send to server's **MAC address**.

The identical issue exists even with communication between devices on a LAN. Even if the Web server is sitting on the same desk as the client, the communication is logically at the IP layer, but must also be accomplished at the data link layer. This means we need a way of translating between the addresses at these two layers. This process is called *address resolution*.

**Key Concept:** Address resolution is required because internetworked devices communicate logically using layer three addresses, but the actual transmissions between devices take place using layer two (hardware) addresses.

---

**Figure 44: Why Address Resolution Is Necessary**

In this example, a client on the local network is accessing a server somewhere on the Internet. Logically, this connection can be made “directly” between the client and server, but in reality it is a sequence of physical links at layer two. In this case there are six such links, most of them between routers that lie between the client and server. At each step the decision of where to send the data is made based on a layer three address, but the actual transmission must be performed using the layer two address of the next intended recipient in the route.

### **General Address Resolution Methods**

In fact, not only do we need to have way of making this translation, we need to be concerned with the manner in which it is done. Since the translation occurs for each hop of every datagram sent over an internetwork, the efficiency of the process is extremely important. We don't want to use a resolution method that takes a lot of network resources.

Address resolution can be accomplished in two basic ways:

- 🕒 **Direct Mapping:** A formula is used to map the higher-layer address into the lower-layer address. This is the simpler and more efficient technique but has some limitations, especially regarding the size of the data link layer address compared to the network layer address.

- 
- ☉ **Dynamic Resolution:** A special protocol is used that allows a device with only an IP address to determine the corresponding data link layer address, even if they take completely different forms. This is normally done by interrogating one or more other devices on a local network to determine what data link layer address corresponds to a given IP address. This is more complex and less efficient than direct mapping but is more flexible.

The next two topics explore these two methods in more detail.

You should bear in mind that of necessity, it is not possible to have a fully general address resolution method that works automatically. Since it deals with linking data link layer addresses to network layer addresses, the implementation must be specific to the technologies used in each of these layers. The only method that could really be considered generic would be the use of static, manually-updated tables that say “link this layer three address to this layer two address”. This, of course, is not automatic and brings with it all the limitations of manual configuration.

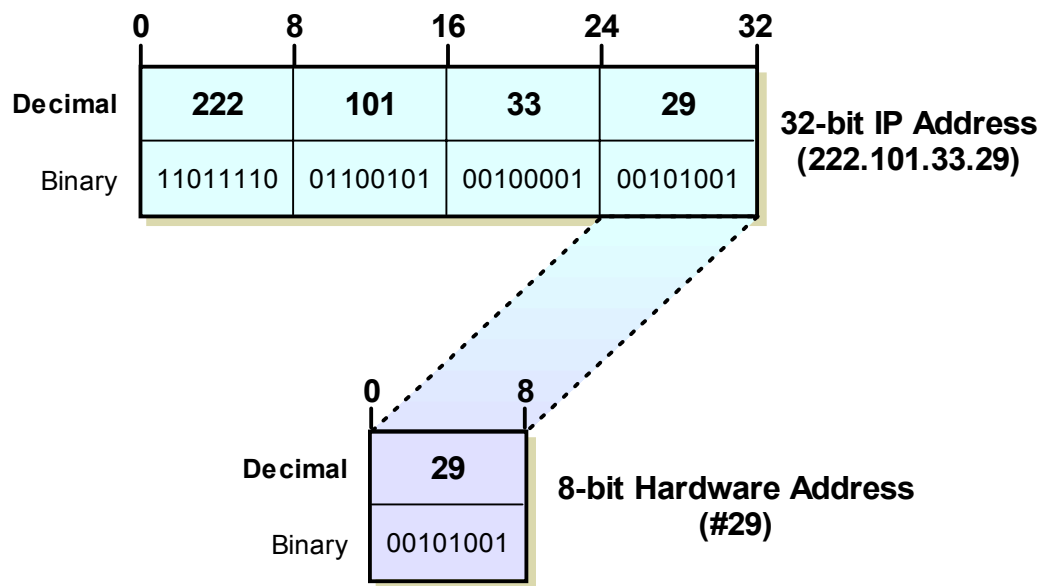

## **Address Resolution Through Direct Mapping**

Network layer addresses must be resolved into data link layer addresses numerous times during the travel of each datagram across an internetwork. We therefore want the process to be as simple and efficient as possible. The easiest method of accomplishing this is to do *direct mapping* between the two types of addresses.

The basic idea behind direct mapping is to choose a scheme for layer two and layer three addresses so that you can determine one from the other using a simple algorithm. This enables you to take the layer three address, and follow a short procedure to convert it into a layer two address. In essence, whenever you have the layer three address you already have the layer two address.

The simplest example of direct mapping would be if we used the same structure and semantics for both data link and network layer addresses. This is generally impractical, because the two types of addresses serve different purposes, and are therefore based on incompatible standards. However, we can still perform direct mapping if we have the flexibility of creating layer three addresses that are large enough to encode a complete data link layer address within them. Then, determining the layer two address is a simple matter of selecting a certain portion of the layer two address.

As an example, consider a simple LAN technology like ARCNet. It uses a short 8-bit data link layer address, with valid values of 1 to 255, which can be assigned by an administrator. We could easily set up an IP network on such a LAN by taking a [class C](#) (or /24) network and using the ARCNet data link layer as the last octet. So, if our network were, for example, 222.101.33.0/24, we could assign the device with ARCNet address #1 the IP address 222.101.33.1, the device with ARCNet address #29 would be 222.101.33.29 and so forth, as shown in [Figure 45](#).

**Figure 45: Address Resolution Through Direct Mapping**

When the hardware address is small, it is easy to define a mapping that directly corresponds to a portion of a layer three address. In this example, an 8-bit MAC address, such as that used for ARCNet, is mapped to the last byte of the device's IP address, making address resolution a trivial matter.

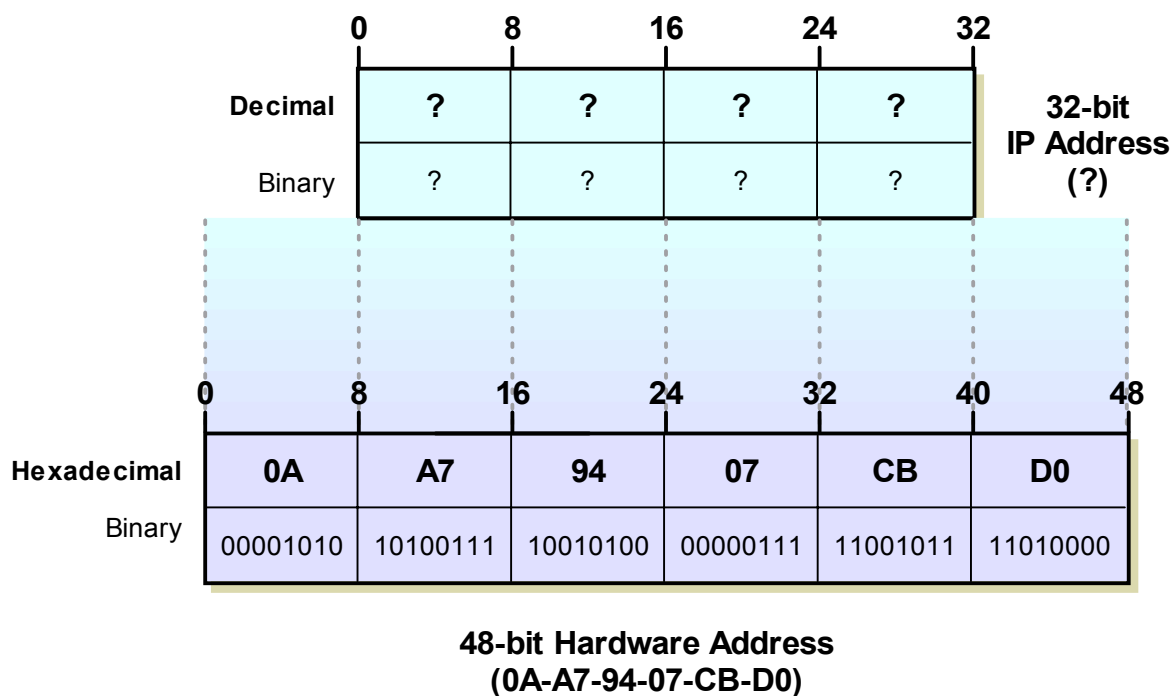

The appeal of this system is obvious. Conceptually, it is trivially simple to understand—to get the hardware address for a device, you just use the final eight bits of the IP address. It's also very simple to program devices to perform, and highly efficient, requiring no exchange of data on the network at all.

**Key Concept:** When the layer two address is smaller than the layer three address, it is possible to define a direct mapping between them, so that the hardware address can be determined directly from the network layer address. This makes address resolution extremely simple, but reduces flexibility in how addresses are assigned.

### ***Direct Mapping Not Possible With Large Hardware Addresses***

Unfortunately, direct mapping only works when it is possible to express the data link layer address as a function of the network layer address. Consider instead the same IP address, 222.101.33.29, running on an Ethernet network. Here, the data link layer addresses are “hard-wired” into the hardware itself (they can sometimes be overridden but usually this is not done). More importantly, the MAC address is 48 bits wide, not 8. This means the layer two address is bigger than the layer three address, and there is no way to do direct mapping, as [Figure 46](#) illustrates.

**Figure 46: Address Resolution Problems With Large Hardware Address Size**

When the layer two address is larger in size than the layer three address, it is not possible to define a mapping between them that can be used for address resolution.

**Note:** In the case where the hardware address size exceeds the network layer address size, we could do a “partial mapping”. For example, we could use the IP address to get *part* of the MAC address and hope we don’t have duplication in the bits we didn’t use. This method is not well-suited to regular transmissions, but is in fact used for [resolving multicast addresses in IPv4 to Ethernet addresses](#).

In general, then, direct mapping is not possible when the layer three address is smaller than the layer two address. Consider that Ethernet is the most popular technology at layer two and uses a [48-bit address](#), and IP is the most popular technology at layer three and uses a 32-bit address. This is one reason why direct mapping is a technique that is not only not widely used, but that most people don’t know about!

### ***Inflexibility of Direct Mapping***

Now let’s consider the next generation, [IP version 6](#)? IPv6 supports massive 128-bit addresses. Furthermore, regular (unicast) addresses are even defined using a method that creates them from data link layer addresses using a special mapping. This would in theory allow IPv6 to use direct mapping for address resolution.

---

However, the decision was made to have IPv6 use dynamic resolution just as IPv4 does. One reason might be historical, since IPv4 uses dynamic resolution. However, the bigger reason is probably due to a disadvantage of direct mapping: its inflexibility. **Dynamic resolution** is a more generalized solution, because it allows data link layer and network layer addresses to be independent, and its disadvantages can be mostly neutralized through careful implementation, as we will see.

In fact, evidence for this can be seen in the fact that dynamic resolution of IP is in fact defined on ARCNet, the example we just used. We could do direct mapping there, but it restricts us to a certain pattern of IP addressing that reduces flexibility.

## **Dynamic Address Resolution**

**Direct mapping** provides a simple and highly efficient means of resolving network layer addresses into data link layer addresses. Unfortunately, it is a technique that we either cannot or should not use in a majority of cases. We cannot use it when the size of the data link layer address is larger than that of the network layer address. We shouldn't use it when we need flexibility, because direct mapping requires us to make layer three and layer two addresses correspond.

The alternative to direct mapping is a technique called *dynamic address resolution*. To understand how this works, we can consider a simple analogy. I'm sure you've seen limousine drivers waiting to pick up a person at the airport they do not know personally. (Well, you've seen it in a movie, haven't you?) This is similar to our problem: they know the name of the person they must transport, but not the person's face (a type of "local address" in a manner of speaking!) To find the person, they hold up a card bearing that person's name. Everyone other than that person ignores the card, but hopefully the individual being sought will recognize it and approach the driver.

We do the same thing with dynamic address resolution in a network. Let's say that device *A* wants to send to device *B* but knows only device *B*'s network layer address (its "name") and not its data link layer address (its "face"). It broadcasts a layer two frame containing the layer three address of device *B*—this is like holding up the card with someone's name on it. The devices other than *B* don't recognize this layer three address and ignore it. *Device B*, however, knows its own network layer address. It recognizes this in the broadcast frame and sends a direct response back to device *A*. This tells device *A* what device *B*'s layer two address is, and the resolution is complete. [Figure 47](#) illustrates the process.

**Key Concept:** *Dynamic address resolution* is usually implemented using a special protocol. A device that knows only the network layer address of another device can use this protocol to request the other device's hardware address.

---

**Figure 47: Dynamic Address Resolution**

Device A needs to send data to Device B but knows only its IP address ("IPB"), and not its hardware address. A broadcasts a request asking to be sent the hardware address of the device using the IP address "IPB". B responds back to A directly with the hardware address.

Direct mapping is very simple, but as you can see, dynamic resolution isn't exactly rocket science. It's a very simple technique that is easily implemented. Furthermore, it removes the restrictions associated with direct mapping. There is no need for any specific relationship between the network layer address and the data link layer address; they can have a completely different structure and size.

There is one nagging issue though: the efficiency problem. Where direct mapping involves a quick calculation, dynamic resolution requires us to use a protocol to send a message over the network. Fortunately, there are techniques that we can employ to remove some of the sting of this cost through careful implementation.

## **Dynamic Address Resolution Caching and Efficiency Issues**

**Dynamic address resolution** removes the restrictions that we saw in our look at **direct mapping**, and allows us to easily associate layer two and layer three addresses of any size or structure. The only problem with it is that each address resolution requires us to send an extra message that would not be required in direct mapping. Worse yet, since we don't know the layer two identity of the recipient, we must use a **broadcast message** (or at least a multicast), which means that many devices on the local network must take resources to examine the data frame and check which IP address is being resolved.

---

Sure, sending one extra message may not seem like that big a deal, and the frame doesn't have to be very large since it contains only a network layer address and some control information. However, when we have to do this for **every** hop of **every** datagram transmission, the overhead really adds up. For this reason, while basic dynamic address resolution as described in the previous topic is simple and functional, it's usually not enough. We must add some **intelligence** to the implementation of address resolution to reduce the impact on performance of continual address resolutions.

### ***The Benefits of Caching***

Consider that most devices on a local network send to only a small handful of other physical devices, and tend to do so over and over again. This is a phenomenon known as *locality of reference*, and is observed in a variety of different areas in the field of computing. If you send a request to an Internet Web site from your office PC, it will need to go first to your company network's local router, so you will need to resolve the router's layer two address. If you later click a link on that site, that request will also need to go to the router. In fact, almost everything you do off your local network probably goes first to that same router (commonly called a *default gateway*). Having to do a fresh resolution each time is, well, stupid. It would be like having to look up the phone number of your best friend every time you want to call to say hello. (Reminds me of that sketch on Saturday Night Live where the guy had no short-term memory—but I digress.)

To avoid being accused of making address resolution protocols that are, well, stupid, designers always include a *caching* mechanism. After a device's network layer address is resolved to a data link layer address, the link between the two is kept in the memory of the device for a period of time. When it needs the layer two address the next time, the device just does a quick lookup in its cache. This means instead of doing a broadcast on every datagram, we only do it once for a whole sequence of datagrams.

Caching is by far the most important performance-enhancing tool in dynamic resolution. It transforms what would otherwise be a very wasteful process into one which most of the time is no less efficient than direct mapping. It does, however, add complexity. The cache table entries must be maintained. There is also the problem that the information in the table may become *stale* over time; what happens if we change the network layer address or the data link layer address of a device? For this reason, cache entries must be set to expire periodically. [The topic on caching in the TCP/IP ARP protocol](#) shows some of the particulars of how these issues are handled.

### ***Other Enhancements to Dynamic Resolution***

Other enhancements are also possible to the basic dynamic resolution scheme. Let's consider again our example of sending a request to the Internet. We send a request that needs to go to our local router, so we resolve its address and send it the request. A moment later the reply comes back to the router to be sent to us, so the router needs *our* address. Thus, it would have to do a dynamic resolution on us even though we just exchanged frames. Again: stupid. Instead, we can improve efficiency through *cross-resolution*; when device *A* resolves the address of device *B*, device *B* also adds the entry for device *A* to *its* cache.

---

Another improvement can be made too. If you think about it, the devices on a local network are going to talk to each other fairly often, even if they aren't chatting right now. If *A* is resolving *B*'s network layer address, it will broadcast a frame that devices *C*, *D*, *E* and so on all see. Why not have them also update **their** cache tables with resolution information that they see, for future use?

These and other enhancements all serve to cut down on the efficiency problems with dynamic address resolution. They combine to make dynamic resolution close enough to direct mapping in overall capability that there is no good reason not to use it. Once again, you can see some more particulars of this in [the topic that describes the TCP/IP ARP protocol's caching feature](#).

Incidentally, one other performance-improving idea sometimes is brought up in this discussion: instead of preceding a datagram transmission with an extra broadcast step for address resolution, why not just broadcast the datagram and be done with it? We actually could do this, and if the datagram were small enough it would be more efficient. Usually, though, datagrams are large, while resolution frames can be quite compact; it makes sense to do a small broadcast and then a large unicast rather than a large broadcast. Also, suppose we did broadcast this one datagram: what about the next datagram and the one after that? Each of these would then need to be broadcast also. When we do a resolution, with caching, we need to broadcast only once in a while instead of continually.

---

## TCP/IP Address Resolution Protocol (ARP)

The most widely used network layer protocol in the world—by far—is the [TCP/IP Internet Protocol](#). It's no surprise then, that the most important address resolution protocol is the TCP/IP protocol bearing the same name as the technique itself: the *Address Resolution Protocol (ARP)*. ARP is a full-featured [dynamic resolution protocol](#) used to match IP addresses to underlying data link layer addresses. Originally developed for Ethernet, it has now been generalized to allow IP to operate over a wide variety of layer two technologies.

In this section I describe the operation and features of ARP. I begin with an overview of the protocol, and a discussion of its defining standards and history. I briefly outline how addresses are specified in ARP and its general operation, as well as describing the message format used for ARP messages. I then turn to the important matter of caching in ARP and how that is used to improve performance. I conclude with a discussion of proxying in ARP, which is needed to support special network connectivity situations.

**Background Information:** The general explanation of address resolution, what it is, and how it works, can be found in [the preceding section on address resolution concepts](#). Except for a brief recap at the start of the [overview](#), I assume you have familiarity with these concepts.

---

**Note:** The Address Resolution Protocol described here is used for resolving unicast addresses in [version 4 of the Internet Protocol](#). Multicast addresses under IPv4 use a direct mapping method, [described in a separate topic](#). IPv6 uses the new [Neighbor Discovery protocol](#) instead of ARP; this is discussed in [the overview of IPv6 address resolution](#).

---

**Related Information:** For a discussion of ARP-related issues in networks with mobile IP devices, see [the section on Mobile IP](#).

---

**Related Information:** The software application “arp”, which is used to administer the TCP/IP ARP implementation on a host, is covered in [its own topic](#) in [the section on TCP/IP utilities](#).

---

---

## ARP Overview, Standards and History

Physical networks function at layers one and two of the OSI Reference Model, and use data link layer addresses. In contrast, internetworking protocols function at layer three, interconnecting these physical networks to create a possibly huge internetwork of devices specified using network layer addresses. Address resolution is the process where network layer addresses are resolved into data link layer addresses, to permit data to be sent one hop at a time across an internetwork. [I describe address resolution in detail in the preceding section on concepts.](#)

The problem of address resolution was apparent from the very start in the development of the TCP/IP protocol suite. Much of the early development of IP was performed on the then-fledgling [Ethernet local area networking technology](#); this was even before Ethernet had been officially standardized as IEEE 802.3. It was necessary to define a way to map IP addresses to Ethernet addresses to allow communication over Ethernet networks.

There are two basic methods that resolution could have been used to accomplish this correlation of addresses: [direct mapping](#) or [dynamic resolution](#). However, Ethernet addresses are 48 bits long while IP addresses are only 32 bits, which immediately rules out direct mapping. Furthermore, the designers of IP wanted the flexibility that results from using the dynamic resolution model. To this end, they developed the TCP/IP *Address Resolution Protocol (ARP)*. This protocol is described in one of the earliest of the Internet RFCs still in common use: RFC 826, *An Ethernet Address Resolution Protocol*, published in 1982.

The name makes clear that ARP was originally developed for Ethernet. Thus, it represents a nexus between the most popular layer two LAN protocol and the most popular layer three internetworking protocol—this is true even two decades later. However, it was also obvious from the beginning that even if Ethernet was a very common way of transporting IP, it would not be the only one. Therefore, ARP was made a general protocol capable of resolving addresses from IP to not just Ethernet but numerous other data link layer technologies.

The basic operation of ARP involves encoding the IP address of the intended recipient in a broadcast message. It is sent on a local network to allow the intended recipient of an IP datagram to respond to the source with its data link layer address. This is done using a simple request/reply method described in [the following topic on general operation](#). A [special format is used for ARP messages](#), which are passed down to the local data link layer for transmission.

**Key Concept:** *ARP* was developed to facilitate dynamic address resolution between IP and Ethernet, and can now be used on other layer two technologies as well. It works by allowing an IP device to send a broadcast on the local network, requesting that another device on the same local network respond with its hardware address.

---

---

This basic operation is supplemented by methods to improve performance. Since it was known from the start that having to perform a resolution using broadcast for each datagram was ridiculously inefficient, ARP has always used a [cache](#), where it keeps bindings between IP addresses and data link layer addresses on the local network. Over time, various techniques have been developed to improve the methods used for maintaining cache entries. Refinements and additional features, such as support for cross-resolution by pairs of devices as well as [proxy ARP](#), have also been defined over the years and added to the basic ARP feature set.

## **ARP Address Specification and General Operation**

An Address Resolution Protocol transaction begins when a source device on an IP network has an IP datagram to send. It must first decide whether the destination device is on the local network or a distant network. If the former, it will send directly to the destination; if the latter, it will send the datagram to one of the routers on the physical network for forwarding. Either way, it will determine the IP address of the device that needs to be the immediate destination of its IP datagram on the local network. After packaging the datagram it will pass it to its ARP software for address resolution.

Basic operation of ARP is a *request/response* pair of transmissions on the local network. The source (the one that needs to send the IP datagram) transmits a [broadcast](#) containing information about the destination (the intended recipient of the datagram). The destination then responds unicast back to the source, telling the source the hardware address of the destination.

### ***ARP Message Types and Address Designations***

The terms source and destination apply to the same devices throughout the transaction. However, there are two different messages sent in ARP, one from the source to the destination and one from the destination to the source. For each ARP message, the *sender* is the one that is transmitting the message and the *target* is the one receiving it. Thus, the identity of the sender and target change for each message:

- ☉ **Request:** For the initial request, the sender is the source, the device with the IP datagram to send, and the target is the destination.
- ☉ **Reply:** For the reply to the ARP request, the sender is the destination; it replies to the source, which becomes the target.

It's a bit confusing, but you'll get used to it. ☺ Each of the two parties in any message has two addresses (layer two and layer three) to be concerned with, so four different addresses are involved in each message:

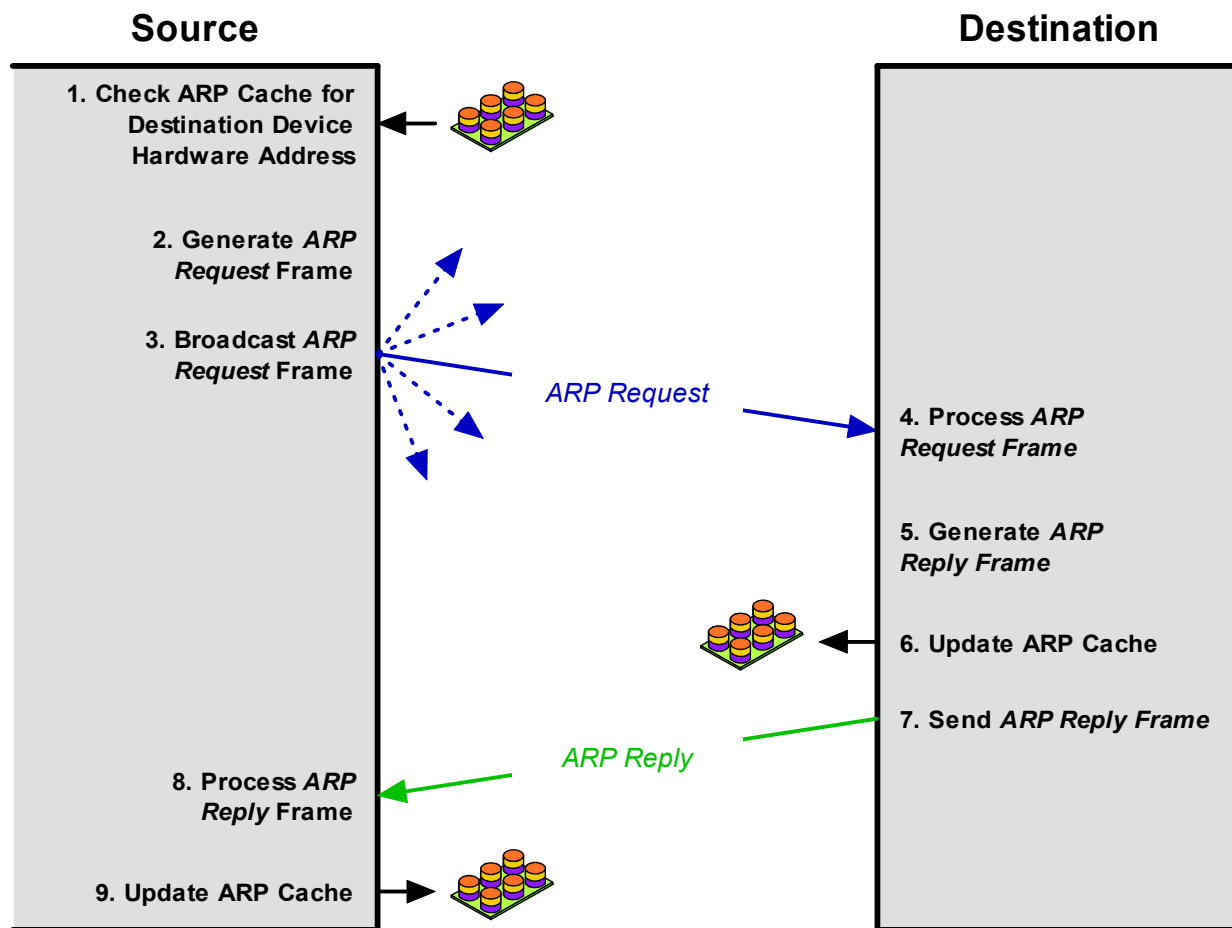

- ☉ **Sender Hardware Address:** The layer two address of the sender of the ARP message.
- ☉ **Sender Protocol Address:** The layer three (IP) address of the sender of the ARP message.
- ☉ **Target Hardware Address:** The layer two address of the target of the ARP message.

- ☹ **Target Protocol Address:** The layer three (IP) address of the target.

These addresses each have a position in the [ARP message format](#).

### ARP General Operation

With that background in place, let's look at the steps followed in an ARP transaction (which are also shown graphically in the illustration in [Figure 48](#)):

**Figure 48: Address Resolution Protocol (ARP) Transaction Process**

This diagram shows the sequence of steps followed in a typical ARP transaction, as well as the message exchanges between a source and destination device, and cache checking and update functions. (Those little columns are supposed to be hard disks, not cans of soup! ☺)

1. **Source Device Checks Cache:** The source device will first check its [cache](#) to determine if it already has a resolution of the destination device. If so, it can skip to the last step of this process, step #9.

- 
2. **Source Device Generates ARP Request Message:** The source device generates an *ARP Request* message. It puts its own data link layer address as the *Sender Hardware Address* and its own IP address as the *Sender Protocol Address*. It fills in the IP address of the destination as the *Target Protocol Address*. (It must leave the *Target Hardware Address* blank, since that is what it is trying to determine!)
  3. **Source Device Broadcasts ARP Request Message:** The source broadcasts the *ARP Request* message on the local network.
  4. **Local Devices Process ARP Request Message:** The message is received by each device on the local network. It is processed, with each device looking for a match on the *Target Protocol Address*. Those that do not match will drop the message and take no further action.
  5. **Destination Device Generates ARP Reply Message:** The one device whose IP address matches the contents of the *Target Protocol Address* of the message will generate an *ARP Reply* message. It takes the *Sender Hardware Address* and *Sender Protocol Address* fields from the *ARP Request* message and uses these as the values for the *Target Hardware Address* and *Target Protocol Address* of the reply. It then fills in its own layer two address as the *Sender Hardware Address* and its IP address as the *Sender Protocol Address*. Other fields are filled in as explained in [the topic describing the ARP message format](#).
  6. **Destination Device Updates ARP Cache:** If the source needs to send an IP datagram to the destination now, it makes sense that the destination will probably need to send a response to the source at some point soon. (After all, most communication on a network is bidirectional.) As an optimization, then, the destination device will add an entry to its own ARP cache containing the hardware and IP addresses of the source that sent the *ARP Request*. This saves the destination from needing to do an unnecessary resolution cycle later on.
  7. **Destination Device Sends ARP Reply Message:** The destination device sends the *ARP reply* message. This reply is, however, sent unicast to the source device, as there is no need to broadcast it.
  8. **Source Device Processes ARP Reply Message:** The source device processes the reply from the destination. It stores the *Sender Hardware Address* as the layer two address of the destination, to use for sending its IP datagram.
  9. **Source Device Updates ARP Cache:** The source device uses the *Sender Protocol Address* and *Sender Hardware Address* to update its ARP cache for use in the future when transmitting to this device.

**Key Concept:** ARP is a relatively simple request/reply protocol. The source device broadcasts an *ARP Request* looking for a particular device based on its IP address. That device responds with its hardware address in an *ARP Reply* message.

---

Note that this description goes a bit beyond the basic steps in address resolution, because two enhancements are mentioned. One is caching, which is described in [its own topic](#) but had to be mentioned here because it is the first step in the process, for obvious reasons. The other is cross-resolution (described in [the overview of caching issues in dynamic](#)

[resolution](#)), which is step #6 of the process. This is why the source device includes its IP address in the request. It isn't really needed for any other reason, so you can see that this feature was built into ARP from the start.

## **ARP Message Format**

Address resolution using [ARP](#) is accomplished through the [exchange of messages](#) between the source device seeking to perform the resolution, and the destination device that responds to it. As with other protocols, a special *message format* is used containing the information required for each step of the resolution process.

ARP messages use a relatively simple format. It includes a field describing the type of message (its *operational code* or *opcode*) and information on both layer two and layer three addresses. In order to support addresses that may be of varying length, the format specifies the type of protocol used at both layer two and layer three and the length of addresses used at each of these layers. It then includes space for all four of the address combinations we saw in [the previous topic](#).

The format used for ARP messages is described fully in [Table 43](#), and illustrated in [Figure 49](#).

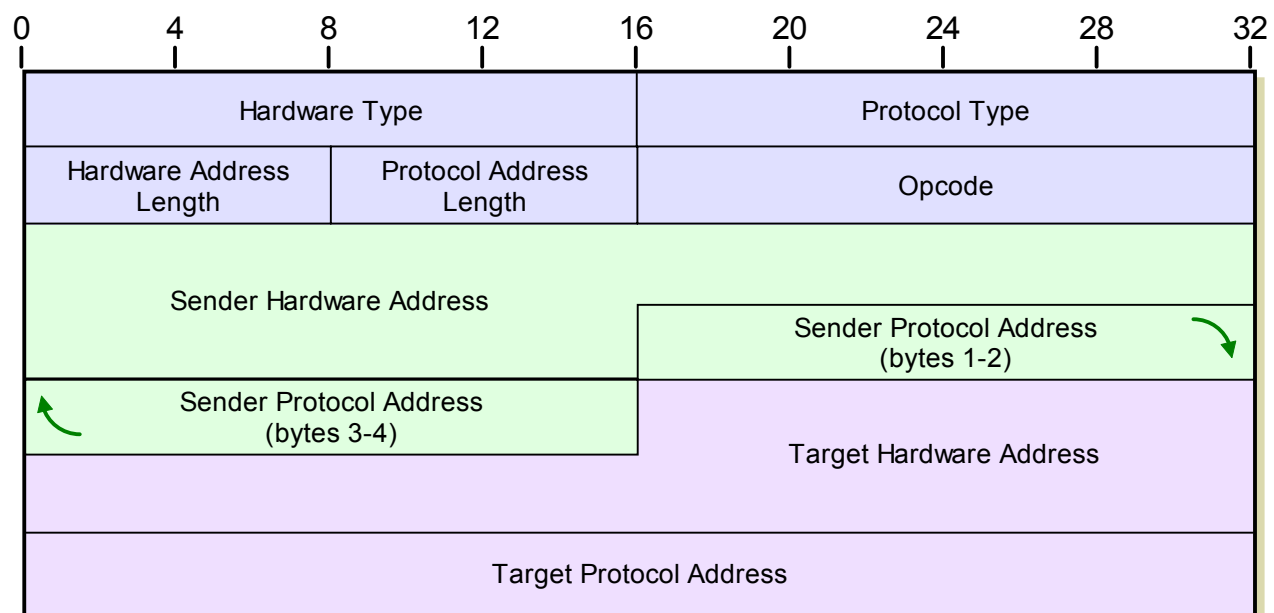

**Table 43: Address Resolution Protocol (ARP) Message Format (Page 1 of 2)**

Field Name	Size (bytes)	Description																				
HRD	2	<b>Hardware Type:</b> This field specifies the type of hardware used for the local network transmitting the ARP message; thus, it also identifies the type of addressing used. Some of the most common values for this field: <table><tr><th>HRD Value</th><th>Hardware Type</th></tr><tr><td>1</td><td>Ethernet (10 Mb)</td></tr><tr><td>6</td><td>IEEE 802 Networks</td></tr><tr><td>7</td><td>ARCNET</td></tr><tr><td>15</td><td>Frame Relay</td></tr><tr><td>16</td><td>Asynchronous Transfer Mode (ATM)</td></tr><tr><td>17</td><td>HDLC</td></tr><tr><td>18</td><td>Fibre Channel</td></tr><tr><td>19</td><td>Asynchronous Transfer Mode (ATM)</td></tr><tr><td>20</td><td>Serial Line</td></tr></table>	HRD Value	Hardware Type	1	Ethernet (10 Mb)	6	IEEE 802 Networks	7	ARCNET	15	Frame Relay	16	Asynchronous Transfer Mode (ATM)	17	HDLC	18	Fibre Channel	19	Asynchronous Transfer Mode (ATM)	20	Serial Line
		HRD Value	Hardware Type																			
		1	Ethernet (10 Mb)																			
		6	IEEE 802 Networks																			
		7	ARCNET																			
		15	Frame Relay																			
		16	Asynchronous Transfer Mode (ATM)																			
		17	HDLC																			
		18	Fibre Channel																			
		19	Asynchronous Transfer Mode (ATM)																			
		20	Serial Line																			
PRO	2	<b>Protocol Type:</b> This field is the complement of the <i>Hardware Type</i> field, specifying the type of layer three addresses used in the message. For IPv4 addresses, this value is 2048 (0800 hex), which corresponds to the EtherType code for the Internet Protocol.																				

**Table 43: Address Resolution Protocol (ARP) Message Format (Page 2 of 2)**

Field Name	Size (bytes)	Description																				
HLN	1	<b>Hardware Address Length:</b> Specifies how long hardware addresses are in this message. For Ethernet or other networks using IEEE 802 MAC addresses, the value is 6.																				
PLN	1	<b>Protocol Address Length:</b> Again, the complement of the preceding field; specifies how long protocol (layer three) addresses are in this message. For IP(v4) addresses this value is of course 4.																				
OP	2	<b>Opcode:</b> This field specifies the nature of the ARP message being sent. The first two values (1 and 2) are used for regular ARP. Numerous other values are also defined to support other protocols that use the ARP frame format, such as RARP, some of which are more widely used than others: <table><tr><th>Opcode</th><th>ARP Message Type</th></tr><tr><td>1</td><td>ARP Request</td></tr><tr><td>2</td><td>ARP Reply</td></tr><tr><td>3</td><td>RARP Request</td></tr><tr><td>4</td><td>RARP Reply</td></tr><tr><td>5</td><td>DRARP Request</td></tr><tr><td>6</td><td>DRARP Reply</td></tr><tr><td>7</td><td>DRARP Error</td></tr><tr><td>8</td><td>InARP Request</td></tr><tr><td>9</td><td>InARP Reply</td></tr></table>	Opcode	ARP Message Type	1	ARP Request	2	ARP Reply	3	RARP Request	4	RARP Reply	5	DRARP Request	6	DRARP Reply	7	DRARP Error	8	InARP Request	9	InARP Reply
Opcode	ARP Message Type																					
1	ARP Request																					
2	ARP Reply																					
3	RARP Request																					
4	RARP Reply																					
5	DRARP Request																					
6	DRARP Reply																					
7	DRARP Error																					
8	InARP Request																					
9	InARP Reply																					
SHA	(Variable, equals value in HLN field)	<b>Sender Hardware Address:</b> The hardware (layer two) address of the device sending this message (which is the IP datagram source device on a request, and the IP datagram destination on a reply, as discussed in the topic on ARP operation).																				
SPA	(Variable, equals value in PLN field)	<b>Sender Protocol Address:</b> The IP address of the device sending this message.																				
THA	(Variable, equals value in HLN field)	<b>Target Hardware Address:</b> The hardware (layer two) address of the device this message is being sent to. This is the IP datagram destination device on a request, and the IP datagram source on a reply)																				
TPA	(Variable, equals value in PLN field)	<b>Target Protocol Address:</b> The IP address of the device this message is being sent to.																				

**Figure 49: Address Resolution Protocol (ARP) Message Format**

The ARP message format is designed to accommodate layer two and layer three addresses of various sizes.

This diagram shows the most common implementation, which uses 32 bits for the layer three (“Protocol”) addresses, and 48 bits for the layer two hardware addresses. These numbers of course correspond to the address sizes of the [Internet Protocol version 4](#) and [IEEE 802 MAC addresses](#), used by Ethernet.

After the ARP message has been composed it is passed down to the data link layer for transmission. The entire contents of the message becomes the payload for the message actually sent on the network, such as an Ethernet frame. Note that the total size of the ARP message is variable, since the address fields are of variable length. Normally, though, these messages are quite small: for example, they are only 28 bytes for a network carrying IPv4 datagrams in IEEE 802 MAC addresses.

## ARP Caching

ARP is a [dynamic resolution protocol](#), which means that every resolution requires the interchange of messages on the network. Each time a device sends an ARP message, it ties up the local network, consuming network bandwidth that cannot be used for “real” data traffic. ARP messages aren't large, but having to send them for every hop of every IP datagram would represent an unacceptable performance hit on the network. It also wastes time compared to the simpler direct mapping method of resolution. On top of this, the *ARP Request* message is broadcasted, which means every device on the local network must spend CPU time examining the contents of each one.

The general solution to the efficiency issues with dynamic resolution is to employ *caching*, which I described in general terms in the [section on address resolution concepts](#). In addition to reducing network traffic, caching also ensures that the resolution of commonly-used addresses is fast, making overall performance comparable to direct mapping. For this reason, caching functionality has been [built into ARP](#) from the start.

---

## Static and Dynamic ARP Cache Entries

The ARP cache takes the form of a table containing matched sets of hardware and IP addresses. Each device on the network manages its own ARP cache table. There are two different ways that cache entries can be put into the ARP cache:

- ① **Static ARP Cache Entries:** These are address resolutions that are manually added to the cache table for a device and are kept in the cache on a permanent basis. Static entries are typically managed using a tool such as the [arp software utility](#).
- ② **Dynamic ARP Cache Entries:** These are hardware/IP address pairs that are added to the cache by the software itself as a result of successfully-completed past ARP resolutions. They are kept in the cache only for a period of time and are then removed.

A device's ARP cache can contain both static and dynamic entries, each of which has advantages and disadvantages. However, dynamic entries are used most often because they are automatic and don't require administrator intervention.

Static ARP entries are best used for devices that a given device has to communicate with on a regular basis. For example, a workstation might have a static ARP entry for its local router and file server. Since the entry is static it is always found in [step #1 of the ARP transaction process](#), there is no need to ever send resolution messages for the destination in that entry. The disadvantage is that these entries must be manually added, and they must also be changed if the hardware or IP addresses of any of the hardware in the entries change. Also, each static entry takes space in the ARP cache, so you don't want to "overuse" static entries. It wouldn't be a good idea to have static entries for every device on the network, for example.

## Cache Entry Expiration

Dynamic entries are added automatically to the cache on an "as needed" basis, so they represent mappings for hosts and routers that a given device is actively using. They do not need to be manually added or maintained. However, it is also important to realize that dynamic entries cannot be added to the cache and left there forever. The reason for this is that due to changes in the network, dynamic entries left in place for a long time can become *stale*.

Consider device A's ARP cache, which contains a dynamic mapping for device B, another host on the network. If dynamic entries stayed in the cache forever, the following situations might arise:

- ① **Device Hardware Changes:** Device B might experience a hardware failure that requires its network interface card to be replaced. The mapping in device A's cache would become invalid, since the hardware address in the entry is no longer on the network.
- ② **Device IP Address Changes:** Similarly, the mapping in device A's cache also would become invalid if device B's IP address changed.
- ③ **Device Removal:** Suppose device B is removed from the local network. Device A would never need to send to it again at the data link layer, but the mapping would remain in device A's cache, wasting space and possibly taking up search time.

---

To avoid these problems, dynamic cache entries must be set to automatically expire after a period of time. This is handled automatically by the ARP implementation, with typical timeout values being 10 or 20 minutes. After a particular entry times out, it is removed from the cache. The next time that address mapping is needed a fresh resolution is performed to update the cache. This is very slightly less efficient than static entries, but sending two 28-byte messages every 10 or 20 minutes isn't a big deal.

As mentioned in [the overview of ARP operation](#), dynamic cache entries are added not only when a device initiates a resolution, but when it is the destination device as well. This is another enhancement that reduces unnecessary address resolution traffic.

### ***Additional Caching Features***

Other enhancements are also typically put into place, depending on the implementation. Standard ARP requires that if device *A* initiates resolution with a broadcast, each device on the network should update its own cache entries for device *A* even if they are not the device that *A* is trying to reach. However, these “third party” devices are ***not*** required to create new cache entries for *A* in this situation.

The issue here is a trade-off: creating a new cache entry would save any of those devices from needing to resolve device *A*'s address in the near future. However, it also means every device on the network will quickly have an ARP cache table filled up with the addresses of most of the other devices on the network. This may not be desirable in larger networks. Even in smaller ones, this model may not make sense, given that modern computing is [client/server in nature](#) and peer devices on a LAN may not often communicate directly. Some devices may choose to create such cache entries, but set them to expire after a very short time to avoid filling the cache.

Each ARP implementation is also responsible for any other “housekeeping” required to maintain the cache. For example, if a device is on a local network with many hosts and its cache table is too small, it might be necessary for older, less-frequently-used entries to be removed to make room for newer ones. Ideally, the cache should be large enough to hold all other devices on the network that a device communicates with on a regular basis, along with some room for ones it occasionally talks to.

### **Proxy ARP**

ARP was designed to be used by devices that are directly connected on a local network. Each device on the network should be capable of sending both unicast and broadcast transmissions directly to each other one. Normally, if device *A* and device *B* are separated by a router, they would not be considered local to each other. Device *A* would not send directly to *B* or vice-versa; they would send to the router instead at layer two, and would be considered “two hops apart” at layer three.

---

## Why Proxy ARP Is Needed

In contrast to the normal situation, in some networks there might be two physical network segments connected by a router that are in the same IP network or subnet. In other words, device *A* and device *B* might be on different networks at the data link layer level, but on the same IP network or subnet. When this happens, *A* and *B* will each think the other is on the local network when they look to send IP datagrams.

In this situation, suppose that *A* wants to send a datagram to *B*. It doesn't have *B*'s hardware address in the cache, so it begins an address resolution. When it broadcasts the *ARP Request* message to get *B*'s hardware address, however, it will quickly run into a problem: *B* is in fact not on *A*'s local network. The router between them will not pass *A*'s broadcast onto *B*'s part of the network, because routers don't pass hardware-layer broadcasts. *B* will never get the request and thus *A* will not get a reply containing *B*'s hardware address.

## Proxy ARP Operation

The solution to this situation is called *ARP proxying* or *Proxy ARP*. In this technique, the router that sits between the local networks is configured to respond to device *A*'s broadcast on behalf of device *B*. It does not send back to *A* the hardware address of device *B*; since they are not on the same network, *A* cannot send directly to *B* anyway. Instead, the router sends *A* its own hardware address. *A* then sends to the router, which forwards the message to *B* on the other network. Of course, the router also does the same thing on *A*'s behalf for *B*, and for every other device on both networks, when a broadcast is sent that targets a device not on the same actual physical network as the resolution initiator. This is illustrated in [Figure 50](#).

Proxy ARP provides flexibility for networks where hosts are not all actually on the same physical network but are configured as if they were at the network layer. It can be used to provide support in other special situations where a device cannot respond directly to ARP message broadcasts. It may be used when a firewall is configured for security purposes. A type of proxying is also used [as part of the Mobile IP protocol](#), to solve the problem of address resolution when a mobile device travels away from its home network.

**Key Concept:** Since ARP relies on broadcasts for address resolution, and broadcasts are not propagated beyond a physical network, ARP cannot function between devices on different physical networks. When such operation is required, a device, such as a router, can be configured as an ARP proxy to respond to ARP requests on the behalf of a device on a different network.

---

## Advantages and Disadvantages of Proxying

The main advantage of proxying is that it is transparent to the hosts on the different physical network segments. The technique has some drawbacks though. First, it introduces added complexity. Second, if more than one router connects two physical networks using the

**Figure 50: ARP Proxy Operation**

In this small internetwork, a single router connects two LANs that are on the same IP network or subnet. The router will not pass ARP broadcasts, but has been configured to act as an ARP proxy. In this example, device A and device D are each trying to send an IP datagram to the other, and so each broadcasts an *ARP Request*.

The router responds to the request sent by Device A as if it were Device D, giving to A its own hardware address (without propagating Device A's broadcast.) It will forward the message sent by A to D on D's network. Similarly, it responds to Device D as if it were Device A, giving its own address, then forwarding what D sends to it over to the network where A is located.

same network ID, problems may arise. Third, it introduces potential security risks; since it essentially means that a router “impersonates” devices in acting as a proxy for them, raising the potential for a device to spoof another. For these reasons, it may be better to redesign the network so routing is done between physical networks separated by a router, if possible.

---

## TCP/IP Address Resolution For IP Multicast Addresses

Like most discussions of address resolution, the preceding sections all focus on [unicast communication](#), where a datagram is sent from one source device to one destination device. Whether direct mapping or dynamic resolution is used for resolving a network layer address, it is a relatively simple matter to resolve addresses when there is only one intended recipient of the datagram. TCP/IP uses [ARP](#) for its dynamic resolution scheme, which is designed for unicast resolution only.

However, the Internet Protocol also supports *multicasting* of datagrams, as I explain in the topics on [IP multicasting](#) and [IP multicast addressing](#). In this situation, the datagram must be sent to multiple recipients, which complicates matters considerably. We need to establish a relationship of some sort between the IP multicast group address and the addresses of the devices at the data link layer. We could do this by converting the IP multicast datagram to individual unicast transmissions at the data link layer, each using ARP for resolution, but this would be horribly inefficient.

### ***Direct Mapping Technique for IEEE 802 Multicast MAC Addresses***

When possible, IP makes use of the multicast addressing and delivery capabilities of the underlying network to deliver multicast datagrams on a physical network. Perhaps surprisingly, even though ARP employs dynamic resolution, multicast address resolution is done using a version of the [direct mapping technique](#). By defining a *mapping* between IP multicast groups and data link layer multicast groups we enable physical devices to know when to pay attention to multicasted datagrams.

The most commonly used multicast-capable data link addressing scheme is the [IEEE 802 addressing system](#) best known for its use in Ethernet networks. These data link layer addresses have 48 bits, arranged into two blocks of 24. The upper 24 bits are arranged into a block called the *organizationally unique identifier (OUI)*, with different values assigned to individual organizations; the lower 24 bits are then used for specific devices.

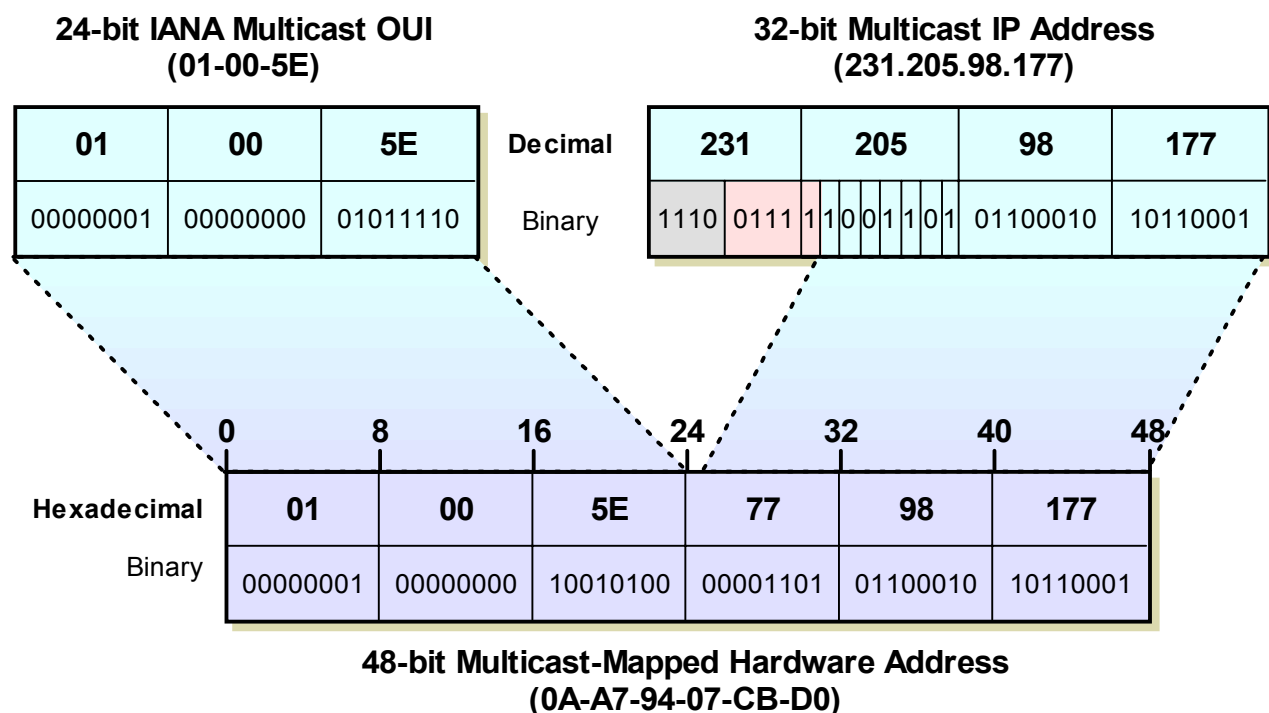

The [Internet Assigned Number Authority \(IANA\)](#) itself has an OUI that it uses for mapping multicast addresses to IEEE 802 addresses. This OUI is "01:00:5E". To form a mapping for Ethernet, 24 bits are used for this OUI and the 25th (of the 48) is always zero. This leaves 23 bits of the original 48 to encode the multicast address. To do the mapping, the lower-order 23 bits of the multicast address are used as the last 23 bits of the Ethernet address starting with "01:00:5E" for sending the multicast message. This process is illustrated in [Figure 51](#).

**Key Concept:** IP multicast addresses are resolved to IEEE 802 (Ethernet) MAC addresses using a direct mapping technique that uses 23 of the 28 bits in the IP multicast group address.

---

**Figure 51: Mapping of Multicast IP Addresses to IEEE 802 Multicast MAC Addresses**

IP multicast addresses consist of the bit string “1110” followed by a 28-bit multicast group address. To create a 48-bit multicast IEEE 802 (Ethernet) address, the top 24 bits are filled in with the IANA’s multicast OUI, 01-00-5E, the 25th bit is zero, and the bottom 23 bits of the multicast group are put into the bottom 23 bits of the MAC address. This leaves 5 bits (shown in pink) that are not mapped to the MAC address, meaning that 32 different IP addresses may have the same mapped multicast MAC address.

### ***Dealing With Multiple IP Addresses Mapped To One Multicast Hardware Address***

Of course, there are 28 unique bits in IP multicast addresses, so this is a “bit” of a problem. ☺ What it means is that there is no unique mapping between IP multicast addresses and Ethernet multicast addresses. Since 5 of the 28 bits of the multicast group cannot be encoded in the Ethernet address, 32 ( $2^5$ ) different IP multicast addresses map onto each possible Ethernet multicast address. In theory, this would be a problem, but in practice, it isn’t. The chances of any two IP multicast addresses on a single network mapping to the same Ethernet multicast address at the same time are pretty small.

Still, it is possible that two IP multicast groups might be in use on the same physical network and might map to the same data link layer multicast address. For this reason, devices must not assume that all multicast messages they receive are for their groups; they must pass up the messages to the IP layer to check the full IP multicast address to make sure they really were supposed to get the multicast datagram they received. If they accidentally get one that was intended for a multicast group they are not a member of, they discard it. This happens infrequently so the relative lack of efficiency is not a large concern.

---

## TCP/IP Address Resolution For IP Version 6

The [TCP/IP Address Resolution Protocol \(ARP\)](#) is a fairly generic protocol for dynamically resolving network layer addresses into data link layer addresses. Even though it was designed for IP version 4, the message format allows for variable-length addresses at both the hardware and network layers. This flexibility means it would have been theoretically possible to use it for the new version of IP—[version 6, or IPv6](#)—that is in our future. Some minor changes might have been required, but the technique could have been about the same.

The designers of IPv6 chose not to do this, however. Changing IP is a big job that has been underway for many years, and represents a rare opportunity to change various aspects of TCP/IP. The IETF decided to take advantage of the changes in IPv6 to overhaul not only IP itself, but also many of the protocols that “support” or “assist” IP. In IPv6, the address resolution job of ARP has been combined with several functions performed by ICMP in the original TCP/IP suite, supplemented with additional capabilities and defined as the new [Neighbor Discovery \(ND\) protocol](#).

The term “neighbor” in IPv6 simply refers to devices on a local network, and as the name implies, ND is responsible for tasks related to communicating information between neighbors (among other things). I describe ND briefly in [its own section](#), including a discussion of the various tasks it performs. Here I want to focus specifically on how ND performs address resolution.

### **Basic IPv6 Address Resolution Method**

The basic concepts of address resolution in IPv6 ND aren't all that different from those in IPv4 ARP. Resolution is still dynamic and is based on the use of a cache table that maintains pairings of IPv6 addresses and hardware addresses. Each device on a physical network keeps track of this information for its neighbors. When a source device needs to send an IPv6 datagram to a local network neighbor but doesn't have its hardware address, it initiates the resolution process. For clarity in the text let's say that, as usual, device *A* is trying to send to device *B*.

Instead of sending an *ARP Request* message, *A* creates an ND *Neighbor Solicitation* message. Now, here's where the first big change can be seen from ARP. If the underlying data link protocol supports multicasting, like Ethernet does, the *Neighbor Solicitation* message is not broadcast. Instead, it is sent to the *solicited-node address* of the device whose IPv6 address we are trying to resolve. So *A* won't broadcast the message, it will multicast it to device *B*'s solicited-node multicast address.

Device *B* will receive the *Neighbor Solicitation* and respond back to device *A* with a *Neighbor Advertisement*. This is analogous to the *ARP Reply* and tells device *A* the physical address of *B*. Device *A* then adds device *B*'s information to its neighbor cache. For efficiency, cross-resolution is supported as in IPv4 address resolution. This is done by having Device *A* include its own layer two address in the *Neighbor Solicitation*, assuming it knows it. Device *B* will record this along with *A*'s IP address in *B*'s neighbor cache.

---

## Using Solicited-Node Multicast Addresses For Resolution

The solicited-node multicast address is a special mapping that each device on a multicast-capable network creates from its unicast address; [it is described in the topic on IPv6 multicast addresses](#). The solicited-node address isn't unique for every IPv6 address, but the odds of any two neighbors on a given network having the same one are small. Each device that receives a multicasted *Neighbor Solicitation* must still check to make sure it is the device whose address the source is trying to resolve. (This is [similar to how multicast is handled in IPv4](#), with 32 different IP addresses potentially sharing a multicast MAC address.)

Why bother with this, if devices still have to check each message? Simple: the multicast will affect at most a small number of devices. With a broadcast, each and every device on the local network would receive the message, while the use of the solicited-node address means at most a couple of devices will need to process it. Other devices don't even have to bother checking the *Neighbor Solicitation* message at all.

**Key Concept:** Address resolution in IPv6 uses the new *Neighbor Discovery (ND)* protocol instead of the Address Resolution Protocol. A device trying to send an IPv6 datagram sends a *Neighbor Solicitation* message to get the address of another device, which responds with a *Neighbor Advertisement*. When possible, the request is sent using a special type of multicast address rather than broadcast, to improve efficiency.

---

This is actually a fairly simplified explanation of how resolution works in IPv6—the Neighbor Discovery protocol is quite complicated. Neighbor solicitations and advertisements are also used for other functions such as testing reachability of nodes and determining if duplicate addresses are in use. There are many special cases and issues that ND addresses to ensure that no problems result during address resolution. ND also supports proxied address resolution.

**Note:** Even though I put this topic where it would be near the other discussions of address resolution, the Neighbor Discovery protocol really isn't a “layer connection” or “lower level” protocol like ARP. It is analogous to [ICMP](#) in its role and function, and in fact makes use of [ICMP\(v6\) messages](#). One advantage of this architectural change is that there is less dependence on the characteristics of the physical network, so resolution is accomplished in a way more similar to other network support activities. Thus it is possible to make use of facilities that can be applied to all IP datagram transmissions, such as [IP security features](#). [The section on ND contains much more information on this subject.](#)

---

---

## **Reverse Address Resolution and the TCP/IP Reverse Address Resolution Protocol (RARP)**

The [TCP/IP Address Resolution Protocol \(ARP\)](#) is used when a device needs to determine the layer two (hardware) address of some other device but has only its layer three (network, IP) address. It broadcasts a hardware layer request and the target device responds back with the hardware address matching the known IP address. In theory, it is also possible to use ARP in the exact opposite way. If we know the hardware address of a device but not its IP address, we could broadcast a request containing the hardware address and get back a response containing the IP address.

### ***The Motivation For Reverse Address Resolution***

Of course the obvious question is: why would we ever need to do this? Since we are dealing with communication on an IP internetwork, we are always going to know the IP address of the destination of the datagram we need to send—it's right there in the datagram itself. We also know our own IP address as well. Or do we?

In a traditional TCP/IP network, every normal host on a network knows its IP address because it is stored somewhere on the machine. When you turn on your PC, the TCP/IP protocol software reads the IP address from a file, which allows your PC to “learn” and start using its IP address. However, there are some devices, such as diskless workstations, that don't have any means of storing an IP address where it can be easily retrieved. When these units are powered up they know their physical address only (because it's wired into the hardware) but not their IP address.

The problem we need to solve here is what is commonly called *bootstrapping* in the computer industry. This refers to the concept of starting something from a zero state; it is analogous to “pulling yourself up by your own bootstraps”. This is seemingly impossible, just as it seems paradoxical to use a TCP/IP protocol to configure the IP address that is needed for TCP/IP communications. However, it is indeed possible to do this, by making use of [broadcasts](#), which allow local communication even when the target's address is not known.

### ***The Reverse Address Resolution Protocol (RARP)***

The first method devised to address the bootstrapping problem in TCP/IP was the backwards use of ARP I mentioned above. This technique was formalized in RFC 903, [\*A Reverse Address Resolution Protocol \(RARP\)\*](#), published in 1984. Where ARP allows device *A* to say “I am device *A* and I have device *B*'s IP address, device *B* please tell me your hardware address”, RARP is used by device *A* to say “I am device *A* and I am sending this broadcast using my hardware address, can someone please tell me *my* IP address?”. The two-step operation of RARP is illustrated in [Figure 52](#).

**Figure 52: Operation of the Reverse Address Resolution Protocol (RARP)**

RARP, as the name suggests, works like ARP but in reverse, so this diagram is similar to [Figure 47](#). Here, instead of Device A providing the IP address of another device and asking for its hardware address, it is providing its own hardware address and asking for an IP address it can use. The answer, in this case, is provided by Device D, which is serving as an RARP server for this network.

The next question then is: who knows A's IP address if device A doesn't? The answer is that a special *RARP server* must be configured to listen for RARP requests and issue replies to them. Each physical network where RARP is in use must have RARP software running on at least one machine.

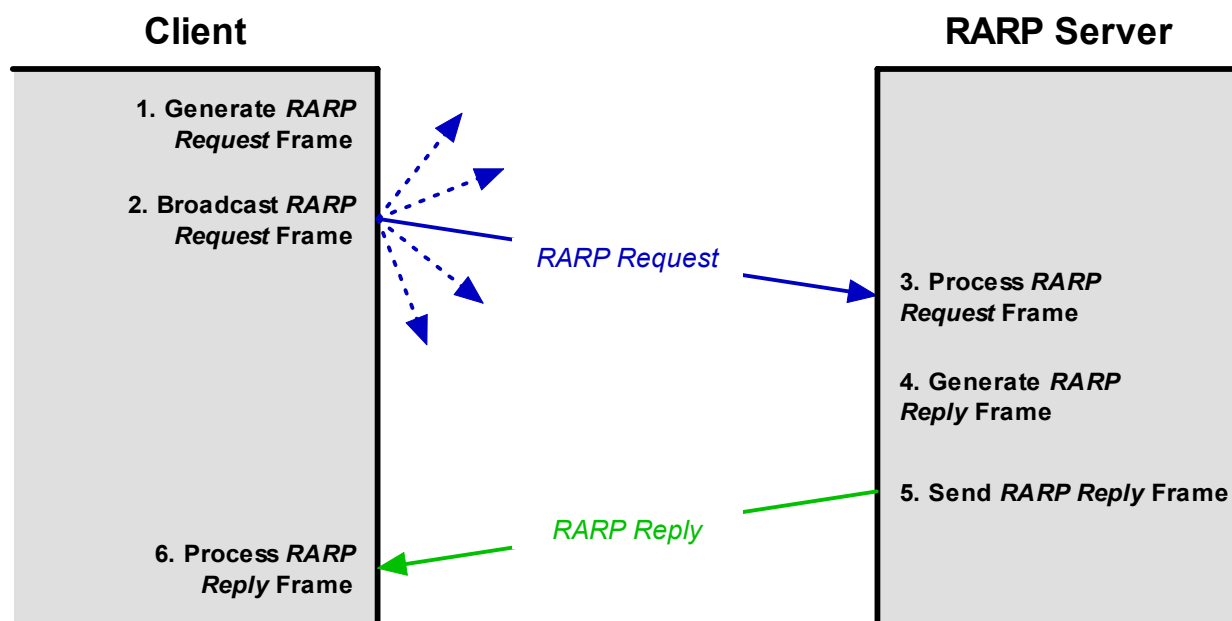

RARP is not only very similar to ARP, it basically *is* ARP. What I mean by this is that RFC 903 doesn't define a whole new protocol from scratch, it just describes a new method for using ARP to perform the opposite of its normal function. RARP uses ARP messages in [exactly the same format as ARP](#), but uses different opcodes to accomplish its reverse function. Just as in ARP, a request and reply are used in an exchange. [The meaning of the address fields is the same](#) too: the sender is the device transmitting a message while the target is the one receiving it.

**Key Concept:** The *Reverse Address Resolution Protocol (RARP)* is the earliest and simplest protocol designed to allow a device to obtain an IP address for use on a TCP/IP network. It is based directly on ARP and works in basically the same way, but in reverse: a device sends a request containing its hardware address and a device set up as an RARP server responds back with the device's assigned IP address.

### **RARP General Operation**

Here are the steps followed in a RARP transaction (illustrated in [Figure 53](#)):

**Figure 53: Reverse Address Resolution Protocol (RARP) Operation**

RARP uses a simple request/reply exchange to allow a device to obtain an IP address.

1. **Source Device Generates RARP Request Message:** The source device generates an *RARP Request* message. Thus, it uses the value 3 for the *Opcode* in the message. It puts its own data link layer address as both the *Sender Hardware Address* and also the *Target Hardware Address*. It leaves both the *Sender Protocol Address* and the *Target Protocol Address* blank, since it doesn't know either.
2. **Source Device Broadcasts RARP Request Message:** The source broadcasts the *ARP Request* message on the local network.
3. **Local Devices Process RARP Request Message:** The message is received by each device on the local network and processed. Devices that are not configured to act as RARP servers ignore the message.

- 
4. **RARP Server Generates RARP Reply Message:** Any device on the network that is set up to act as an RARP server responds to the broadcast from the source device. It generates an *RARP Reply* using an *Opcode* value of 4. It sets the *Sender Hardware Address* and *Sender Protocol Address* to its own hardware and IP address of course, since it is the sender of the reply. It then sets the *Target Hardware Address* to the hardware address of the original source device. It looks up in a table the hardware address of the source, determines that device's IP address assignment, and puts it into the *Target Protocol Address* field.
  5. **RARP Server Sends RARP Reply Message:** The RARP server sends the *RARP Reply* message unicast to the device looking to be configured.
  6. **Source Device Processes RARP Reply Message:** The source device processes the reply from the RARP server. It then configures itself using the IP address in the *Target Protocol Address* supplied by the RARP server.

It is possible that more than one RARP server may respond to any request, if two or more are configured on any local network. The source device will typically use the first reply and discard the others.

### ***Limitations of RARP***

RARP is the earliest and most rudimentary of the class of technologies I call *host configuration protocols*, which I describe in general terms in a dedicated section. As the first of these protocols, RARP was a useful addition to the TCP/IP protocol in the early 1980s, but has several shortcomings, the most important of which are:

- ☉ **Low-Level Hardware Orientation:** RARP works using hardware broadcasts. This means that if you have a large internetwork with many physical networks, you need an RARP server on **every** network segment. Worse, if you need reliability to make sure RARP keeps running even if one RARP server goes down, you need **two** on each physical network. This makes centralized management of IP addresses difficult.
- ☉ **Manual Assignment:** RARP allows hosts to configure themselves automatically, but the RARP server must still be set up with a manual table of bindings between hardware and IP addresses. These must be maintained for each server, which is again a lot of work on an administrator.
- ☉ **Limited Information:** RARP only provides a host with its IP address. It cannot provide other needed information such as, for example, [a subnet mask or default gateway](#).

Today, the importance of host configuration has increased since the early 1980s. Many organizations assign IP addresses dynamically even for hosts that have disk storage, because of the many advantages this provides in administration and efficient use of address space. For this reason, RARP has been replaced by two more capable technologies that operate at higher layers in the TCP/IP protocol stack: [BOOTP](#) and [DHCP](#). They are discussed in [the application layer section on host configuration protocols](#).

---

## **TCP/IP Internet Layer (OSI Network Layer) Protocols**

The first two layers of the [OSI Reference Model](#), the physical layer and data link layer, deal primarily with physical network details. The various LAN, WLAN and WAN protocols function primarily at these two layers to connect devices to create networks, and perform functions such as physical connection and signaling, media access control and local delivery of data between devices on the same network. Above these layers, we move beyond the hardware aspects of networking and closer to the more abstract realm of software-related network functions.

The third OSI layer is the [network layer](#). We are of course talking about networks in this Guide, and it is no coincidence that the layer bearing that name is one of the most important in comprehending how networks function. It is here that we find protocols that tie networks together to create internetworks, and also where cross-network addressing and routing are performed. The network layer is also called the *internet layer* in the [TCP/IP model](#).

In this section I provide details for the various TCP/IP protocols that reside architecturally at the TCP/IP internet layer / OSI network layer. Much of the focus here is on the all-important Internet Protocol; the section covering IP includes extensive coverage of IP version 4, IP version 6, and IP-related protocols such as IPSec, Mobile IP and IP Network Address Translation (NAT). The following three subsections cover IP support protocols such as the Internet Control Message Protocol (ICMP) and IPv6 Neighbor Discovery (ND) protocol, and the complete set of IP routing protocols.

---

## Internet Protocol (IP/IPv4, IPng/IPv6) and IP-Related Protocols (IP NAT, IPSec, Mobile IP)

The idea of singling out any one protocol as being more important than the others in a network is kind of pointless, if you think about it. The protocols and technologies work as a team to accomplish the goal of communication across the network. Like any team, no single member can get the job done alone, no matter how good they are. Still, if we *were* to try to pick a “most valuable player” in the world of networking, a good case could be made that we have it here in this section: the TCP/IP *Internet Protocol (IP)*.

Even though it gets “second billing” in the name of the TCP/IP protocol suite, IP is in fact the “workhorse” of TCP/IP. It implements key [network-layer functions](#) including addressing, datagram handling and routing, and is the foundation upon which other TCP/IP protocols are built. Even the ones lower in the [TCP/IP architecture](#) such as [ARP](#) and [PPP](#) are easier to understand when you know how IP works. In addition to the main functions implemented by the IP protocol itself, there are also several protocols that have been developed over the years that I call “IP-Related” because they are based on IP but add new functionality or capabilities for special purposes.

In this section I provide considerable coverage of the TCP/IP Internet Protocol and to several protocols that are closely related to IP. I begin with a section that takes a general look at IP concepts and provides an overview of how IP works. I then have a large section that looks at IP version 4, the current version of the protocol that is in use on TCP/IP networks everywhere. Following this I look at the “next generation” of IP, IP version 6. I then provide sections covering three IP-related protocols: the IP Network Address Translation protocol (IP NAT), the IP Security protocol set (IPSec), and the adaptation of IP for mobile devices (Mobile IP).

**Note:** The primary focus in this section is on the current version of IP, IPv4, because it is the one that is in widest use at the present time. I would therefore advise reading the IPv4 section before proceeding to the other sub-sections here, unless you are already familiar with it. To avoid duplication, the section on IP version 6 is structured primarily to show how IPv6 differs from IPv4. Similarly, the sections on IP NAT, IPSec and Mobile IP build upon some of the concepts in the IPv4 section.

**Background Information:** If you have not yet read the [introductory section describing TCP/IP in general terms](#), you may find it helpful to review it before proceeding here.

---

## **Internet Protocol Concepts and Overview**

IP is a very important protocol in internetworking; it wouldn't be an exaggeration to say that you can't really comprehend modern networking without a good understanding of IP. Unfortunately, IP can be somewhat difficult to understand. This is probably because due to its importance, a large amount of complexity has become associated with the protocol over the years, to allow it to meet the many demands placed upon it.

Before diving into the details of how IP works, I feel it is worthwhile to take a high-level look at IP and what it does. In this section I provide a brief examination of basic concepts related to the Internet Protocol and how it works. I begin with an overview of IP, how it operates in basic terms and the most important characteristics of how it does its job. I then expand on this discussion by describing the main functions of the Internet Protocol, which can be used as an introduction to the remainder of the sections that explain IP in considerably more detail. I conclude with a brief look at the history of development of IP, its versions, and how it has spawned the development of several IP-related protocols.

### **IP Overview and Key Operational Characteristics**

The Internet Protocol (IP) is the core of the TCP/IP protocol suite and its main protocol at the [network layer](#). The network layer is primarily concerned with the delivery of data, not between devices on the same physical network, but between devices that may be on different networks that are interconnected in an arbitrary manner: an *internetwork*. IP is the mechanism by which this data is sent on TCP/IP networks. (It does have help from other protocols at the network layer too, of course!)

Let's [look at the TCP/IP layer model](#) and consider what IP does from an architectural standpoint. As the layer three protocol, it provides a service to layer four in the TCP/IP stack, represented mainly by the [TCP and UDP protocols](#). This service is to take data that has been packaged by either TCP or UDP, manipulate it as necessary, and send it out. This service is sometimes called *internetwork datagram delivery*, as shown in [Figure 54](#). As we will see, there are many details to how exactly this service is accomplished, but in a nutshell, that's what IP does: sends data from point A to point B over an internetwork of connected networks.

**Key Concept:** While the Internet Protocol has many functions and characteristics, it can be boiled down to one primary purpose: the delivery of datagrams across an internetwork of connected networks.

---

### ***Key IP Characteristics***

Of course there are a myriad of ways in which IP could have been implemented in order to accomplish this task. To understand how the designers of TCP/IP made IP work, let's take a look at the key characteristics used to describe IP and the general manner in which it operates. The Internet Protocol is said to be:

**Figure 54: The Main Function of IP: Internetwork Datagram Delivery**

The fundamental job of the Internet Protocol is the delivery of datagrams from one device to another over an internetwork. In this generic example, a distant client and server communicate with each other by passing IP datagrams over a series of interconnected networks.

- ☛ **Universally-Addressed:** In order to send data from point A to point B, it is necessary to ensure that devices know how to identify which device is “point B”. IP defines the addressing mechanism for the network and uses these addresses for delivery purposes.
- ☛ **Underlying-Protocol Independent:** IP is designed to allow the transmission of data across any type of underlying network that is designed to work with a TCP/IP stack. It includes provisions to allow it to adapt to the requirements of various lower-level protocols such as [Ethernet](#) or [IEEE 802.11](#). IP can also run on the [special data link protocols SLIP and PPP](#) that were created for it. An important example is IP's ability to fragment large blocks of data into smaller ones to match the size limits of physical networks, and then have the recipient reassemble the pieces again as needed.
- ☛ **Delivered Connectionlessly:** IP is a *connectionless protocol*. This means that when A wants to send data to B, it doesn't first set up a connection to B and then send the data—it just makes the datagram and sends it. [See the topic in the networking fundamentals section on connection-oriented and connectionless protocols](#) for more information on this.
- ☛ **Delivered Unreliably:** IP is said to be an “unreliable protocol”. That doesn't mean that one day your IP software will decide to go fishing rather than run your network. ☺ It does mean that when datagrams are sent from device A to device B, device A just sends each one and then moves on to the next. IP doesn't keep track of the ones it

---

sent. It does not provide reliability or service quality capabilities such as error protection for the data it sends (though it does on the IP header), flow control or retransmission of lost datagrams.

For this reason, IP is sometimes called a *best-effort* protocol. It does what it can to get data to where it needs to go, but “makes no guarantees” that the data will actually get there.

- ☹ **Delivered Without Acknowledgments:** In a similar manner to its unreliable nature, IP doesn't use acknowledgements. When device *B* gets a datagram from device *A*, it doesn't send back a “thank you note” to tell *A* that the datagram was received. It leaves device *A* “in the dark” so to speak.

### ***IP's Success Despite Its Limitations***

The last three characteristics in the preceding list might be enough to make you cringe, thinking that giving your data to IP would be somewhat like trusting a new car to your sixteen-year-old son. If we are going to build our entire network around this protocol, why design it so that it works without connections, doesn't guarantee that the data will get there, and has no means of acknowledging receipt of data?

The reason is simple: establishing connections, guaranteeing delivery, error-checking and similar “insurance” functions have a cost: **performance**. It takes time, computer resources and network bandwidth to perform these tasks, and they aren't always necessary for every application. Now, consider that IP carries pretty much **all** user traffic on a TCP/IP network. To build this complexity into IP would burden all traffic with this overhead whether it was needed or not.

The solution taken by the designers of TCP/IP was to exploit [the power of layering](#). If service quality features such as connections, error-checking or guaranteed delivery are required by an application, they are provided at the transport layer (or possibly, the application layer). On the other hand, applications that don't need these features can avoid using them. This is in fact the major distinction between the two TCP/IP transport layer protocols: [TCP](#) and [UDP](#). TCP is full-featured but a bit slower than UDP; UDP is spartan in its capabilities, but faster than TCP. This system is really the “best of both worlds”. And unlike your teenager with the shiny new license, it has been proven to work well in the real world. ☺

So how is datagram delivery accomplished by IP? In the following topic I discuss in more detail the main functions that IP performs to “get the job done”, so to speak.

## **IP Functions**

In the preceding topic I described the general operation of IP and boiled down its primary job as *internetwork datagram delivery*. I also explained the most important characteristics of how IP does this job. With that as a foundation, let's now look a bit deeper, at **how** IP “gets the job done”. A good way to do this is to examine the various functions that the Internet Protocol includes.

---

The exact number of IP functions depends on where you “draw the line” between certain activities. For explanatory purposes, however, I view IP as having four basic functions (or more accurately, function sets):

- ① **Addressing:** In order to perform the job of delivering datagrams, IP must know where to deliver them to! For this reason, IP includes a mechanism for host addressing. Furthermore, since IP operates over internetworks, its system is designed to allow unique addressing of devices across arbitrarily large networks. It also contains a structure to facilitate the routing of datagrams to distant networks if that is required.

Since most of the other TCP/IP protocols use IP, [understanding the IP addressing scheme](#) is of vital importance to comprehending much of what goes on in TCP/IP.

- ② **Data Encapsulation and Formatting/Packaging:** As the TCP/IP network layer protocol, IP accepts data from [the transport layer protocols UDP and TCP](#). It then [encapsulates this data into an IP datagram using a special format](#) prior to transmission.
- ③ **Fragmentation and Reassembly:** IP datagrams are passed down to the data link layer for transmission on the local network. However, the maximum frame size of each physical/data-link network using IP may be different. For this reason, IP includes the ability to *fragment* IP datagrams into pieces so they can each be carried on the local network. The receiving device uses the *reassembly* function to recreate the whole IP datagram again.

**Note:** Some people view fragmentation and reassembly as distinct functions, though clearly they are complementary and I view them as being part of the same function.

---

- ④ **Routing / Indirect Delivery:** When an IP datagram must be sent to a destination on the same local network, this can be done easily using the network's underlying LAN/WLAN/WAN protocol using what is sometimes called *direct delivery*. However, in many (if not most cases) the final destination is on a distant network not directly attached to the source. In this situation the datagram must be delivered *indirectly*. This is accomplished by [routing the datagram](#) through intermediate devices (shockingly called *routers*). IP accomplishes this in concert with support from the other protocols including [ICMP](#) and the [TCP/IP gateway/routing protocols](#) such as [RIP](#) and [BGP](#).

As you continue on in this section on IP will find that I have structured the sub-sections that provide more detail on the main IP version and IP-related protocols based on these general functions.

## **IP History, Standards, Versions and Closely-Related Protocols**

Since the Internet Protocol is really the architectural foundation for the entire TCP/IP suite, one might have expected that it was created first, and the other protocols built upon it. That's usually how one builds a structure, after all. The history of IP, however, is a bit more complex. The functions it **performs** were defined at the birth of the protocol, but IP itself didn't exist for the first few years that the protocol suite was being defined.

---

I explore the early days of TCP/IP in the section that overviews the suite as a whole. What is notable about the development of IP is that its functions were originally part of the [Transmission Control Protocol \(TCP\)](#). As a formal protocol, IP was “born” when an early version of TCP developed in the 1970s for predecessors of the modern Internet was split into TCP at layer four and IP at layer three. The key milestone in the development of the Internet Protocol was the publishing of RFC 791, *Internet Protocol*, in September 1981. This standard, which was a revision of the similar RFC 760 of the previous year, defined the core functionality and characteristics of the IP that has been in widespread use for the last two decades.

### ***IP Versions and Version Numbers***

The IP defined in RFC 791 was the first widely-used version of the Internet Protocol. Interestingly, however, it is not version 1 of IP but version 4! This would of course imply that there were earlier versions of the protocol at one point. Interestingly, however, there really weren't. As I mentioned above, IP was created when its functions were split out from an early version of TCP that combined both TCP and IP functions. TCP evolved through three earlier versions, and was split into TCP and IP for version 4. That version number was applied to both TCP and IP for consistency.

**Key Concept:** Version 4 of the *Internet Protocol* is in fact the first version that was widely deployed and is the one in current widespread use.

---

So, when you use IP today, you are using IP version 4, also frequently abbreviated *IPv4*. Unless otherwise qualified, it's safe to assume that “IP” means “IP version 4”—[at least for the next few years!](#) This version number is carried in the appropriate field of all IP datagrams, as described in [the topic discussing the IP datagram format](#).

Given that it was originally designed for an internetwork a tiny fraction of the size of our current Internet, IPv4 has proven itself remarkably capable. Various additions and changes have been made over time to how IP is used, especially with respect to addressing, but the core protocol is basically what it was in the early 1980s. There's good reason for this: changing something as fundamental as IP requires a great deal of development effort and also introduces complexities during transition.

Despite how well IPv4 has served us, it was recognized that for various reasons a new version of IP would eventually be required. Due to the difficulties associated with making such an important change, development of this new version of IP has actually been underway since the mid-1990s. This new version of IP is formally called *Internet Protocol version 6 (IPv6)* and also sometimes referred to as *IP Next Generation* or *IPng*. I discuss the reasons why IPv6 was developed and how it differs from IPv4 in considerable detail in [the IPv6 section of this Guide](#).

---

A natural question at this point of course is: what happened to version 5 of IP? The answer is: it doesn't exist. While this may seem confusing, version 5 was in fact intentionally skipped to **avoid** confusion, or at least to rectify it. The problem with version 5 relates to an experimental TCP/IP protocol called the *Internet Stream Protocol, Version 2*, originally defined in RFC 1190. This protocol was originally seen by some as being a peer of IP at the Internet Layer in the TCP/IP architecture, and in its standard, these packets were assigned IP version 5 to differentiate them from “normal” IP packets (version 4). This protocol apparently never went anywhere, but to be absolutely sure that there would be no confusion, version 5 was skipped over in favor of version 6.

### ***IP-Related Protocols***

In addition to our “old” and “new” versions of IP, there are several protocols that I call *IP-related*. They are not parts of IP proper, but protocols that add to or expand on the capabilities of IP functions for special circumstances. These are:

- ☉ **IP Network Address Translation (IP NAT / NAT):** [This protocol provides IP address translation capabilities](#) to allow private networks to be interfaced to public networks in a flexible manner. It allows public IP addresses to be shared and improves security by making it more difficult for hosts on the public network to gain unauthorized access to hosts. It is commonly called just “NAT” but it works on IP addresses so I think “IP NAT” is more clear.
- ☉ **IP Security (IPSec):** [Defines a set of sub-protocols that provide a mechanism for secure transfer of data using IP.](#) IPSec is rapidly growing in popularity as a security protocol to enable virtual private networks (VPNs).
- ☉ **Mobile IP:** A protocol that addresses some of the difficulties associated with using IP on computers that frequently move from one network to another. [It provides a mechanism to allow data to be automatically routed to a mobile host](#) (such as a notebook computer) without requiring the device's IP address to be constantly re-configured.

The remainder of the discussion of IP is divided into five sections corresponding to [IPv4](#), [IPv6](#), [IP NAT](#), [IPSec](#) and [Mobile IP](#).

---

## **Internet Protocol Version 4 (IP, IPv4)**

Even though the name seems to imply that it's the fourth iteration of the key Internet Protocol, [version 4 of IP was the first that was widely used](#) in modern TCP/IP. *IPv4*, as it is sometimes called to differentiate it from the newer [IPv6](#), is the Internet Protocol version in use on the Internet today, and an implementation of the protocol is running on hundreds of millions of computers. It provides the basic datagram delivery capabilities upon which all of TCP/IP functions, and it has proven its quality in use over a period of more than two decades.

In this section I provide extensive detail on the operation of the current version of the Internet Protocol, IPv4. There are four main subsections, which represent the four main functions of IP. The first subsection provides a comprehensive discussion of IP addressing. The second discusses how data is encoded and formatted into IP datagrams for transmission. The third describes datagram size issues and how fragmentation and reassembly are used to convey large datagrams over networks designed to carry small frames. The last subsection covers matters related to the delivery and routing of IP datagrams. After the four main subsections I conclude our look at IPv4 with an overview of IP multicasting, which is used for delivering a single datagram to more than one recipient.

**Related Information:** As the title of this section implies, our coverage here is limited to IP version 4; version 6 is covered in its separate section, as are the IP-related protocols. That said, some of the principles here will also apply to [IPv6](#), [IP NAT](#), [IPSec](#) or [Mobile IP](#) in a limited manner. For simplicity, in this section I use the simpler designation “IP” rather than “IPv4”, except where the longer abbreviation is required for clarity.

---

---

## IP Addressing

The primary job of IP is delivering messages between devices, and like any good delivery service, it can't do its job too well if it doesn't know where the recipients are located. Obviously then, one of the most important functions of the Internet Protocol is *addressing*. IP addresses are used not only to uniquely identify IP addresses but to facilitate the [routing of IP datagrams](#) over internetworks. They are used and referred to extensively in TCP/IP networking.

In this section I provide a comprehensive explanation of the issues and techniques associated with IP addressing. There are five subsections. The first provides an overview of IP addressing concepts and issues. The second discusses the original class-based (“classful”) IP addressing scheme and how the different classes work. The third and fourth subsections are devoted to IP subnets and subnet addressing. This includes a discussion of subnetting concepts and also a thorough illustration of practical step-by-step subnetting. The last subsection describes the new classless addressing system, also sometimes called “supernetting”.

**Note:** This section contains over 30 subsections and individual topics. The sheer size of this discussion may surprise you; it certainly surprised me when I set out to organize it. ☺ There are two main reasons why I felt that so much detail was necessary. The first is that really understanding both the concepts and practice of IP addressing is **essential** to having any substantial comprehension of TCP/IP operation as a whole, so I didn't want to skimp on anything. The second is that IP addressing has become somewhat complicated. There is more than one way that IP networks are configured, and it's essential to explore them all for a complete coverage of the subject.

---

---

## **IP Addressing Concepts and Issues**

Even though the original IP addressing scheme was relatively simple, it has become complex over time as changes have been made to it to allow it to deal with various addressing requirements. The more advanced styles of IP addressing, such as [subnetting](#) and [classless addressing](#), are the ones used most in modern networks. However, they can be a bit confusing to understand. To help make sense of them we must start at the beginning with a discussion of the fundamentals of IP addressing.

In this section I begin our larger exploration of IP addressing by explaining the key concepts and issues behind it. I begin with an overview of IP addressing and discussion of what it is all about in general terms. I describe the size of IP addresses, the concept of its “address space” and the notation usually used for IP addresses. I provide basic information on the structure of an IP address and how it is divided into a network identifier and host identifier. I then describe the different types of IP addresses and the additional information such as a subnet mask and default gateway that often accompanies an IP address on larger networks. I provide a brief description of how multiple addresses are sometimes assigned to single devices and why. I conclude with a description of the process by which public IP addresses are registered and managed, and the organizations that do this work for the global Internet.

**Background Information:** If you are not familiar with at least the basics of how binary numbers work, and also with how to convert between binary and decimal numbers, I'd recommend reading [the background section on data representation](#) and [the mathematics of computing](#) before you proceed here. You can probably get by in this particular section without that knowledge, but [you'll need it anyway when we proceed to subnetting](#), so you might as well get familiar now.

---

**Note:** Remember that most operating systems have a calculator program that incorporates scientific functions, including conversions between binary, decimal and hexadecimal numbers.

---

## **IP Addressing Overview and Fundamentals**

In [the introduction of this section](#), I mentioned that IP addressing is important because it facilitates the primary function of the Internet Protocol—the delivery of datagrams across an internetwork. Understanding this in more detail requires us to examine a few different but essential issues related to how IP and its addresses operate.

### ***IP Address Functions: Identification and Routing***

The first point that bears making is that there are actually two different functions of the IP address:

- 
- 🕒 **Network Interface Identification:** Like a street address, the IP address provides unique identification of the interface between a device and the network. This is required to ensure that the datagram is delivered to the correct recipients.
  - 🕒 **Routing:** When the source and destination of an IP datagram are not on the same network, the datagram must be delivered “indirectly” using intermediate systems, a process called *routing*. The IP address is an essential part of [the system used to route datagrams](#).

You may have noticed a couple of things about this short list. One is that I said the IP address identifies the **network interface**—not that it identifies the **device** itself. This distinction is important because it underscores the concept that IP is oriented around connections to a large “virtual network” at layer three, which can span multiple physical networks. Some devices, such as routers, will have more than one network connection: they must, in order to take datagrams from one network and route them onto another. This means they will also have more than one IP address, one per connection.

You might also find it curious that I said the IP address facilitates routing. How can it do that? The answer is that the addressing system is designed with [a structure that can be interpreted to allow routers to determine what to do with a datagram](#) based on the values in the address. Numbers related to the IP address, such as the subnet mask when subnetting is used, support this function.

Let’s now look at some other important issues and characteristics associated with IP addresses in general terms.

### ***Number of IP Addresses Per Device***

Any device that has data sent to it at the network layer will have at least one IP address: one per network interface. As I mentioned above, this means that normal hosts such as computers and network-capable printers usually get one IP address, while routers get more than one IP address. Some special hosts may have more than one IP address if they are [multihomed](#)—connected to more than one network.

Lower-level network interconnection devices such as repeaters, bridges and switches don’t require an IP address because they pass traffic based on layer two (data link layer) addresses. Network segments connected by bridges and switches form a single broadcast domain and any devices on them can send data to each other directly without routing. To the Internet Protocol, these devices are “invisible”, they are no more significant than the wires that connect devices together (with a couple of exceptions). Such devices may, however, optionally have an IP address for management purposes. In this regard, they are acting like a regular host on the network. See [Figure 55](#) for an illustration.

### ***Address Uniqueness***

Each IP address on a single internetwork must be unique. This seems rather obvious (although there are exceptions in IPv6, in the form of special [anycast addresses](#)!)

**Figure 55: IP Interfaces for Common Network Devices**

This illustration shows the IP interfaces of a few common of LAN devices as small cyan circles. Each regular host has one interface, while the router that serves this LAN has three, since it connects to three different networks. Note that the LAN switch has no IP interfaces; it connects the hosts and router at layer two. Also see [Figure 59](#), which shows the IP interfaces of devices in a more complex configuration.

### ***Network-Specificity of IP Addresses***

Since IP addresses represent network interfaces and are used for routing, the IP address is specific to the network to which it is connected. If the device moves to a new network, the IP address will usually have to change as well. For the full reason why, see [the discussion of basic IP address structure](#). This issue was a primary motivation for the creation of [Mobile IP](#).

### ***Contrasting IP Addresses and Data Link Layer Addresses***

IP addresses are used for network-layer data delivery across an internetwork. This makes IP addresses quite different from the data link layer address of a device, such as its [Ethernet MAC address](#). (In TCP/IP parlance these are sometimes called *physical addresses* or *hardware addresses*.) At the network layer, a single datagram may be sent “from device A to device B”. However, the actual delivery of the datagram may require that it passes through a dozen or more physical devices, if A and B are not on the same network.

It is also necessary to provide a function that maps between IP and data link layer addresses. In TCP/IP this is the job of the [Address Resolution Protocol \(ARP\)](#).

---

## ***IP Address Datagram Delivery Issues***

In a physical network such as an Ethernet, the MAC address is all the information needed to send data between devices. In contrast, an IP address represents only the final delivery point of the datagram. The route taken depends on the characteristics of the network paths between the source and destination devices. It is even possible that there may not be a route between any two devices, which means two devices cannot exchange data even if they know each other's addresses!

## ***Private and Public IP Network Addresses***

There are two distinct ways that a network can be set up with IP addresses. On a *private network* a single organization controls the assignment of the addresses for all devices; they have pretty much absolute control to do what they wish in selecting numbers as long as each address is unique. In contrast, on a *public network* a mechanism is required to ensure both that organizations don't use overlapping addresses and also to enable efficient routing of data between organizations. The best-known example of this is of course the Internet, where [public IP registration and management facilities](#) have been created to address this issue. There are also advanced techniques now such as [IP Network Address Translation](#) that allow a network using private addresses to be interfaced to a public TCP/IP network.

## ***IP Address Configuration***

There are two basic ways that IP addresses can be configured. In a *static configuration* setup, each device is manually configured with an IP address that doesn't change. This is fine for small networks but quickly becomes an administrative nightmare in larger networks when changes are required. The alternative, *dynamic configuration*, allows IP addresses to be assigned to devices and changed under software control. The two [host configuration protocols](#), [BOOTP](#) and [DHCP](#), were created to fill this latter function.

## ***Unicast, Multicast and Broadcast Addressing***

Provision is included in the IP addressing scheme for [all three basic types of addressing](#).

**Key Concept:** IP addresses serve the dual function of device identification and routing. Each network interface requires one IP address, which is network-specific. IP addresses can be either statically or dynamically allocated, and come in unicast, multicast and broadcast forms.

---

The topics that follow in this section, and the other sections in our discussion of IP, expand upon these concepts with more particulars.

---

## **IP Address Size, Address Space and "Dotted Decimal" Notation**

Now that we have looked at [the general issues and characteristics associated with IP addresses](#), it's time to get past the introductions and dig into the “meat” of our IP address discussion. Let's start by looking at the physical construction and size of the IP address and how it is referred to and used.

### ***IP Address Size and Binary Notation***

At its simplest, the IP address is just a 32-bit [binary number](#): a set of 32 ones or zeroes. At the lowest levels computers always work in binary and this also applies to networking hardware and software. While different meanings are ascribed to different bits in the address as we shall soon see, the address itself is just this 32-digit binary number.

Humans don't work too well with binary numbers, because they are long and complicated, and the use of only two digits makes them hard to differentiate. (Quick, which of these is larger: 11100011010100101001100110110001 or 1110001101010010100110110110001? ☺) For this reason, when we use IP addresses we don't work with them in binary except when absolutely necessary.

The first thing that humans would naturally do with a long string of bits is to split it into four eight-bit octets (or bytes, [even though the two aren't technically the same](#)), to make it more manageable. So, 1110001101010010100110110110001 would become “11100011 - 01010010 - 10011101 - 10110001”. Then, we could convert each of those octets into a more manageable two-digit [hexadecimal number](#), to yield the following: “E3 - 52 - 9D - B1”. This is in fact the notation used for [IEEE 802 MAC addresses](#), except that they are 48 bits long so they have six two-digit hex numbers, and they are usually separated by colons, not dashes as I used here.

### ***IP Address "Dotted Decimal" Notation***

Most people still find hexadecimal a bit difficult to work with. So IP addresses are normally expressed with each octet of 8 bits converted to a decimal number and the octets separated by a period (a “dot”). Thus, the example above would become 227.82.157.177, as shown in [Figure 56](#). This is usually called *dotted decimal notation* for rather obvious reasons. Each of the octets in an IP address can take on the values from 0 to 255 (not 1 to 256, note!) so the lowest value is theoretically 0.0.0.0 and the highest is 255.255.255.255.

**Key Concept:** IP addresses are 32-bit binary numbers, which can be expressed in binary, hexadecimal or decimal form. Most commonly, they are expressed by dividing the 32 bits into four bytes and converting each to decimal, then separating these numbers with dots to create *dotted decimal notation*.

---

---

Dotted decimal notation provides a convenient way to work with IP addresses when communicating amongst humans. Never forget that to the computers, the IP address is always a 32-bit binary number; the importance of this will come in when we look at how [the IP address is logically divided into components](#) in the next topic, as well as when we examine techniques that manipulate IP addresses, such as [subnetting](#).

	0	8	16	24	32
Binary	11100011	01010010	10011101	10110001	
Hexadecimal	E3	52	9D	B1	
Dotted Decimal	227	82	157	177	

**Figure 56: IP Address Binary, Hexadecimal and Dotted Decimal Representations**

The binary, hexadecimal and decimal representations of an IP address are all equivalent.

### ***IP Address Space***

Since the IP address is 32 bits wide, this provides us with a theoretical *address space* of  $2^{32}$ , or 4,294,967,296 addresses. This seems like quite a lot of addresses! And in some ways it is. However, as we will see, due to how IP addresses are structured and allocated, not every one of those addresses can actually be used. One of the unfortunate legacies of the fact that IP was originally created on a rather small internetwork is that decisions were made that “wasted” much of the address space. For example, all IP addresses starting with “127” in the first octet are reserved for the [loopback function](#). Just this one decision makes 1/256th of the total number of addresses, or 16,277,216 addresses, no longer available. There are also other ways that the IP address space was not “conserved”, which caused difficulty as the Internet grew in size. [We'll see more about this in the section on “classful” addressing](#).

**Key Concept:** Since IP addresses are 32 bits long, the total *address space* of IPv4 is  $2^{32}$  or 4,294,967,296 addresses. However, not all of these addresses can be used, for a variety of reasons.

---

This IP address space dictates the limit on the number of addressable interfaces in *each* IP internetwork. So, if you have a private network you can in theory have 4 billion plus addresses. However, in a public network such as the Internet, all devices must share the available address space. Techniques such as [CIDR \(“supernetting”\)](#) and [Network Address Translation \(NAT\)](#) were designed in part to more efficiently utilize the existing Internet IP address space. Of course, [IP version 6](#) expands the IP address size from 32 bits all the way up to 128, which increases the address space to a ridiculously large number and makes the entire matter of address space size moot.

---

(Incidentally, the second binary number is the larger one.)

## **IP Basic Address Structure and Main Components: Network ID and Host ID**

As I mentioned in the IP addressing overview, one of the ways that IP addresses are used is to facilitate [the routing of datagrams in an IP internet](#). This is made possible because of the way that IP addresses are structured, and how that structure is interpreted by network routers.

### ***Internet IP Address Structure***

[As we just saw](#), each version 4 IP address is 32 bits long. When we refer to the IP address we use a dotted-decimal notation, while the computer converts this into binary. However, even though these sets of 32 bits are considered a single “entity”, they have an internal structure containing two components:

- 🕒 **Network Identifier (Network ID):** A certain number of bits, starting from the left-most bit, is used to identify the network where the host or other network interface is located. This is also sometimes called the *network prefix* or even just the *prefix*.
- 🕒 **Host Identifier (Host ID):** The remainder of the bits are used to identify the host on the network.

---

**Note:** By convention, IP devices are often called *hosts* for simplicity, as I do throughout this Guide. Even though each host **usually** has a single IP address, remember that IP addresses are strictly associated with network-layer network interfaces, not physical devices, and a device may therefore have more than one IP address.

---

As you can see in [Figure 57](#), this really is a fairly simple concept; it's the same idea as the structure used for phone numbers in North America. The telephone number (401) 555-7777 is a ten-digit number usually referred to as a single “phone number”. However, it has a structure. In particular, it has an area code (“401”) and a local number (“555-7777”).

### ***Implications of Including the Network ID in IP Addresses***

The fact that the network identifier is contained in the IP address is what partially facilitates the routing of IP datagrams when the address is known. Routers look at the network portion of the IP address to determine first of all if the destination IP address is on the same network as the host IP address. Then routing decisions are made based on information the routers keep about where various networks are located. Again, this is conceptually similar to how the area code is used by the equivalent of “routers” in the phone network to switch telephone calls. The host portion of the address is used by devices on the local portion of the network.

	0	8	16	24	32
Binary	11100011	01010010	10011101	10110001	
Dotted Decimal	227	82	157	177	

**IP Address: 227.82.157.177**  
**Split Into 8-Bit Network ID and 24-Bit Host ID**

**Figure 57: Basic IP Address Division: Network ID and Host ID**

The fundamental division of the bits of an IP address is into a network ID and host ID. Here, the network ID is 8 bits long, shown in cyan, and the host ID is 24 bits in length.

Since the IP address can be split into network ID and host ID components, it is also possible to use either one or the other by itself, depending on context. [These addresses are assigned special meanings](#). For example, if the network ID is used with all ones as the host ID, this indicates a broadcast to the entire network. Similarly, if the host ID is used by itself with all zeroes for the network ID, this implies an IP address sent to the host of that ID on “the local network”, whatever that might be.

It is the inclusion of the network identifier in the IP address of each host on the network that causes the IP addresses to be network-specific. If you move a device from one network to a different one the network ID must change to that of the new network. Therefore, the IP address must change as well. [This is an unfortunate drawback that shows up most commonly when dealing with mobile devices](#).

### ***Location of the Division Between Network ID and Host ID***

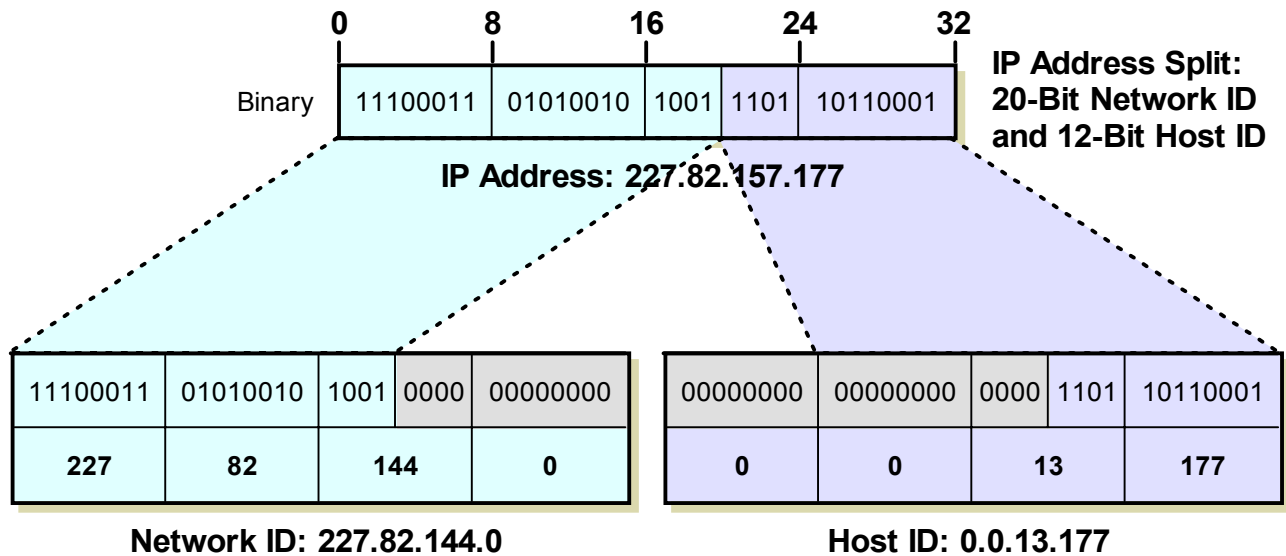

One difference between IP addresses and phone numbers is that the dividing point between the bits used to identify the network and those that identify the host isn't fixed. It depends on the nature of the address, the type of addressing being used, and other factors. Let's take the example from the last topic, 227.82.157.177. It is possible to divide this into a network identifier of “227.82” and a host identifier of “157.177”. Alternately, the network identifier might be “227” and the host identifier “82.157.177” within that network.

To express the network and host identifiers as 32-bit addresses, we add zeroes to replace the missing “pieces”. In the latter example just above, the address of the network becomes “227.0.0.0” and the address of the host “0.82.157.177”. (In practice, network addresses of this sort are routinely seen with the added zeroes; network IDs are not as often seen in 32-bit form this way.)

Lest you think from these examples that the division must always be between whole octets of the address, it's also possible to divide it in the middle of an octet. For example, we could split the IP address 227.82.157.177 so there were 20 bits for the network ID and 12 bits for

---

the host ID. The process is the same, but determining the dotted decimal ID values is more tricky because here, the “157” is “split” into two binary numbers. The results are “227.82.144.0” for the network ID and “0.0.0.13.177” for the host ID, as shown in [Figure 58](#).

**Figure 58: Mid-Octet IP Address Division**

Since IP addresses are normally expressed as four dotted-decimal numbers, educational resources often show the division between the Network ID and Host ID occurring on an octet boundary. However, it's essential to remember that the dividing point often appears in the middle of one of these eight-bit numbers. In this example, the Network ID is 20 bits long and the Host ID 12 bits long. This results in the third number of the original IP address, 157, being split into 144 and 13.

The place where the “line is drawn” between the network ID and the host ID must be known in order for devices such as routers to know how to interpret the address. This information is conveyed either implicitly or explicitly depending on the type of IP addressing in use. [I describe this in the following topic.](#)

**Key Concept:** The basic structure of an IP address consists of two components: the *network ID* and *host ID*. The dividing point of the 32-bit address is not fixed, but rather, depends on a number of factors, and can occur in a variety of places, including in the middle of a dotted-decimal octet.

---

### **IP Addressing Categories (Classful, Subnetted and Classless) and IP Address Adjuncts (Subnet Mask and Default Gateway)**

The [preceding topic](#) illustrated how the fundamental division of the 32 bits in an IP address is into the network identifier (network ID) and host identifier (host ID). The network ID is used for routing purposes while the host ID uniquely identifies each network interface on

---

the network. In order for devices to know how to use IP addresses on the network they must be able to tell which bits are used for each ID. However, the “dividing line” is not predefined. It depends on the type of addressing used in the network.

## ***IP Addressing Scheme Categories***

Understanding how these IDs are determined leads us into a larger discussion of the three main categories of IP addressing schemes. Each of these uses a slightly different system of indicating where in the IP address the host ID is found.

### **Conventional (“Classful”) Addressing**

The original IP addressing scheme is set up so that the dividing line occurs only in one of a few locations: on octet boundaries. Three main classes of addresses, A, B and C are differentiated based on how many octets are used for the network ID and how many for the host ID. For example, class C addresses devote 24 bits to the network ID and 8 to the host ID. This type of addressing is now often referred to by the made-up word “classful” to differentiate it from newer “classless” scheme.

This most basic addressing type uses the simplest method to divide the network and host identifiers: the class, and therefore the dividing point, are encoded into the first few bits of each address. Routers can tell from these bits which octets belong to which identifier.

### **Subnetted “Classful” Addressing**

In the subnet addressing system, the two-tier network/host division of the IP address is made into a three-tier system by taking some number of bits from a class A, B or C host ID and using them for a *subnet identifier*. The network ID is unchanged. The *subnet ID* is used for routing within the different subnetworks that constitute a complete network, providing extra flexibility for administrators. For example, consider a class C address that normally uses the first 24 bits for the network ID and remaining 8 bits for the host ID. The host ID can be split into, say, 3 bits for a subnet ID and 5 for the host ID.

This system is based on the original “classful” scheme, so the dividing line between the network ID and “full” host ID is based on the first few bits of the address as before. The dividing line between the subnet ID and the “sub-host” ID is indicated by a 32-bit number called a *subnet mask*. In the example above, the subnet mask would be 27 ones followed by 5 zeroes—the zeroes indicate what part of the address is the host. In dotted decimal notation, this would be 255.255.255.224.

### **Classless Addressing**

In the classless system, the classes of the original IP addressing scheme are tossed out the window. The division between the network ID and host ID can occur at an arbitrary point, not just on octet boundaries like in the “classful” scheme.

---

The dividing point is indicated by putting the number of bits used for the network ID, called the *prefix length*, after the address (recall that the network ID bits are also sometimes called the *network prefix*, so the network ID size is the prefix length). For example, if 227.82.157.177 is part of a network where the first 27 bits are used for the network ID, that network would be specified as 227.82.157.160/27. The “/27” is conceptually the same as the 255.255.255.224 subnet mask, since it has 27 one bits followed by 5 zeroes.

**Key Concept:** An essential factor in determining how an IP address is interpreted is the addressing scheme in which it is used. The three methods, arranged in increasing order of age, complexity and flexibility, are “*classful*” addressing, subnetted “*classful*” addressing, and *classless* addressing.

---

Did I just confuse the heck out of you? Sorry—and don't worry. I'm simply introducing the concepts of “classful”, subnetted and classless addressing and showing you how they impact the way the IP address is interpreted. This means of necessity that I have greatly summarized important concepts here. All three methods are explained in their own sections in full detail.

### ***IP Address Adjuncts: Subnet Mask and Default Gateway***

As you can see, in the original “classful” scheme the division between network ID and host ID is implied. However, if either subnetting or classless addressing is used, then the subnet mask or “slash number” are required to fully qualify the address. These numbers are considered adjuncts to the IP address and usually mentioned “in the same breath” as the address itself, because without them, it is not possible to know where the network ID ends and the host ID begins.

One other number that is often specified along with the IP address for a device is the *default gateway* identifier. In simplest terms, this is the IP address of the router that provides default routing functions for a particular device. When a device on an IP network wants to send a datagram to a device it can't see on its local IP network, it sends it to the default gateway which takes care of routing functions. Without this, each IP device would also have to have knowledge of routing functions and routes, which would be inefficient. See the sections on [routing concepts](#) and [TCP/IP routing protocols](#) for more information.

### **Number of IP Addresses and Multihoming**

Each network interface on an IP internetwork has a separate IP address. In a classical network, each regular computer, usually called a *host*, attaches to the network in exactly only one place, so it will have only one IP address. This is what most of us are familiar with when using an IP network (and is also why most people use the term “host” when they really mean “network interface”).

---

If a device has more than one interface to the internetwork, it will have more than one IP address. The most obvious case where this occurs is with routers, which connect together different networks and thus must have an IP address for the interface on each one. It is also possible for hosts to have more than one IP address, however. Such a device is sometimes said to be *multihomed*.

### **Multihoming Methods**

There are two ways that a host can be multihomed:

- 🕒 **Two Or More Interfaces To The Same Network:** Devices such as servers or high-powered workstations may be equipped with two physical interfaces to the same network for performance and/or reliability reasons. They will have two IP addresses on the same network with the same network ID.
- 🕒 **Interfaces To Two Or More Different Networks:** Devices may have multiple interfaces to different networks. The IP addresses will typically have different network IDs in them.

Figure 59 shows examples of both types of multihomed device. Of course, these could be combined, with a host having two connections to one network and a third to another network. There are also some other “special cases”, such as a host with a single network connection having multiple IP address aliases.

**Note:** When subnetting is used the same distinction can be made between multihoming to the same subnet or a different subnet.

---

### **Using a Multihomed Host as a Router**

Now, let's consider the second case. If a host has interfaces to two or more different networks, then could it not pass IP datagrams between them? Of course, it certainly could, if it had the right software running on it. If it does this, wouldn't that make the host a router, of sorts? In fact, that is exactly the case! A multihomed host with interfaces to two networks can use software to function as a router. This is sometimes called *software routing*.

Using a host as a router has certain advantages and disadvantages compared to a hardware router. A server that is multihomed can perform routing functions and also, well, act as a server. A dedicated hardware router is designed for the job of routing and usually will be more efficient than a software program running on a host.

**Key Concept:** A host with more than one IP network interface is said to be *multihomed*. A multihomed device can have either multiple connections to the same network or to different networks, or both. A host connected to two networks can be configured to function as a router.

---

**Figure 59: Multihomed Devices On An IP Internetwork**

This internetwork consists of two LANs, A (shown in purple) and B (shown in blue). LAN A has a multihomed workstation, shown with two IP network interface “circles”. The two LANs are connected together through a multihomed, shared server, that has been configured to route traffic between them. Note that this server also handles all traffic passing between LAN B and the Internet (since the Internet connection is in LAN A only.)

### ***Popularity of Multihoming***

Multihoming was once considered a fairly “esoteric” application, but has become more common in recent years. This is also true of multihoming on different networks for software routing use. In fact, you may be doing this in your home without realizing it!

---

Suppose you have two PCs networked together and a single phone line to connect to the Internet. One computer dials up to your Internet Service Provider, and runs software such as Microsoft's Internet Connection Sharing (ICS) to let the other computer access the Internet. Millions of people do this every day—they have a multihomed system (the one connecting to the Internet and the other PC) with ICS acting in the role of a software router (though there are some technical differences between ICS and a true router, of course.)

## **IP Address Management and Assignment Methods and Authorities**

What would happen if you told someone that you lived at 34 Elm Street, and when they turned onto your road they found four different houses with the number “34” on them? They'd probably find your place eventually but wouldn't be too pleased. Neither would you or your mail carrier. ☺ And all of you folks are much smarter than computers. Where I am going with this is that like street addresses, IP addresses must be unique for them to be useful.

### ***The Need for Centralized Registration of IP Addresses***

Since IP datagrams are sent only within the confines of the IP internetwork, they must be unique within each internetwork. If you are a company with your own private internetwork, this isn't really a big problem. Whoever is in charge of maintaining the internetwork keeps a list of what numbers have been used where and makes sure that no two devices are given the same address. However, what happens in a public network with many different organizations? Here, it is essential that the IP address space be managed across the organizations to ensure that they use different addresses. It's not feasible to have each organization coordinate its activities with each other one. Therefore, some sort of centralized *management authority* is required.

At the same time that we need someone to ensure that there are no conflicts in address assignment, we don't want every user of the network to have to go to this central authority every time they need to make a change to their network. It makes more sense to have the authority assign numbers in blocks or chunks to organizations based on the number of devices they want to connect to the network. The organizations can manage those blocks as they see fit, and the authority's job is made easier because it deals in blocks instead of billions of individual addresses and machines.

### ***The Original IP Address Authority: IANA***

The Internet is of course “the” big IP internetwork, and requires this coordination task to be performed for millions of organizations worldwide. The job of managing IP address assignment on the Internet was originally carried out by a single organization: the [Internet Assigned Number Authority \(IANA\)](#). IANA was responsible for allocating IP addresses, along with other important centralized coordination functions such as managing universal parameters used for TCP/IP protocols. In the late 1990s, a new organization called the *Internet Corporation for Assigned Names and Numbers (ICANN)* was created. ICANN now oversees the IP address assignment task of IANA, as well as managing other tasks such as [DNS name registration](#).

---

## ***Modern IP Address Registration and Authorities***

IP addresses were originally allocated directly to organizations. The [original IP addressing scheme was based on classes](#), and so IANA would assign addresses in Class A, Class B and Class C blocks. Today, addressing is classless, using [CIDR's hierarchical addressing scheme](#). IANA doesn't assign addresses directly, but rather delegates them to regional Internet registries (RIRs). These are APNIC, ARIN, LACNIC, and RIPE NCC. Each RIR can in turn delegate blocks of addresses to lower-level registries such as national Internet registries (NIRs) and local Internet registries (LIRs).

Eventually, blocks of addresses are obtained by Internet Service Providers (ISPs) for distribution to end-user organizations. Some of the ISP's customers are "end-user" organizations, but others are (smaller) ISPs themselves. They can in turn use or "delegate" the addresses in their blocks. This can continue for several stages in a hierarchical fashion. This arrangement helps ensure that IP addresses are assigned and used in the most efficient manner possible. [See the section on CIDR for more information on how this works](#).

IANA, ICANN and the RIRs are responsible for more than just IP address allocation, though I have concentrated on IP addresses here for obvious reasons. For more general information on IANA, ICANN, APNIC, ARIN, LACNIC and RIPE NCC, try a can of alphabet soup... or [the topic on Internet registration authorities](#). ☺

---

## **IP "Classful" (Conventional) Addressing**

The [prior section on IP addressing concepts](#) describes the three different ways that IP addresses are assigned in TCP/IP. The original addressing method worked by dividing the IP address space into chunks of different sizes called *classes* and assigning blocks of addresses to organizations from these classes based on the size and requirements of the organization. In the early 1980s, when the Internet was in its infancy, this conventional system really had no name; today, to contrast it to the newer “classless” addressing scheme, it is usually called the “*classful*” IP addressing system.

In this section I describe the first scheme used for IP addressing: so-called “classful” IP addressing. I begin with an overview of the concept and general description of the different classes. I discuss the network and host IDs and address ranges associated with the different classes. I discuss the “capacities” of each of the commonly-used classes, meaning how many networks belong to each, and how many hosts each network can contain. I discuss the special meanings assigned to certain IP address patterns, and also the special ranges reserved for private IP addressing, loopback functions, and multicasting. I conclude with a discussion of the problems with this type of addressing, which led to it eventually being abandoned in favor of subnetting, and eventually, classless assignment of the IP address space.

I should note that the “classful” addressing scheme has now been replaced on the Internet by the newer [classless addressing system described later in this section](#). However, I think it is still important to understand how this original system operates, as it forms the foundation upon which the more sophisticated addressing mechanisms were built. Just keep in mind that the class system isn't really used on the Internet any more.

I should also point out that the word “classful” is also sometimes seen as “classfull”. That would be a misspelling, except, well, “classful” is not really an English word at all. That's why I always put the word “classful” in double-quotes. In fact, I must admit that I pretty much hate the word. It sounds like something an elementary school kid made up because he didn't know the opposite of the word “classless”. (The right word is *classed*, in case anyone cares.)

My wife suggests the word “classy” would sound nicer than “classful”. She's right, but IP addresses don't wear tuxedos.

Of course, nobody ever asked *my* opinion on this subject. Not even my wife.

Okay, rant over. ☺

### **IP "Classful" Addressing Overview and Address Classes**

When the [first precursor of the Internet](#) was developed, some of the requirements of the internetwork, both present and future, were quickly realized. The Internet would start small but eventually grow. It would be shared by many organizations. Since it is necessary for all IP addresses on the internetwork to be unique, a system had to be created for dividing up

---

the available addresses and share them amongst those organizations. A [central authority](#) had to be established for this purpose, and a scheme developed for it to effectively allocate addresses.

The developers of IP recognized that organizations come in different sizes and would therefore need varying numbers of IP addresses on the Internet. They devised a system whereby the IP address space would be divided into *classes*, each of which contained a portion of the total addresses and were dedicated to specific uses. Some would be devoted to large networks on the Internet, while others would be for smaller organizations, and still others reserved for special purposes.

Since this was the original system, it had no name; it was just “the” IP addressing system. Today, in reference to its use of classes, it is called the “classful” addressing scheme, to differentiate it from the newer classless scheme. As I said [at the end of the introduction to this section](#), “classful” isn't really a word, but it's what everyone uses.

### ***IP Address Classes***

There are five classes in the “classful” system, which are given letters A through E. [Table 44](#) provides some general information about the classes, their intended uses and other general characteristics about them:

**Table 44: IP Address Classes and Class Characteristics and Uses**

IP Address Class	Fraction of Total IP Address Space	Number Of Network ID Bits	Number Of Host ID Bits	Intended Use
<b>Class A</b>	1/2	8	24	Unicast addressing for very large organizations with hundreds of thousands or millions of hosts to connect to the Internet.
<b>Class B</b>	1/4	16	16	Unicast addressing for medium-to-large organizations with many hundreds to thousands of hosts to connect to the Internet.
<b>Class C</b>	1/8	24	8	Unicast addressing for smaller organizations with no more than about 250 hosts to connect to the Internet.
<b>Class D</b>	1/16	n/a	n/a	IP multicasting.
<b>Class E</b>	1/16	n/a	n/a	Reserved for “experimental use”.

Looking at this table (and at [Figure 60](#)) you can see that the first three, classes A, B and C, comprise most of the total address space (7/8ths of it). These are the classes used for *unicast* IP addressing, which means for messages sent to a single network interface. (The blocks also include associated broadcast addresses for these networks.) This is what we usually consider “normal” IP addressing. You can think of classes A, B and C as the “papa bear”, “mama bear” and “baby bear” of traditional IP addressing. They allow the Internet to provide addressing for a small number of very large networks, a moderate number of

---

medium-sized organizations, and a large number of smaller companies. This approximately reflects the distribution of organization sizes, approximately, in the real world, though the large gulf in the maximum number of hosts allowed for each address class leads to [inflexibility and problems](#).

As you can see, the classes differ in the place where the “[dividing line](#)” is drawn between the network ID and the host ID portions of the addresses they contain. However, in each case the division is made on octet boundaries: in classful addressing, the division does not occur within an octet.

**Figure 60: Division of IPv4 Address Space Into Classes**

(I don't really need to explain this one, do I? ☺)

Classes D and E are special—to the point where many people don't even realize they exist. Class D is used for [IP multicasting](#), while class E was reserved for “experimental use”. [I discuss IP multicast addressing later in this section.](#)

### ***Rationale for “Classful” Addressing***

While the drawbacks of the “classful” system are often discussed today (and that includes myself as well, [later in this section](#)), it's important to keep in context what the size of the Internet was when this system was developed—it was tiny, and the 32-bit address space seemed enormous by comparison to even the number of machines its creators envisioned years into the future. It's only fair to also remember the many **advantages** of the “classful” system developed over 25 years ago:

- 
- ☉ **Simplicity and Clarity:** There are only a few classes to choose from and it's very simple to understand how the addresses are split up. The distinction between classes is clear and obvious. The divisions between network ID and host ID in classes A, B and C are on octet boundaries, making it easy to tell what the network ID is of any address.
  - ☉ **Reasonable Flexibility:** Three levels of “granularity” match the sizes of large, medium-sized and small organizations reasonably well. The original system provided enough capacity to handle the anticipated growth rate of the Internet at the time.
  - ☉ **Routing Ease:** As we will see shortly, the class of the address is encoded right into the address to make it easy for routers to know what part of any address is the network ID and what part is the host ID. There was no need for “adjunct” information such as a [subnet mask](#).
  - ☉ **Reserved Addresses:** Certain addresses are reserved for special purposes. This includes not just classes D and E but also [special reserved address ranges](#) for “private” addressing.

Of course it turned out that some of the decisions in the original IP addressing scheme were regrettable—but that's the benefit of hindsight. I'm sure we'd all like to have back the 268 odd million addresses that were set aside for Class E. While it may seem wasteful now to have reserved a full 1/16th of the address space for “experimental use”, remember that the current size of the Internet was never anticipated even ten years ago, never mind twenty-five. Furthermore, it's good practice to reserve some portion of any scarce resource for future use. (And besides, if we're going to play Monday morning quarterback, the real decision that should be changed in retrospect was the selection of a 32-bit address instead of a 48-bit or 64-bit one!)

**Key Concept:** The “classful” IP addressing scheme divides the IP address space into five classes, A through E, of differing sizes. Classes A, B and C are the most important ones, designated for conventional unicast addresses and comprising 7/8ths of the address space. Class D is reserved for IP multicasting, and Class E for experimental use.

---

## IP “Classful” Addressing Network and Host Identification and Address Ranges

The “classful” IP addressing scheme divides the total IP address space into five classes, A through E. One of the benefits of the relatively simple “classful” scheme is that information about the classes is encoded directly into the IP address. This means we can determine in advance which address ranges belong to each class. It also means the opposite is possible: we can identify which class is associated with any address by examining just a few bits of the address.

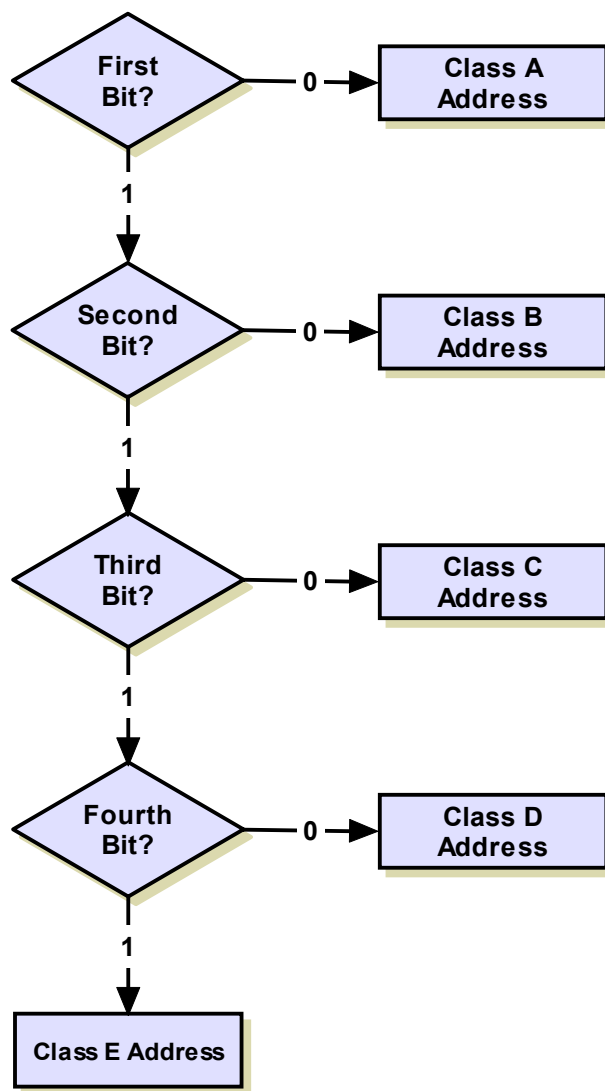

This latter benefit was one of the main motivators for the initial creation of the “classful” system, as we saw in the previous topic.

---

### ***"Classful" Addressing Class Determination Algorithm***

When TCP/IP was first created computer technology was still in its infancy, compared to its current state. [Routers](#) needed to be able to quickly make decisions about how to move IP datagrams around. The [IP address space](#) was split into classes in a way that looking at only the first few bits of any IP address would tell the router where to “draw the line” between the network ID and host ID, and thus what to do with the datagram.

The number of bits the router needs to look at may be as few as one or as many as four, depending on what it finds when it starts looking. The algorithm used corresponds to the system used to divide the address space; it involves four very basic steps (see [Figure 61](#)):

**Figure 61: Class Determination Algorithm for “Classful” IP Addresses**

The simplicity of the “classful” IP addressing can be seen in the very uncomplicated algorithm used to determine the class of an address.

1. If the first bit is a “0”, it's a class A address and we're done. (Half the address space has a “0” for the first bit, so this is why class A takes up half the address space.) If it's a “1”, continue to step two.
2. If the second bit is a “0”, it's a class B address and we're done. (Half of the remaining non-class-A addresses, or one quarter of the total.) If it's a “1”, continue to step three.
3. If the third bit is a “0”, it's a class C address and we're done. (Half again of what's left, or one eighth of the total.) If it's a “1”, continue to step four.
4. If the fourth bit is a “0”, it's a class D address. (Half the remainder, or one sixteenth of the address space.) If it's a “1”, it's a class E address. (The other half, one sixteenth.)

And that's pretty much it.

### ***Determining Address Class From the First Octet Bit Pattern***

As humans, of course, we generally work with addresses in dotted decimal notation and not in binary, but it's pretty easy to see the ranges that correspond to the classes. For example, consider class B. The first two bits of the first octet are “10”. The remaining bits can be any combination of ones and zeroes. This is normally represented as “10xx xxxx” (shown as two groups of four for readability.) Thus, the binary range for the first octet can be from “1000 0000” to “1011 1111”. This is 128 to 191 in decimal. So, in the “classful” scheme, any IP address whose first octet is from 128 to 191 (inclusive) is a class B address.

In [Table 45](#) I have shown the bit patterns of each of the five classes, and the way that the first octet ranges can be calculated. In the first column is the format for the first octet of the IP address, where the “x”s can be either a zero or a one. Then I show the lowest and highest value for each class in binary (the “fixed” few bits are highlighted so you can see that they do not change while the others do.) I then also show the corresponding range for the first octet in decimal.

**Table 45: IP Address Class Bit Patterns, First-Octet Ranges and Address Ranges**

IP Address Class	First Octet of IP Address	Lowest Value of First Octet (binary)	Highest Value of First Octet (binary)	Range of First Octet Values (decimal)	Octets in Network ID / Host ID	Theoretical IP Address Range
Class A	0xxx xxxx	0000 0001	0111 1110	1 to 126	1 / 3	1.0.0.0 to 126.255.255.255
Class B	10xx xxxx	1000 0000	1011 1111	128 to 191	2 / 2	128.0.0.0 to 191.255.255.255
Class C	110x xxxx	1100 0000	1101 1111	192 to 223	3 / 1	192.0.0.0 to 223.255.255.255
Class D	1110 xxxx	1110 0000	1110 1111	224 to 239	—	224.0.0.0 to 239.255.255.255
Class E	1111 xxxx	1111 0000	1111 1111	240 to 255	—	240.0.0.0 to 255.255.255.255

**Key Concept:** In the “classful” IP addressing scheme, the class of an IP address is identified by looking at the first one, two, three or four bits of the address. This can be done both by humans working with these addresses and routers making routing decisions. The use of these bit patterns means that IP addresses in different classes fall into particular address ranges that allow an address’s class to be determined by looking at the first byte of its dotted-decimal address.

---

### **Address Ranges for Address Classes**

I have also shown in [Table 45](#) the *theoretical* lowest and highest IP address ranges for each of the classes. This means that the address ranges shown are just a result of taking the full span of binary numbers possible in each class. In reality, some of the values are not available for normal use. For example, even though 192.0.0.0 to 192.0.0.255 is technically in class C, it is [reserved](#) and not actually used by hosts on the Internet.

Also, there are IP addresses that can't be used because they have [special meaning](#). For example, you can't use an IP address of 255.255.255.255, as this is a reserved “all ones” broadcast address. In a similar vein, note that the range for Class A is from 1 to 126 and not 0 to 127 like you might have expected. This is because class A networks 0 and 127 are reserved; 127 is the network containing the [IP loopback address](#). These special and reserved addresses are discussed later in this section.

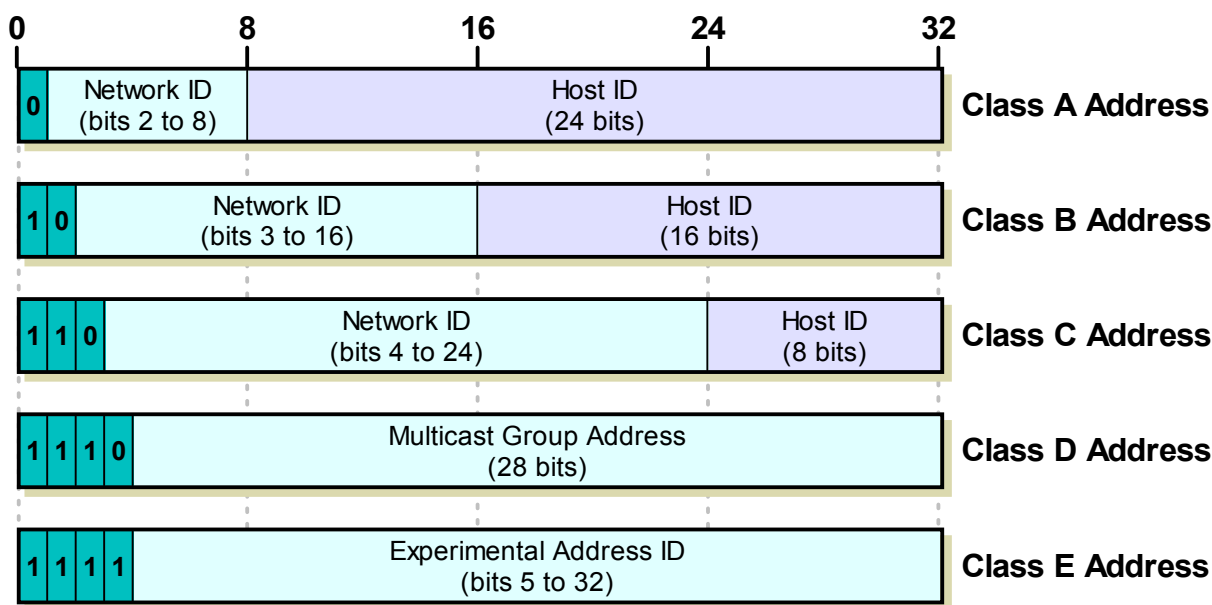

Now, recall that classes A, B and C differ in where the dividing line is between the network ID and the host ID: 1 for network and 3 for host for class A, 2 for each for class B, and 3 for network and 1 for host for class C. Based on this division, I have highlighted the network ID portion of the IP address ranges for each of classes A, B and C. The plain text corresponds to the range of host IDs for each allowable network ID. [Figure 62](#) shows graphically how bits are used in each of the five classes.

Phew, time for another example methinks. Let's look at class C. The lowest IP address is [192.0.0.0](#) and the highest is [223.255.255.255](#). The first three octets are the network ID, and can range from [192.0.0](#) to [223.255.255](#). For each network ID in that range, the host ID can range from 0 to 255.

**Note:** It is common to see resources refer to the network ID of a “classful” address as including only the “significant” bits, that is, only the ones that are not common to all networks of that class. For example, you may see a Class B network ID shown in a diagram as having 14 bits, with the “[10](#)” that starts all such networks shown separately, as if it were not part of the network ID. Remember that the network ID **does** include those bits as well; it is 8 full bits for Class A, 16 for Class B and 24 for Class C. In the case of Class D addresses, all 32 bits are part of the address, but only the lower 28 bits are part of the multicast group address; see [the topic on multicast addressing](#) for more.

---

**Figure 62: IP Address Class Bit Assignments and Network/Host ID Sizes**

This illustration shows how the 32 bits of IP address are assigned for each of the five IP address classes. Classes A, B and C are the “normal” classes used for regular unicast addresses; each has a different dividing point between the Network ID and Host ID. Classes D and E are special and are not divided in this manner.

### **IP Address Class A, B and C Network and Host Capacities**

In the preceding topics I introduced the concepts of [IP address classes](#) and showed how [the classes related to ranges of IP addresses](#). Of the five classes, D and E are dedicated to special purposes, so I will leave those alone for now. Classes A, B and C are the ones actually assigned for normal (unicast) addressing purposes on IP internetworks, and therefore the primary focus of our continued attention.

As we've seen, they differ in the number of bits (and octets) used for the network ID compared to the host ID. The number of different networks possible in each class is a function of the number of bits assigned to the network ID, and likewise, the number of hosts possible in each network depends on the number of bits provided for the host ID. We must also take into account the fact that one, two or three of the bits in the IP address is used to indicate the class itself, so it is effectively "excluded" from use in determining the number of networks (though again, it is still part of the network ID).

---

Based on this information, we can calculate the number of networks in each class, and for each class, the number of host IDs per network. [Table 46](#) shows the calculations.

**Table 46: IP Address Class Network and Host Capacities**

IP Address Class	Total # Of Bits For Network ID / Host ID	First Octet of IP Address	# Of Network ID Bits Used To Identify Class	Usable # Of Network ID Bits	Number of Possible Network IDs	# Of Host IDs Per Network ID
Class A	8 / 24	0xxx xxxx	1	8-1 = 7	$2^7-2 = 126$	$2^{24}-2 = 16,277,214$
Class B	16 / 16	10xx xxxx	2	16-2 = 14	$2^{14} = 16,384$	$2^{16}-2 = 65,534$
Class C	24 / 8	110x xxxx	3	24-3 = 21	$2^{21} = 2,097,152$	$2^8-2 = 254$

Let's walk through one line of this table so we can see how it works. I'll stick with class B since it's "in the middle". The basic division is into 16 bits for network ID and 16 bits for host ID. However, the first two bits of all class B addresses must be "10", so that leaves only 14 bits to uniquely identify the network ID. This gives us a total of  $2^{14}$  or 16,384 class B network IDs. For each of these, we have  $2^{16}$  host IDs, **less two**, for a total of 65,534.

Why less two? For each network ID, two host IDs cannot be used: the host ID with all zeroes and the ID with all ones. These are addresses with "special meanings" as described in [the topic that follows](#). You will also notice that 2 has been subtracted from the number of network IDs for class A. This is because two of the class A network IDs (0 and 127) are reserved. There are actually several other address ranges that are set aside in all three of the classes that I haven't shown here. They are listed in [the topic on reserved, private and loopback addresses](#). (The exclusion of 0 and 127 from class A is probably the best-known address range reservation which is why I am explicit with that one in the table above.)

**Key Concept:** In the "classful" IP addressing scheme, a Class A network contains addresses for about 16 million network interfaces; a Class B about 65,000; and a Class C, 254.

---

As you can see, there is quite a disparity in the number of hosts available for each network in each of these classes. What happens if an organization needs 1,000 IP addresses? They have to either use four class Cs or use one class B (and in so doing waste over 90% of the possible addresses in the class B network.) Bear in mind that there are only about 16,000 class B network IDs available worldwide and you begin to understand one of the big [problems with "classful" addressing](#).

---

## IP Addresses With Special Meanings

Most IP addresses have the “usual” meaning I have described in the preceding topics in this section: they refer to an interface to a device on a TCP/IP network. However, some IP addresses do not refer directly to specific hardware devices in this manner. Instead, they are used to refer “indirectly” to one or more devices. To draw an analogy with language, most IP addresses refer to proper nouns, like “John” or “the red table in the corner”. However, some are used more the way we use pronouns such as “this one” or “that group over there”. I call these IP addresses with *special meanings*.

### ***Special Network ID and Host ID Address Patterns***

Special IP addresses are constructed by replacing the normal network ID or host ID (or both) in an IP address with one of two special patterns. The two patterns are:

- ☉ **All Zeroes:** When the network ID or host ID bits are replaced by a set of all zeroes, the special meaning is the equivalent of the pronoun “***this***”, referring to whatever was replaced. It can also be interpreted as “the default” or “the current”. So for example, if we replace the network ID with all zeroes but leave the host ID alone, the resulting address means “the device with the host ID given, on ***this network***”. Or alternatively, “the device with the host ID specified, on ***the default network*** or ***the current network***”.
- ☉ **All Ones:** When the network ID or host ID bits are replaced by a set of all ones, this has the special meaning of “***all***”. So replacing the host ID with all ones means the IP address refers to all hosts on the network. This is generally used as a broadcast address for sending a message to “***everyone***”.

**Key Concept:** When the network ID or host ID of an IP address is replaced by a pattern of all ones or all zeroes, the result is an address with a *special meaning*. Examples of such addresses include “all hosts” broadcast addresses, and addresses that refer to a specific host or a whole network.

---

### ***Specific IP Address Patterns With Special Meanings***

Since there are many network IDs and host IDs, there are also many of these “special” addresses. A small number are universal across the entire TCP/IP network, while others exist for each network ID or host ID. Since there are two “special patterns” that can be applied to the network ID, host ID or both, this yields six potential combinations, each of which has its own special meaning. Of these, five are used.

[Table 47](#) describes each of these special meanings. In the table I have also provided three examples, one from each of Class A, B and C. This shows how an IP address in each of the common classes can be modified to each of the “special meaning” forms. (The first row shows the examples in their normal form, for reference.)

**Table 47: IP Address Patterns With Special Meanings**

Network ID	Host ID	Class A Example	Class B Example	Class C Example	Special Meaning and Description
Network ID	Host ID	77.91.215.5	154.3.99.6	227.82.157.160	<b>Normal Meaning:</b> Refers to a specific device.
Network ID	All Zeroes	77.0.0.0	154.3.0.0	227.82.157.0	<b>“The Specified Network”:</b> This notation, with a “0” at the end of the address, refers to an entire network.
All Zeroes	Host ID	0.91.215.5	0.0.99.6	0.0.0.160	<b>“Specified Host On This Network”:</b> This addresses a host on the current or default network when the network ID is not known, or when it doesn't need to be explicitly stated.
All Zeroes	All Zeroes	0.0.0.0			<b>“Me”:</b> (Alternately, “this host”, or “the current/default host”). Used by a device to refer to itself when it doesn't know its own IP address. The most common use is when a device attempts to determine its address using a <a href="#">host-configuration protocol</a> like <a href="#">DHCP</a> . May also be used to indicate that any address of a multihomed host may be used.
Network ID	All Ones	77.255.255.255	154.3.255.255	227.82.157.255	<b>“All Hosts On The Specified Network”:</b> Used for broadcasting to all hosts on the local network.
All Ones	All Ones	255.255.255.255			<b>“All Hosts On The Network”:</b> Specifies a global broadcast to all hosts on the directly-connected network. Note that there is no address that would imply sending to all hosts everywhere on the global Internet, since this would be very inefficient and costly.

**Note:** The missing combination from [Table 47](#) is that of the network ID being all ones and the host ID normal. Semantically, this would refer to “all hosts of a specific ID on all networks”, which doesn't really mean anything useful in practice, so it's not used. Note also that in theory, a special address where the network ID is all zeroes and the host ID is all ones would have the same meaning as the all-ones limited broadcast address. The latter is used instead, however, because it is more general, not requiring knowledge of where the division is between the network ID and host ID.

---

### ***IP Address Limitations Due to Special Meaning Patterns***

Since the all-zeroes and all-ones patterns are reserved for these special meanings, they cannot be used for regular IP addresses. This is why, when [we looked at the number of hosts per network](#) in each of the classes, we had to subtract two from the theoretical maximum: one for the all-zeroes case and one for the all-ones case.

Similarly, the network ID cannot be all zeroes either. However, this doesn't require specific exclusion because the entire block of addresses with “0” in the first octet (0.x.x.x) is one of the reserved sets of IP addresses. These reserved addresses, described in [the next topic](#), further restrict the use of certain addresses in the IP address space for “regular” uses.

### **IP Reserved, Loopback and Private Addresses**

In [the preceding topic](#) I showed how certain IP addresses cannot be used for regular network devices because they are addresses with “special meanings”. These special addresses reduce the total number of networks that are possible in the “classful” addressing scheme, and also the total number of hosts available in each network.

In addition to these unusable numbers, there are several other sets of IP addresses set aside for various special uses, which are not available for normal address assignment. These ranges of IP addresses generally fall into the following three categories: reserved, loopback and private addresses.

### ***Reserved Addresses***

Several blocks of addresses were designated just as “reserved” with no specific indication given of what they were reserved for. They may have been set aside for future experimentation, or for internal use in managing the Internet, or for other purposes. (In general, it's a good idea to set aside some portion of any limited resource for unanticipated needs!) There are a couple of these blocks in each of the [three main classes \(A, B, and C\)](#), appearing right at the beginning and end of each class. (In a manner of speaking, all of classes D and E are also “reserved”, since they aren't used for regular addressing, though the term “reserved” is usually used to refer to unusable parts of classes A, B and C.

---

## Loopback Addresses

Normally, when a TCP/IP application wants to send information, that information travels down the protocol layers to IP where it is [encapsulated in an IP datagram](#). That datagram then passes down to the data link layer of the device's physical network for transmission to the next hop, on the way to the IP destination.

However, one special range of addresses is set aside for *loopback* functionality. This is the range 127.0.0.0 to 127.255.255.255. IP datagrams sent by a host to a 127.x.x.x loopback address are not passed down to the data link layer for transmission. Instead, they “loop back” to the source device at the IP level. In essence, this represents a “short-circuiting” of the normal protocol stack; data is sent by a device's layer three IP implementation and then immediately received by it.

The purpose of the loopback range is testing of the TCP/IP protocol implementation on a host. Since the lower layers are short-circuited, sending to a loopback address allows the higher layers (IP and above) to be effectively tested without the chance of problems at the lower layers manifesting themselves. **127.0.0.1** is the address most commonly used for testing purposes.

**Key Concept:** Portions of the IP address space are set aside for reserved, private and loopback addresses.

---

## Private/Unregistered/Non-Routable Addresses

Recall that [in the IP address overview I contrasted private and public IP addresses](#). Every IP address on a IP network must be unique, and in the case of a public IP network, addresses are allocated using a [central authority](#) to ensure that there is no overlap. In contrast, if you set up a private network you can use whatever addresses you want; it's your show and nobody else has a say on what you do.

So, if this is the case, why not just pick any random block of class A, B or C addresses for your private network and use that? Well, you could; since you aren't connected to the Internet you could use, say, the class A network 18.x.x.x that is reserved on the Internet to the [Massachusetts Institute of Technology \(MIT\)](#). Since you aren't connected to MIT, what does it matter?

In the past, there were people who **did** choose to do this—and ended up regretting that decision. As the Internet grew in importance, they would later decide that such private networks needed to connect to the public Internet after all. If that happened and you had used 18.x.x.x addresses, you'd find yourself having to renumber all your devices to avoid getting a big bunch of geeks really angry. (There were in fact cases where companies that had used IP address space belonging to other companies accidentally connected those machines to the Internet, causing a small amount of ruckus in the process.)

---

From a more mundane standpoint, having internal devices with MIT's IP addresses is a source of confusion. It's just not a great idea to have lots of different companies “borrowing” IP addresses for their private networks.

As an alternative, RFC 1918 (superseding RFC 1597) defines a set of special address blocks that are set aside just for private addresses. These addresses simply don't exist to the public Internet. Anyone can use them with no need to contact any authority for permission. At the same time, they cannot connect to the global Internet, because routers are not programmed with entries to forward traffic with these address ranges outside of local organizations. RFC 1918 was in fact published to encourage the use of these private blocks, in order to cut down on the number of devices on the public Internet that didn't really need to be publicly-accessible. This was in response to the need to [conserve the public address space](#).

In order to connect a network using private addressing to the public Internet, it is necessary to employ additional hardware and/or software. A gateway machine can be used as an interface between the public and private networks. Technologies such as [IP Network Address Translation \(NAT\)](#) are often used in conjunction with private IP addresses to allow these hosts to communicate on the public IP network.

**Key Concept:** Private address blocks were created to allow private IP internets to be created using addresses that were guaranteed not to conflict with public IP addresses. They are commonly used in internetworks not connected to the global Internet; devices using them can also access the global Internet by using [NAT](#).

---

### ***Reserved, Loopback and Private Addressing Blocks***

[Table 48](#) shows all of the special blocks set aside from the normal IP address space in numerical order, with a brief explanation of how each is used:

**Table 48: Reserved, Loopback and Private IP Addresses (Page 1 of 2)**

Range Start Address	Range End Address	“Classful” Address Equivalent	Classless Address Equivalent	Description
0.0.0.0	0.255.255.255	Class A network 0.x.x.x	0/8	Reserved.
10.0.0.0	10.255.255.255	Class A network 10.x.x.x	10/8	Class A private address block.
127.0.0.0	127.255.255.255	Class A network 127.x.x.x	127/8	Loopback address block.
128.0.0.0	128.0.255.255	Class B network 128.0.x.x	128.0/16	Reserved.

**Table 48: Reserved, Loopback and Private IP Addresses (Page 2 of 2)**

Range Start Address	Range End Address	“Classful” Address Equivalent	Classless Address Equivalent	Description
169.254.0.0	169.254.255.255	Class B network 169.254.x.x	169.254/16	Class B private address block reserved for automatic private address allocation. See the section on DHCP for details.
172.16.0.0	172.31.255.255	16 contiguous Class B networks from 172.16.x.x through 172.31.x.x	172.16/12	Class B private address blocks.
191.255.0.0	191.255.255.255	Class B network 191.255.x.x	191.255/16	Reserved.
192.0.0.0	192.0.0.255	Class C network 192.0.0.x	192.0.0/24	Reserved.
192.168.0.0	192.168.255.255	256 contiguous Class C networks from 192.168.0.x through 192.168.255.x	192.168/16	Class C private address blocks.
223.255.255.0	223.255.255.255	Class C network 223.255.255.x	223.255.255/24	Reserved.

I have shown both the “classful” and [classless notation](#) representing each of these blocks. This is both because the Internet now uses [classless addressing](#), and because some of the private blocks don't correspond to single class A, B or C networks. Note especially the private address block from 192.168.0.0 to 192.168.255.255. This is the **size** of a class B network, but it isn't class B in the “classful” scheme, because the first octet of “192” puts it in the class C part of the address space. It is in fact 256 contiguous class C networks.

You may also notice the special class B (/16) block 169.254.x.x. This is reserved for *Automatic Private IP Addressing (APIPA)*. Systems that are configured to use this feature will automatically assign systems addresses from this block to enable them to communicate even if no server can be found for “proper” IP address assignment using DHCP. This is described in [a special topic in the section describing DHCP](#).

## **IP Multicast Addressing**

The vast majority of traffic on IP internetworks is of the *unicast* variety: one source device sending to one destination device. IP also supports *multicasting*, where a source device can send to a group of devices. Multicasting is not used a great deal on the Internet as a whole at the present time, mainly due to lack of widespread hardware support, so most of our focus in looking at IP is on unicast. Multicast is useful in certain circumstances, however,

---

especially as a more efficient alternative to broadcasting. I include [one summary topic on multicasting](#) for your perusal, and also want to briefly discuss here IP addressing issues related to multicasting.

The “classful” IP addressing scheme sets aside a full one-sixteenth of the address space for multicast addresses: Class D. Multicast addresses are [identified by the pattern “1110” in the first four bits](#), which corresponds to a first octet of 224 to 239. So, the full range of multicast addresses is from 224.0.0.0 to 239.255.255.255. Since multicast addresses represent a group of IP devices (sometimes called a *host group*) they can only be used as the destination of a datagram; never the source.

### **Multicast Address Types and Ranges**

The 28 bits after the leading “1110” in the IP address define the *multicast group address*. The size of the Class D multicast address space is therefore  $2^{28}$  or 268,435,456 multicast groups. There is no substructure that defines the use of these 28 bits; there is no specific concept of a network ID and host ID as in classes A, B and C. However, certain portions of the address space are set aside for specific uses. [Table 49](#) and [Figure 63](#) show the general allocation of the Class D address space.

**Table 49: IP Multicast Address Ranges and Uses**

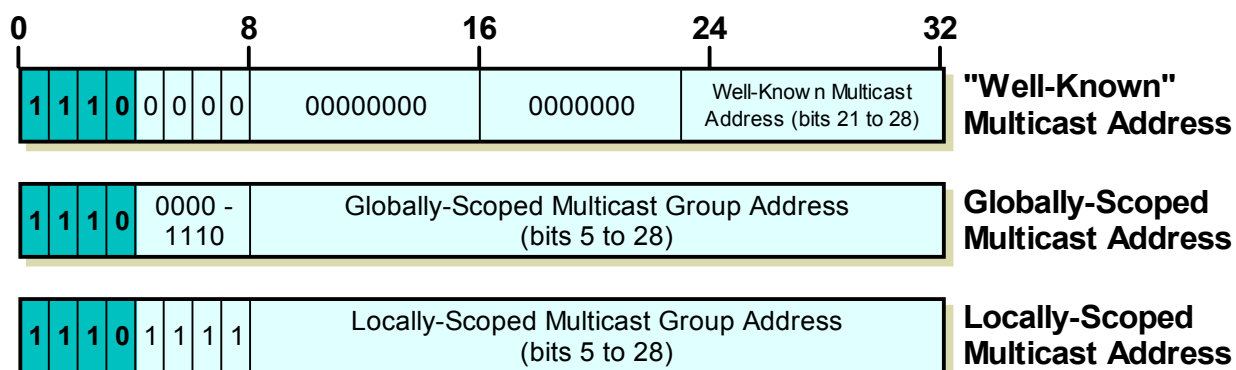

Range Start Address	Range End Address	Description
224.0.0.0	224.0.0.255	Reserved for special “well-known” multicast addresses.
224.0.1.0	238.255.255.255	Globally-scoped (Internet-wide) multicast addresses.
239.0.0.0	239.255.255.255	Administratively-scoped (local) multicast addresses.

**Note:** As with the other IP address classes, the entire 32 bits of the address is always used; we are just only interested in the least-significant 28 bits because the upper four bits never change.

The bulk of the address space is in the middle multicast range, which are “normal” multicast addresses. They are analogous to the Class A, B and C unicast addresses and can be assigned to various groups.

The last address range is for *administratively-scoped* multicast groups. This is a fancy term for multicast groups used within a private organization; this block, representing 1/16th of the total multicast address space, is comparable to the [private addresses we saw in the preceding topic](#). This block is also subdivided further into site-local multicast addresses, organization-local addresses and so forth.

**Figure 63: IP Multicast Address Ranges and Uses**

All multicast addresses begin with “1110” as shown. The “well-known” group has zeroes for the first 20 bits of the multicast group address, with 8 bits available to define 255 special multicast addresses. Multicast addresses starting with “1110 1111” are locally-scoped; all other addresses are globally-scoped (this includes addresses starting with “1110 0000” **other than** the 255 “well-known” addresses.)

**Related Information:** The concept of multicast address scope was more completely defined in IPv6, and I discuss it in more detail in the [in the discussion of IPv6 multicast addresses](#).

## Well-Known Multicast Addresses

The first block of 256 addresses is used to define special, **well-known** multicast address blocks. These do not represent arbitrary groups of devices and cannot be assigned in that manner. Instead, they have special meaning that allows a source to send a message to a predefined group. [Table 50](#) shows some of the “well-known” multicast addresses:

**Table 50: Well-Known IP Multicast Addresses (Page 1 of 2)**

Range Start Address	Description
224.0.0.0	Reserved; not used
224.0.0.1	All devices on the subnet
224.0.0.2	All routers on the subnet
224.0.0.3	Reserved
224.0.0.4	All routers using DVMRP
224.0.0.5	All routers using OSPF
224.0.0.6	Designated routers using OSPF
224.0.0.9	Designated routers using RIP-2

---

**Table 50: Well-Known IP Multicast Addresses (Page 2 of 2)**

Range Start Address	Description
224.0.0.11	Mobile agents (for Mobile IP)
224.0.0.12	DHCP Server / Relay Agent

**Note:** There are some other predefined groups that also refer to routers using particular [routing protocols](#); I didn't bother listing them all as the table would get quite large.

---

Delivery of IP multicast traffic is more complex than unicast traffic due to the existence of multiple recipients. Instead of the normal resolution method through the ARP protocol used for unicast datagrams, [a special mapping is performed between the IP multicast group and a hardware multicast group](#).

### **Problems With "Classful" IP Addressing**

The “classful” addressing system was the first major attempt to define a method for universal addressing of a large IP internetwork. The system had some advantages, as I mentioned in [the overview of the “classful” scheme](#), and given that it was developed decades ago for a network that was limited in size, it did the job remarkably well for a long time.

Nobody ever expected the Internet to mushroom to anything close to its current size. As it grew, problems become apparent with the “classful” IP addressing mechanism—slowly at first, but then more rapidly as growth became more rapid. I've hinted at some of these problems in my explanation of how this type of addressing works, but to help frame the discussion of newer addressing types, I think it is useful to look at this in more detail.

### ***Summary of “Classful” Addressing Issues***

There are three main problems with “classful” addressing, which are somewhat related to each other (making them a bit harder to explain). Let's start with a quick summary of what these issues are:

1. **Lack of Internal Address Flexibility:** Big organizations are assigned large, “monolithic” blocks of addresses that don't match well the structure of their underlying internal networks.
2. **Inefficient Use of Address Space:** The existence of only three block sizes (classes A, B and C) leads to waste of limited IP address space.
3. **Proliferation of Router Table Entries:** As the Internet grows, more and more entries are required for routers to handle the routing of IP datagrams, which causes performance problems for routers. Attempting to reduce inefficient address space allocation leads to even more router table entries.

---

## Addressing Inflexibility

Issue #1 results primarily from the fact that in the “classful” system, big companies get assigned a rather large (Class B) or truly enormous (Class A) block of addresses, all of which is considered by the Internet routers a single “network” with one “network ID”. Now, imagine that you are running a medium-to-large-sized company with 5,000 computers, and you are assigned a Class B address for your network. Do you really have 5,000 computers all hooked into a single network? I sure as heck hope you don’t! Yet you would be forced to try to fit all of these into a single IP “network” in the original “classful” method. There was no way to create an internal hierarchy of addresses.

### *The Key Problem with Classes: Low Granularity*

Issues #2 and #3 are more closely related to each other than issue #1 and are both the result of the fact that the “granularity” in the “classful” system is simply too low to be practical in a large internet. By this I mean that there are too few choices in the sizes of networks available. Three sizes seems fine in principle, but the gaps between the sizes are enormous, and the sizes don’t match up all that well with the distribution of organizations in the real world. Consider the difference in size between Class C and Class B networks—a jump from 254 hosts all the way up to over 65,000! There are many, many companies that need more than 254 IP address but a lot fewer than 65,000. And what about Class A? How many companies need 16 *million* IP addresses, even the truly large ones? Probably none, if you think about it, yet that’s half the IP address space right there.

Considering our company with 5,000 computers again—what class network should they use? As [Figure 64](#) shows, there is no good match for this company’s needs in the “classful” scheme at all. In the past, they would likely have been assigned a Class B network. However, giving a Class B to a company with “only” 5,000 computers means over 90% of the IP addresses are **wasted**. When the Internet was young this wasn’t a big deal, but as it grew these inefficiencies quickly started to become significant.

The alternative to wasting all these IP addresses would be to give the company instead of one Class B, a bunch of Class C addresses. However as you can see, they would need **20** of them. This is more efficient in use of address space, but leads to Issue #3: every router on the Internet replaces the single Class B router table entry with **20** Class C router entries. Now multiply this by a few thousand “medium-sized” companies and you can see that this method would add dramatically to the size of router tables. Router tables have already been growing quickly as the Internet has expanded. The larger these tables, the more time it takes for routers to make routing decisions.

### *Tactics for Dealing with “Classful” Addressing Difficulties*

These issues were addressed through three enhancements or improvements that I discuss in other sections. The first, which primarily addresses Issue #1, was the development of [subnetting](#). The second was the move to [classless addressing and routing](#), which replaces the “classful” system with a new method with higher granularity. This tackles Issues #2 and #3 by letting addresses be assigned based on real organizational needs without requiring

---

Hosts in Class C  
Network (254)

Hosts Needed  
By Organization  
(5,000)

Hosts in Class B  
Network (65,534)

**Figure 64: The Main Problem With “Classful” Addressing**

In this scale diagram, each square represents 50 available addresses. Since a Class C address has only 254 addresses, and a Class B contains 65,534 addresses, an organization with 5,000 hosts is “caught in the middle”. It can only choose to either waste 90% of a Class B address or use 20 different Class C networks.

numerous routing table entries for each organization. The third improvement is the new [IP version 6 protocol](#), which finally does away with the cramped 32-bit IP address space in favor of a [gargantuan 128-bit one](#).

Other support technologies have also helped extend the life of IP version 4. I discussed one important one in the previous topic—the use of [private addressing](#) in conjunction with [IP Network Address Translation \(NAT\)](#) to allow multiple devices to share public addresses. This alone has added years to the life of the IPv4 addressing system.

---

## IP Subnet Addressing ("Subnetting") Concepts

The original "classful" IP addressing scheme conceptually divides a large internetwork into a simple two-level hierarchy: many *networks* of different sizes, each of which contains a number of *hosts*. The system works well for smaller organizations that may connect all their machines in a single network. However, it lacks flexibility for large organizations that often have many subnetworks, or *subnets*. To better meet the administrative and technical requirements of larger organizations, the "classful" IP addressing system was enhanced through a technique known as *subnet addressing*, or more simply, *subnetting*.

In this section I describe the concepts and general techniques associated with IP subnet addressing. I begin with an overview of subnetting, including a discussion of the motivation for the system and its advantages. I discuss how the traditional "two-level" method for dividing IP addresses becomes "three-level" for subnetting. I talk about subnet masks and how they are used in calculations for addressing and routing. I discuss the default subnet masks used to represent the "classful" Class A, B and C networks in a subnetting environment, and then how custom subnet masks are used for classes A, B and C. I then discuss subnet identifiers and general concepts behind determining subnet and host addresses in a subnet environment. I provide summary tables for subnetting Class A, B and C networks. I conclude with a brief discussion of Variable Length Subnet Masking (VLSM), an enhancement of "conventional" subnetting that improves its flexibility further.

**Note:** I provide a great deal of coverage of subnetting, because understanding it is an important part of learning about how IP addresses work, and hence, how TCP/IP functions. However, I need to emphasize something that far too few references mention: the technique is today considered mostly *historical*. The reason is that subnetting is still based on "classful" addressing, which has been replaced by [classless addressing](#) on the Internet. The concept of a subnet and subnet mask has certainly not disappeared altogether, but the idea of being assigned a Class A, B or C Internet address block and then explicitly subnetting it is no longer relevant.

**Related Information:** This is the first of two sections dedicated to IP address subnetting. [The second section follows this one and describes the step-by-step process for subnetting using examples.](#) If you find that after reading this concepts section that you don't quite understand subnetting, try reading the example-based section and you may find that it helps make it all "click". On the other hand, if you are already somewhat familiar with subnetting, you may find that you can skip this concepts section and just go through the step-by-step examples. You will find much more in that section in the way of "gory details" of subnet mask, subnet address and host address calculations. Putting the practical details there allows this section to concentrate on concepts without getting too bogged down in numbers.

**Background Information:** Understanding subnetting requires a certain familiarity with binary numbers and how they are manipulated. This includes the concept of using boolean operators such as *AND* to “mask” binary digits. If reading that last sentence made you go “huh?” I ***strongly recommend*** reviewing [the background section on computing mathematics](#) before you proceed.

---

## **IP Subnet Addressing Overview, Motivation, and Advantages**

IP addressing was originally designed around the assumption of a strict [two-level hierarchy for internetworks](#). The first level was the *network*, and the second level the *host*. Each organization was usually represented by a single network identifier that indicated a [Class A, B or C block](#) dedicated to them. Within that network they had to put all of the devices they wanted to connect to the public IP network.

### ***The Motivation for Subnet Addressing***

It did not take long after the “classful” scheme was developed for serious inadequacies in it to be noticed, especially by larger organizations. The reason is that while dividing a large internetwork into networks that contain hosts is conceptually simple, it doesn't always match well the structure of each of the networks that comprises the internet. A big company with thousands of computers doesn't structure them as one big whomping physical network. Trying to assign and administer IP addresses to an organization's entire network without any form of internal logical structure is very difficult.

Unfortunately, under the original “classful” addressing scheme, there was no good solution to this problem. The most commonly-chosen alternative at the time was to trade a single large block of addresses such as a Class B for a bunch of Class Cs. However, this caused additional problems:

- ☉ It contributed to the explosion in size of IP routing tables.
- ☉ Every time more address space was needed, the administrator would have to apply for a new block of addresses.
- ☉ Any changes to the internal structure of a company's network would potentially affect devices and sites outside the organization.
- ☉ Keeping track of all those different Class C networks would be a bit of a headache in its own right.

**Related Information:** I fully explain [the problems with “classful” addressing](#) within [the section on “classful” addressing](#).

---

---

## ***The Development of Subnet Addressing***

In order to address this problem adequately, an enhancement was required to the “classful” addressing scheme. This change was outlined in RFC 950, which defined a new addressing procedure called *subnet addressing* or *subnetting*. (This RFC was published way back in 1985, which surprises some people!)

The basic idea behind subnet addressing is to add an additional hierarchical level in the way IP addresses are interpreted. The concept of a network remains unchanged, but instead of having just “hosts” within a network, a new two-level hierarchy is created: *subnets* and hosts. Each subnet is a subnetwork, and functions much the way a full network does in conventional classful addressing. A three-level hierarchy is thus created: networks, which contain subnets, each of which then has a number of hosts.

Thus, instead of an organization having to lump all of its hosts under that network in an unstructured manner, it can organize hosts into subnets that reflect the way internal networks are structured. These subnets fit within the network identifier assigned to the organization, just as all the “unorganized” hosts used to.

## ***Advantages of Subnet Addressing***

In essence, subnet addressing allows each organization to have its own “internet within the Internet”. Just as the real Internet looks only at networks and hosts, a two-level hierarchy, each organization can now also have subnets and hosts within their network. This change provides numerous advantages over the old system:

- ☛ **Better Match to Physical Network Structure:** Hosts can be grouped into subnets that reflect the way they are actually structured in the organization's physical network.
- ☛ **Flexibility:** The number of subnets and number of hosts per subnet can be customized for each organization. Each can decide on its own subnet structure and change it as required.
- ☛ **Invisibility To Public Internet:** Subnetting was implemented so that the internal division of a network into subnets is visible only within the organization; to the rest of the Internet the organization is still just one big, flat, “network”. This also means that any changes made to the internal structure are not visible outside the organization.
- ☛ **No Need To Request New IP Addresses:** Organizations don't have to constantly requisition more IP addresses, as they would in the workaround of using multiple small Class C blocks.
- ☛ **No Routing Table Entry Proliferation:** Since the subnet structure exists only within the organization, routers outside that organization know nothing about it. The organization still maintains a single (or perhaps a few) routing table entries for all of its devices. Only routers inside the organization need to worry about routing between subnets.

---

## ***The Impact of Subnetting on Addressing and Routing***

The change to subnetting affects both addressing and routing in IP networks. Addressing changes of course, because instead of having just a network ID and host ID, we now also have a *subnet ID* to be concerned with. The size of the subnet ID can vary for each network, so an additional piece of information is needed to supplement the IP address to indicate what part of the address is the subnet ID and what part is the host ID. This is a 32-bit number commonly called a *subnet mask*. The mask is used both for calculating subnet and host addresses, and by routers for determining how to move IP datagrams around a subnetted network.

Routing changes because of the additional level of hierarchy. In regular “classful” addressing, when a router receives an IP datagram, it only needs to decide if the destination is on the same network or a different network. Under subnetting, it must also look at the subnet ID of the destination and make one of three choices: same subnet, different subnet on the same network, or different network. Again, this is done using the subnet mask. Changes are also required to routing protocols, such as the [Routing Information Protocol \(RIP\)](#), to deal with subnets and subnet masks.

**Key Concept:** Subnet addressing adds an additional hierarchical level to how IP addresses are interpreted, by dividing an organization’s IP network into *subnets*.

This allows each organization to structure its address space to match its internal physical networks, rather than being forced to treat them a flat block. This solves a number of problems with the original “classful” addressing scheme, but requires changes to how addressing and routing work, as well as modifications to several TCP/IP protocols.

---

It’s funny, but the main drawbacks to subnetting, compared with the older addressing scheme, have more to do with understanding how subnetting works than the technology itself! More effort is required to deal with addressing and routing in a subnet environment, and administrators must learn how to subdivide their network into subnets and properly assign addresses. This can be a bit confusing to someone who is new to subnetting. However, the technology today is quite well-established so even this is not much of a problem. For the newcomer, having a handy reference guide like this one certainly helps. 😊

### **IP Subnetting: "Three-Level" Hierarchical IP Subnet Addressing**

The simplest division of IP addresses is into a structure containing two elements: the *network ID* and the *host ID*. [In explaining this concept](#), I drew an analogy to the way North American phone numbers are ten digits long, but are broken down into a three-number area code and a seven-digit local number.

[As I mentioned in the preceding topic](#), subnetting adds an additional level to the hierarchy of structures used in IP addressing. To support this, IP addresses must be broken into three elements instead of two. This is done by leaving the network ID alone and dividing the host

---

ID into a *subnet ID* and host ID. These subnet ID bits are used to identify each subnet within the network. Hosts are assigned to the subnets in whatever manner makes the most sense for that network.

Interestingly, the analogy to telephone numbers that we used before still holds in the world of subnetting, and shows how subnetting changes the way IP addresses are interpreted. A number like (401) 555-7777 has an area code (“401”) and a local number (“555-7777”) as I said before. The local number, however, can itself be broken down into two parts: the exchange (“555”) and the local extension (“7777”). This means phone numbers really are comprised of three hierarchical components just as IP addresses are in subnetting.

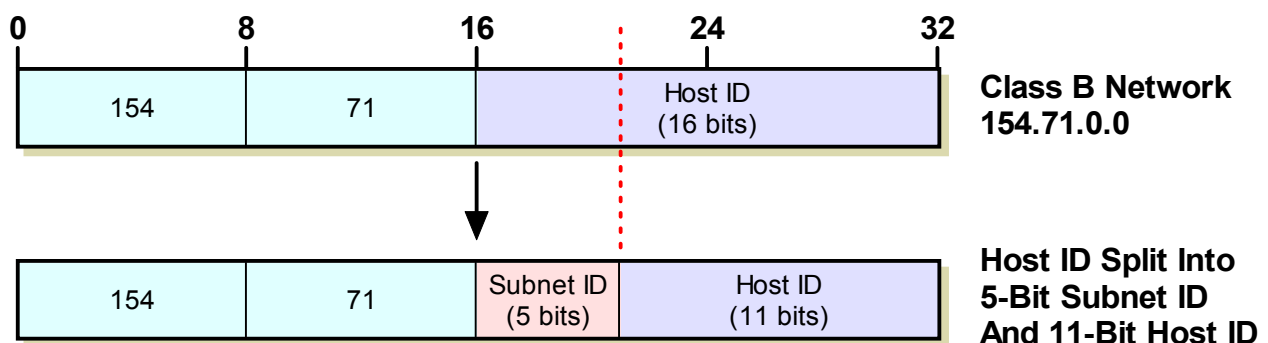

Of course, the number of bits in an IP address is fixed at 32. This means that in splitting the host ID into subnet ID and host ID, we reduce the size of the host ID portion of the address. In essence, we are “stealing” bits from the host ID to use for the subnet ID. Class A networks have 24 bits to split between the subnet ID and host ID: class B networks have 16, and class C networks only 8.

**Key Concept:** A “classful” network is subnetted by dividing its host ID portion, leaving some of the bits for the host ID while allocating others to a new *subnet ID*. These bits are then used to identify individual subnets within the network, into which hosts are assigned.

---

Now, remember when [we looked at the sizes of each of the main classes](#), we saw that for each class, the number of networks and the number of hosts per network are a function of how many bits we use for each. The same applies to our splitting of the host ID. Since we are dealing with binary numbers, the number of subnets is two to the power of the size of the subnet ID field. Similarly, the number of hosts per subnet is two to the power of the size of the host ID field (less two for excluded special cases).

**Figure 65: Subnetting A Class B Network**

We begin with the Class B network 154.71.0.0, which has 16 bits in its host ID block as shown at top. We then subnet this network by dividing the host ID into a subnet ID and host ID. In this case, 5 bits have been allocated to the subnet ID, leaving 11 for the host ID.

---

Let's take a brief example to see how this works. Imagine that we start with Class B network 154.71.0.0. 16 bits are for the network ID (154.71) and 16 for the host ID. In regular “classful” addressing there are no subnets (well, one “subnet” that is the whole network, but never mind about that) and 65,534 hosts total. To subnet this network, we can decide to split those 16 bits however we feel best suits the needs of our network: 1 bit for the subnet ID and 15 for the host ID, or 2 and 14, 3 and 13, and so on. Most any combination will work, as long as the total is 16, such as 5 and 11, which I illustrate in [Figure 65](#). The more bits we “steal” from the host ID for the subnet ID, the more subnets we can have—but the fewer hosts we can have for each subnet.

Deciding how to make this choice is one of the most important design considerations in setting up a subnetted IP network. The number of subnets is generally determined based on the number of physical subnetworks in the overall organizational network. The number of hosts per subnetwork must not exceed the maximum allowed for the particular subnetting choice we make. Choosing how to divide the original host ID bits into subnet ID bits and host ID bits is sometimes called *custom subnetting* and [is described in more detail later in this section](#).

## **IP Subnet Masks, Notation and Subnet Calculations**

[Subnetting](#) divides an organization's network into a two-level structure of subnets and hosts. This division is entirely internal and hidden from all other organizations on the Internet. One of the many advantages of this is that each organization gets to make their own choice about how to divide the “classful” host ID into subnet ID and host ID.

In a non-subnetted “classful” environment, [routers use the first octet of the IP address](#) to determine what the class is of the address, and from this they know which bits are the network ID and which are the host ID. When we use subnetting, these routers also need to know how that host ID is divided into subnet ID and host ID. However, this division can be arbitrary for each network. Furthermore, there is no way to tell how many bits belong to each simply by looking at the IP address.

In a subnetting environment, the additional information about which bits are for the subnet ID and which for the host ID must be communicated to devices that interpret IP addresses. This information is given in the form of a 32-bit binary number called a *subnet mask*. The term “mask” comes from the binary mathematics concept called *bit masking*. This is a technique where a special pattern of ones and zeroes can be used in combination with boolean functions such as *AND* and *OR* to select or clear certain bits in a number. [I explain bit masking in the background section on binary numbers and mathematics](#).

### ***Function of the Subnet Mask***

There's something about subnet masks that seems to set people's hair on end, especially if they aren't that familiar with binary numbers. However, the idea behind them is quite straight-forward. The mask is a 32-bit number, just as the IP address is a 32-bit number. Each of the 32 bits in the subnet mask corresponds to the bit in the IP address in the same

---

location in the number. The bits of the mask in any given subnetted network are chosen so that the bits used for either the network ID or subnet ID are ones, while the bits used for the host ID are zeroes.

**Key Concept:** The *subnet mask* is a 32-bit binary number that accompanies an IP address. It is created so that it has a one bit for each corresponding bit of the IP address that is part of its network ID or subnet ID, and a zero for each bit of the IP address's host ID. The mask thus tells TCP/IP devices which bits in that IP address belong to the network ID and subnet ID, and which are part of the host ID.

---

Why bother doing this with a 32-bit binary number? The answer is the magic of [boolean logic](#). We use the subnet mask by applying the boolean *AND* function between it and the IP address. For each of the 32 “bit pairs” in the IP address and subnet mask we employ the *AND* function, the output of which is 1 only if both bits are 1. What this means in practical terms is the following, for each of the 32 bits:

- ☛ **Subnet Bit Is A One:** In this case, we are *ANDing* either a 0 or 1 in the IP address with a 1. If the IP address bit is a 0, the result of the *AND* will be 0, and if it is a 1, the *AND* will be 1. In other words, *where the subnet bit is a 1, the IP address is preserved unchanged.*
- ☛ **Subnet Bit Is A Zero:** Here, we are *ANDing* with a 0, so the result is always 0 regardless of what the IP address is. Thus, *when the subnet bit is a 0, the IP address bit is always cleared to 0.*

So, when we use the subnet mask on an IP address, the bits in the network ID and subnet ID are left intact, while the host ID bits are removed. Like a mask that blocks part of your face but lets other parts show, the subnet mask blocks some of the address bits (the host bits) and leaves others alone (the network and subnet bits). A router that performs this function is left with the address of the subnet. Since it knows from the class of the network what part is the network ID, it also knows what subnet the address is on.

**Key Concept:** To use a subnet mask, a device performs a boolean *AND* operation between each bit of the subnet mask and each corresponding bit of an IP address. The resulting 32-bit number contains only the network ID and subnet ID of the address, with the host ID cleared to zero.

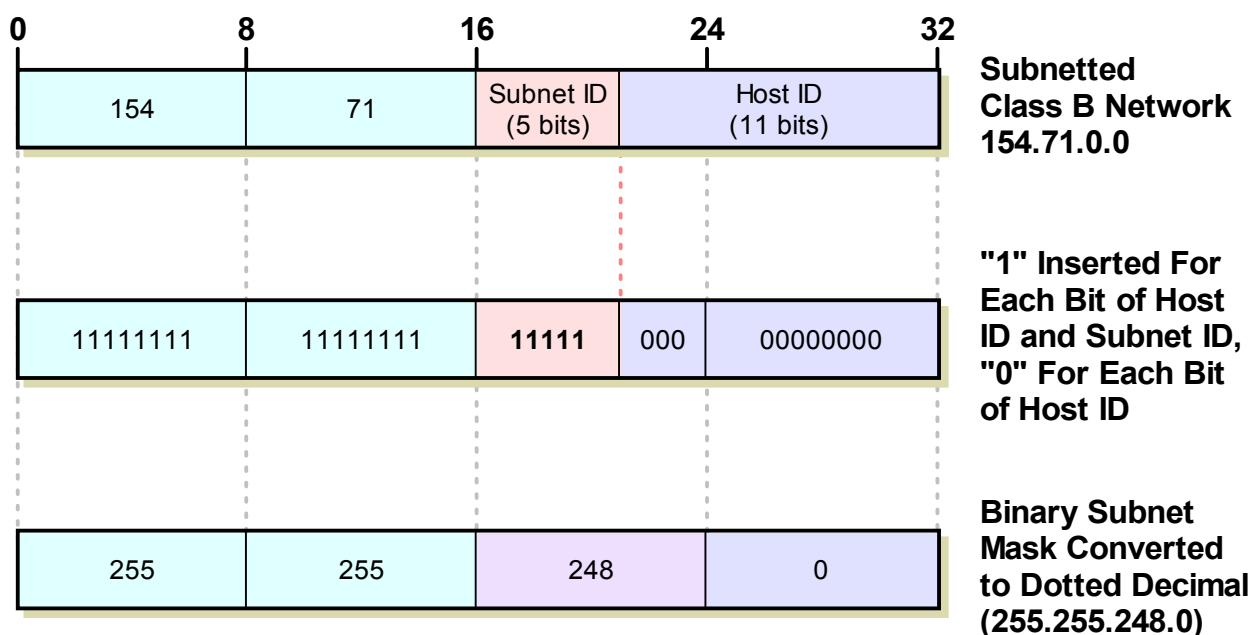

---

### **Subnet Mask Notation**

Like IP addresses, subnet masks are always used as a 32-bit binary number by computers. And like IP addresses, using them as 32-bit binary numbers is difficult for humans. Therefore, they are usually converted to dotted decimal notation for convenience, just like IP addresses are.

Let's take a quick example to show what this is all about. Suppose we have the Class B network 154.71.0.0. We decide to subnet this using 5 bits for the subnet ID and 11 bits for the host ID. In this case, the subnet mask will have 16 ones for the network portion (since this is Class B) followed by 5 ones for the subnet ID, and 11 zeroes for the host ID. That's "11111111 11111111 11111000 00000000" in binary, with the bits corresponding to the subnet ID highlighted. Converting to dotted decimal, the subnet mask would be 255.255.248.0.

Figure 66 illustrates this process.

**Figure 66: Determining the Subnet Mask of a Subnetted Network**

The class B network from Figure 65 has been shown at top, with 5 bits assigned to the subnet ID and 11 bits left for the host ID. To create the subnet mask, we fill in a 32-bit number with "1" for each network ID and subnet ID bit, and "0" for each host ID bit. We can then convert this to dotted decimal.

### Applying the Subnet Mask: An Example

Now, let's see how the subnet mask might be used. Suppose we have a host on this network with an IP of 154.71.150.42. A router needs to figure out which subnet this address is on. This is done by performing the masking operation shown in Table 51 and Figure 67.

**Table 51: Determining the Subnet ID of an IP Address Through Subnet Masking**

Component	Octet 1	Octet 2	Octet 3	Octet 4
IP Address	10011010 (154)	01000111 (71)	10010110 (150)	00101010 (42)
Subnet Mask	11111111 (255)	11111111 (255)	11111000 (248)	00000000 (0)
Result of AND Masking	10011010 (154)	01000111 (71)	10010000 (144)	00000000 (0)

**Figure 67: Determining the Subnet ID of an IP Address Through Subnet Masking**

Subnet masking involves performing a boolean *AND* between each corresponding bit in the subnet mask and the IP address. The subnet mask can be likened to a [physical mask](#); each 1 in it lets the corresponding bit of the IP address “show through”, while each 0 blocks the corresponding IP address bit. In this way the host ID bits of the address are stripped so the device can determine the subnet to which the address belongs.

This result, 154.71.144.0, is the IP address of the subnet to which 154.71.150.42 belongs. There is no need to explicitly differentiate the network ID bits from the subnet ID bits, because we are still using “classful” addresses. Any router can see that since the first two bits of the address are “10”, this is a Class B address. So the network ID is 16 bits, and this means the subnet ID must be bits 17 to 21, counting from the left. Here, the subnet is the portion highlighted above: “10010”, or subnet #18. ([I'll explain this better in the section on custom subnetting.](#))

**Key Concept:** The subnet mask is often expressed in dotted decimal notation for convenience, but is used by computers as a binary number, and usually must be expressed in binary to understand how the mask works and the number of subnet ID bits it represents.

### **Rationale for Subnet Mask Notation**

So, in practical terms, the subnet mask actually conveys only a single piece of information: where the line is drawn between the subnet ID and host ID. You might wonder, why bother with a big 32-bit binary number in that case, instead of just specifying the bit number where

---

the division occurs? Instead of carrying the subnet mask of 255.255.248.0 around, why not just say “divide the IP address after bit #21”? Even if devices want to perform a masking operation, could they not just create the mask as needed?

That's a very good question. There are two historical reasons: efficiency considerations and support for non-contiguous masks.

### Efficiency

The subnet mask expression is efficient, in that it allows routers to perform a quick masking operation to determine the subnet address. This improves performance; remember that computers were much slower when this system was developed. Today this is not really that much of an issue.

### Support For Non-Contiguous Masks

RFC 950 actually specified that when splitting the bits in the host ID for subnet ID and host ID, it was possible to split it in more than one place! In the example above, we could, instead of splitting the 16 bits into 5 bits for subnet ID and 11 for host ID, have done it as 2 bits for the subnet ID, then 4 bits for the host ID, then 3 more bits for the subnet ID and finally 7 more bits for host ID. This would be represented by the subnet mask pattern “11000011 10000000” for those sixteen bits (following the sixteen ones for the network ID).

Why do this instead of just dividing as 5 bits for subnet ID followed by 11 bits for host ID as we did before? I have no idea. ☺ In fact, most other people had no idea either. Trying to subnet this way makes assigning addresses **extremely** confusing. For this reason, while it was technically legal, the use of non-contiguous subnet masking was not recommended, and not done in practice.

Given that non-contiguous masks are not used, and today's computers are more efficient, the alternative method of expressing masks with just a single number is now often used. Instead of specifying “IP address of 154.71.150.42 with subnet mask of 255.255.248.0”, we can just say “154.71.150.42/21”. This is sometimes called *slash notation* or *CIDR notation*. It is more commonly used in [variable-length masking \(VLSM\)](#) environments, and as the second name implies, is also [the standard for specifying classless addresses under the CIDR addressing scheme](#). However, it is also sometimes seen in regular subnetting discussions.

**Note:** Since these weird masks were never really used, some resources say that the subnet mask always had to be contiguous, but this is not true—originally, it was legal but “advised against”. Later this practice became so out-of-favor that many hardware devices would not support it. Today, now that classless addressing and CIDR are standard, it is simply illegal.

---

---

If you've never subnetted before, this topic may have left you with your head spinning, despite our looking at an example. Don't worry. It will all become more clear as you become more familiar with subnetting by following the rest of this section. Remember also that [I have included a whole section that shows how to subnet step by step](#), including determining the subnet mask.

## **IP Default Subnet Masks For Address Classes A, B and C**

[Subnetting](#) is the process of dividing a Class A, B or C network into subnets, as we've seen in the preceding topics. In order to better understand how this “division of the whole” is accomplished, it's worth starting with a look at how the “whole” class A, B and C networks are represented in a subnetted environment. This is also of value because there are situations where you may need to define an unsubnetted network using subnetting notation.

This might seem like a strange concept—if you aren't going to bother creating subnets, why do you need to consider how the old-fashioned classes are used under subnetting? The answer is that after subnetting became popular, most operating systems and networking hardware and software were designed under the assumption that subnetting would be used. Even if you decide not to subnet, you may need to express your unsubnetted network using a subnet mask.

In essence, a non-subnetted class A, B or C network can be considered the “default case” of the more general, custom-subnetted network. Specifically, it is the case where we choose to divide the host ID so that zero bits are used for the subnet ID and all the bits are used for the host ID. I realize that this seems like a bit of a semantic game. However, this default case is the basis for the more practical subnetting [we will examine in the next topic](#).

Just as is always the case, the subnet mask for a default, unsubnetted class A, B or C network has ones for each bit that is used for network ID or subnet ID, and zeroes for the host ID bits. Of course, we just said we aren't subnetting, so there **are** no subnet ID bits! Thus, the subnet mask for this default case has 1s for the network ID portion and 0s for the host ID portion. This is called the *default subnet mask* for each of the IP address classes.

Since classes A, B and C divide the network ID from the host ID on octet boundaries, the subnet mask will always have all ones or all zeroes in an octet. Therefore, the default subnet masks will always have 255s or 0s when expressed in decimal notation. [Table 52](#) summarizes the default subnet masks for each of the classes; they are also shown graphically in [Figure 68](#).

**Table 52: Default Subnet Masks for Class A, Class B and Class C Networks**

IP Address Class	Total # Of Bits For Network ID / Host ID	Default Subnet Mask			
		First Octet	Second Octet	Third Octet	Fourth Octet
Class A	8 / 24	11111111 (255)	00000000 (0)	00000000 (0)	00000000 (0)
Class B	16 / 16	11111111 (255)	11111111 (255)	00000000 (0)	00000000 (0)
Class C	24 / 8	11111111 (255)	11111111 (255)	11111111 (255)	00000000 (0)

**Figure 68: Default Subnet Masks for Class A, Class B and Class C Networks**

---

So, the three default subnet masks are 255.0.0.0 for Class A, 255.255.0.0 for class B, and 255.255.255.0 for Class C. Note that while all default subnet masks use only “255” and “0”, not all subnet masks with “255” and “0” are defaults. There are a small number of custom subnets that divide on octet boundaries as well. These are:

- ☉ **255.255.0.0**: This is the default mask for Class B, but can also be the custom subnet mask for dividing a Class A network using 8 bits for the subnet ID (leaving 16 bits for the host ID).
- ☉ **255.255.255.0**: This is the default subnet mask for Class C, but can be a custom Class A with 16 bits for the subnet ID *or* a Class B with 8 bits for the subnet ID.

**Key Concept:** Each of the three IP unicast/broadcast address classes, A, B and C, has a *default subnet mask* defined that has a one for each bit of the class’s network ID, a zero bit for each bit of its host ID, and no subnet ID bits. The three default subnet masks are 255.0.0.0 for Class A, 255.255.0.0 for class B, and 255.255.255.0 for Class C.

---

## **IP Custom Subnet Masks**

It's important to understand what [default subnet masks](#) are and how they work. A default subnet mask doesn't really represent subnetting, however, since it is the case where we are assigning zero bits to the subnet ID. To do “real” subnetting we must dedicate at least one of the bits of the pre-subnetted host ID to the subnet ID, as shown in [the example in the topic that introduced subnet masks](#).

Since we have the ability to customize our choice of dividing point between subnet ID and host ID to suit the needs of our network, this is sometimes called *customized subnetting*. The subnet mask that we use when creating a customized subnet is, in turn, called a *custom subnet mask*. The custom subnet mask is used by network hardware to determine how we have decided to divide the subnet ID from the host ID in our network.

## ***Deciding How Many Subnet Bits to Use***

The key decision in customized subnetting is how many bits to take from the host ID portion of the IP address to put into the subnet ID. Recall that the number of subnets possible on our network is two to the power of the number of bits we use to express the subnet ID, and the number of hosts possible per subnet is two to the power of the number of bits left in the host ID (less two, which I will explain later in this topic).

Thus, the decision of how many bits to use for each of the subnet ID and host ID represents a fundamental trade-off in subnet addressing:

- ☉ Each bit taken from the host ID for the subnet ID doubles the number of subnets that are possible in the network.
- ☉ Each bit taken from the host ID for the subnet ID (approximately) halves the number of hosts that are possible within each subnet on the network.

---

## Subnetting Bit Allocation Options

Let's take a brief example or two to see how this works. Imagine that we start with a Class B network with the network address 154.71.0.0. Since this is Class B, 16 bits are for the network ID (154.71) and 16 are for the host ID. In the default case there are no subnets (well, one “subnet” that is the whole network) and 65,534 hosts total. To subnet this network, we have a number of choices:

1. We can decide to use 1 bit for the subnet ID and 15 bits for the host ID. If we do this, then the total number of subnets is  $2^1$  or 2: the first subnet is 0 and the second is 1. The number of hosts available for each subnet is  $2^{15}-2$  or 32,766.
2. We can use 2 bits for the subnet ID and 14 for the host ID. In this case, we double the number of subnets: we now have  $2^2$  or 4 subnets: 00, 01, 10 and 11 (subnets 0, 1, 2 and 3). But the number of hosts is now only  $2^{14}-2$  or 16,382.
3. We can use any other combination of bits that add up to 16, as long as they allow us at least 2 hosts per subnet: 4 and 12, 5 and 11, and so on.

## Trading Off Bit Allocations To Meet Subnetting Requirements

How do we decide how to divide the “classful” host ID into subnet ID and host ID bits? This is the key design decision in subnetting. We must make this choice based on our requirements for the number of subnets that exist in the network, and also on the maximum number of hosts that need to be assigned to each subnet in the network. For example, suppose we have 10 total subnets for our Class B network. We need 4 bits to represent this, because  $2^4$  is 16 while  $2^3$  is only 8. This leaves 12 bits for the host ID, for a maximum of 4,094 hosts per subnet.

However, suppose instead that we have 20 subnets. If so, 4 bits for subnet ID won't suffice: we need 5 bits ( $2^5=32$ ). This means in turn that we now have only 11 bits for the host ID, for a maximum of 2,046 hosts per subnet. [Step #2 of the practical subnetting example discusses these decisions in more detail.](#)

Now, what happens if we have 20 subnets and also need a maximum of 3,000 hosts per subnet? Well, we have a problem. We need 5 bits to express 20 different subnets. However, we need 12 bits to express the number 3,000 for the host ID. That's 17 bits—too many. The solution? We might be able to shuffle our physical networks so that we only have 16. If not, we need a second Class B network.

It's also important to realize that in regular subnetting, the choice of how many bits to use for the subnet ID is fixed for the entire network. You can't have subnets of different sizes—they must all be the same. Thus, the number of hosts in **the largest subnet** will dictate how many bits you need for the host ID. This means that in the case above, if you had a strange configuration where 19 subnets had only 100 hosts each but the 20th had 3,000, you'd have a problem. If this were the case, you could solve the problem easily by dividing that one oversized subnet into two or more smaller ones. An enhancement to subnetting called [Variable Length Subnet Masking \(VLSM\)](#) was created in large part to remove this restriction.

**Note:** I have included [summary tables](#) that show the trade-off in subnetting each of Classes A, B and C, and the subnet mask for each of the choices.

---

**Key Concept:** The fundamental trade-off in subnetting: each addition of a bit to the subnet ID (and thus, subtraction of that bit from the host ID) doubles the number of subnets, and approximately halves the number of hosts in each subnet. Each subtraction of a bit from the subnet ID (and addition of that bit to the host ID) does the opposite.

---

### ***Determining the Custom Subnet Mask***

Once we have determined how many bits we are going to devote to the subnet ID and the host ID, we can figure out the subnet mask. This is fairly easy to do, now that we understand how subnetting works. We begin with the default subnet mask in binary for the appropriate class of our network. We then start with the left-most zero in that mask and change as many bits to 1 as we have dedicated to the subnet ID. We can then express the subnet mask in dotted decimal form. [Figure 69](#) shows how the custom subnet mask can be determined for each of the subnetting options of a Class C network, in both binary and decimal.

So, to take the example in that figure, consider the Class C network 200.13.94.0. There are 8 bits in the original host ID, which gives us six different subnetting options (we can't use 7 or 8 bits for the subnet ID, for reasons we will discuss shortly.) Suppose we use three of these for the subnet ID and five are left for the host ID. To determine the custom subnet mask, we start with the Class C default subnet mask:

11111111 11111111 11111111 00000000

We then change the first three zeroes to ones, to get the custom subnet mask:

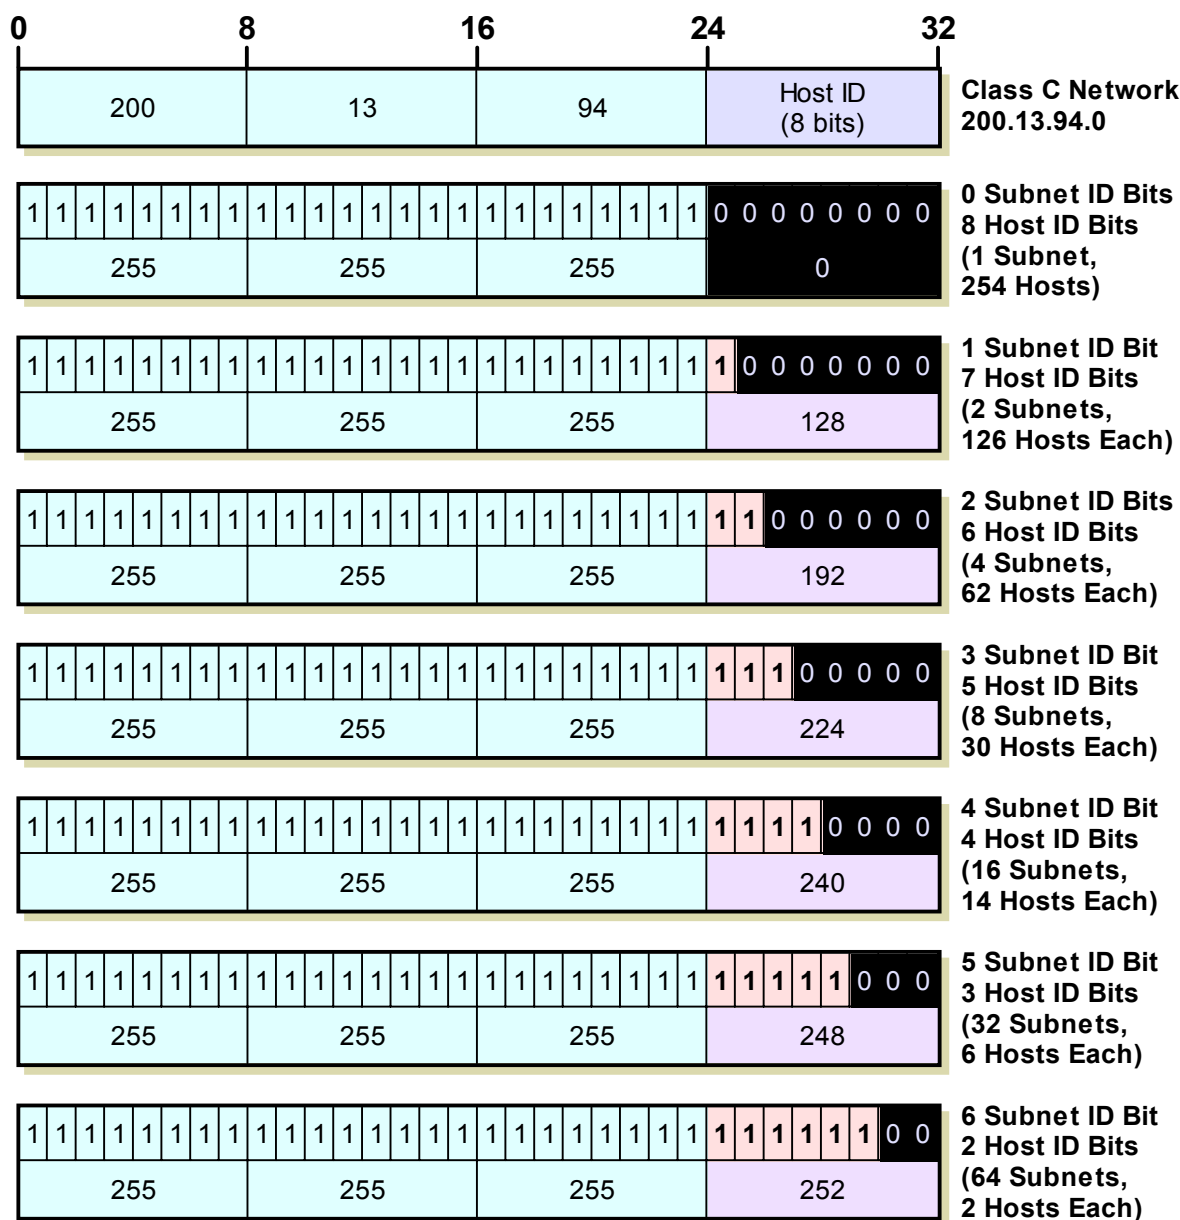

11111111 11111111 11111111 **111**00000

In dotted decimal format, this is 255.255.255.224.

**Key Concept:** Once the choice of how to subnet has been made, the custom subnet mask is determined simply, by starting with the default subnet mask for the network and changing each subnet ID bit from a 0 to a 1.

---

**Figure 69: Custom Subnet Masks for Class C Networks**

Since there are 8 host ID bits in a Class C network address, there are six different ways that the network can be subnetted. Each corresponds to a different custom subnet mask, which is created by changing the allocated subnet ID bits from zero to one.

### ***Subtracting Two From the Number of Hosts Per Subnet and (Possibly) Subnets Per Network***

There's one more issue that needs to be explained regarding the split into subnet ID and host ID. We've already seen how in regular "classful" addressing, we must subtract 2 from the number of hosts allowed in each network. This is necessary because two host IDs in each subnet have "special meanings": the all-zeroes host ID meaning "this network", and

---

the all-ones host ID which is a broadcast to “all hosts on the network”. These restrictions apply also to each subnet under subnetting too, which is why we must continue to subtract 2 from the number of hosts per subnet. (This is also why dividing the 8 host ID bits of a Class C network into 7 bits for subnet ID and 1 bit for host ID is not just silly, but in fact meaningless: it leaves  $2^1-2=0$  hosts per subnet. Not particularly useful.)

There is a similar issue that occurs with the subnet ID as well. When subnetting was originally defined in RFC 950, the standard specifically excluded the use of the all-zeroes and all-ones subnets. This was due to concern that routers might become confused by these cases. A later standard, RFC 1812 (*Requirements for IP Version 4 Routers*) removed this restriction in 1995. Thus, modern hardware now has no problem with the all-zeroes or all-ones subnets, but some very old hardware may still balk at it.

**Key Concept:** The number of hosts allowed in each subnet is the binary power of the number of host ID bits remaining after subnetting, **less two**. The reduction by two occurs because the all-zeroes and all-ones host IDs within each subnet are reserved for two “special meaning” addresses: to refer to the subnetwork itself and its local broadcast address. In some implementations, the number of subnets is also reduced by two because the all-zeroes and all-ones subnet IDs were originally not allowed to be used.

---

For this reason, you will sometimes see discussions of subnetting that exclude these cases. When that is done, you lose 2 potential subnets: the all-zeroes and all-ones subnets. If you do this, then choosing 1 bit for subnet ID is no longer valid, as it yields  $2^1-2=0$  subnets. You must choose 2 bits if you need 2 subnets.

**Note:** In this Guide I assume we are dealing with modern hardware and do not exclude the all-zeroes and all-ones subnets, but I do try to make explicit note of this fact wherever relevant.

---

## **IP Subnet Identifiers, Subnet Addresses and Host Addresses**

The main advantage of [conventional “classful” addressing without subnets](#) is its simplicity. Even though we've seen that there can be problems with how to manage thousands of devices in a single Class B network, for example, there is little complexity in how to assign addresses within the network. They are all lumped together, so any combination of bits can be used within the host ID (except for all-zeroes and all-ones, which are [special](#)).

When we subnet, however, we [create a two-level structure within the “classful” host ID](#)—subnet ID and host ID. This means we must choose IP addresses for devices more carefully. In theory, we are selecting subnets to correspond to our physical networks within the organization, so we want to assign IP addresses in a way that is consistent with our physical network structure.

---

## Subnet Identifiers

Once we decided how many subnets we are going to have, we need to identify the subnets and determine what the addresses are for the subnets. Let's start by looking at the *subnet identifier*. This is just the *subnet ID* of any of the subnets in our network. Subnets are numbered starting with 0 and increasing up to one less than the maximum number of subnets, which is a function of how many bits are in the subnet ID. (If the all-zero and all-one subnet IDs are excluded as specified in RFC 950 then the first subnet identifier is one).

Of course, we may not need all of the subnets that can theoretically be defined. For example, if we have 20 subnets, we need 5 bits for the subnet identifier, which allows a theoretical maximum of 32 subnets. We would use only subnets 0 to 19; 20 through 31 would be reserved for future use. These subnets could be expressed either in decimal form (0, 1, 2 ... up to 19) or in binary (00000, 00001, 00010 ... up to 10011).

## Subnet Addresses

For each subnet we can also determine the *subnet address*. To do this we start with the IP address for the overall network, which recall has all zeroes in the “classful” host ID field (8 bits, 16 bits or 24 bits). We then insert the subnet identifier for a particular subnet into the designated subnet bits.

As an example, let's refer back to the subnetting of a Class B network, 154.71.0.0, shown in Figure 66. We used five subnet ID bits there. We start with the following network IP address, with the subnet ID bits highlighted:

10011010 01000111 00000000 00000000

To find the address of say, subnet #11, we would substitute “01011” for these bits, leaving the host ID bits zero:

10011010 01000111 01011000 00000000

We can then convert this from binary form to dotted decimal, resulting in a subnet address of 154.71.88.0.

**Key Concept:** The *subnet identifier* of a subnet is just its subnet ID. The subnet address of a subnet is determined by substituting its subnet ID into the subnet bits of the overall network address.

---

---

## Subnet Address Formulas

Notice when looking at subnet addressing that when you substitute subnet IDs in sequence, a pattern becomes immediately visible. The first subnet address is always the address of the overall network, because the subnet ID is all zeroes. Then, the second subnet address in decimal form is found by adding a specific multiple of two to one of the octets. The third address is then found by adding this same number to the second address, and so on.

In fact, I realized that the decimal value of each subnet address can be expressed as a formula, based on the class of the original network and the number of bits being used for the subnet ID. For example, consider a Class B network with overall address of “x.y.0.0” (it doesn’t matter what “x” and “y” are for our purposes). Now, say we are using two bits for the subnet ID. We have four subnet addresses here:

1. The address of subnet #0 will be the same as the network address: x.y.0.0.
2. The address of subnet #1 will be found by substituting “01” for the first two bits of the third octet. This yields an address of “x.y.01000000.00000000”, or “x.y.64.0” in straight decimal.
3. Subnet #2’s address is found by substituting “10” for the subnet ID bits, so it is “x.y.10000000.00000000”, or “x.y.128.0” in straight decimal.
4. Subnet #3’s address will be “x.y.192.0”.

So, the formula in this case for subnet #N is “x.y.N\*64.0”. If we use five bits for a subnet, the formula is “x.y.N\*8.0”; as we saw above, the subnet address for subnet #11 in network 154.71.0.0 is 154.71.88.0. I have shown the formulas for all of the combinations of subnet ID and host ID size in [the subnetting summary tables](#). These formulas may seem a bit confusing at first, but they can be a real time-saver once you become more familiar with subnetting.

## Host Addresses Within Each Subnet

Once we know the subnet address for a particular subnet, assigning IP addresses is easy. We just plug in values into the remaining host ID bits. Of course, we skip the all-zeroes value, so the first host in the subnet has all zeroes for the host ID except for a one in the right-most bit position. Then the next host has all zeroes except for “10” at the end (two in decimal). We can do this all the way up to one less than the all-ones value. Again, we then convert each IP address from binary to decimal.

Some more examples would definitely help you understand much better how these addresses are determined. This requires us to deal with a large number of nitty-gritty details and lots of binary numbers. [You can find exactly these details in the section on practical subnetting.](#)

---

## IP Subnetting Summary Tables For Class A, Class B and Class C Networks

Since there are only a few options for how to subnet each of Class A, Class B and Class C networks, I have listed the options for each class in three summary tables below: [Table 53](#), [Table 54](#) and [Table 55](#). These tables can help you quickly [decide how many bits to use for subnet ID and host ID](#), and then what the subnet mask is for their selection. They also summarize nicely what we've discussed in this section.

Each row of each table shows one possible subnetting option for that class, including the number of bits for each of the subnet ID and host ID, and the number of subnets and hosts based on the number of bits. I then show the subnet mask in binary and decimal form, as well as in [CIDR notation](#). Finally, I include the formula for calculating the addresses for each subnet under each of the options.

### Notes on the Three Subnetting Summary Tables

A few additional explanatory notes are in order regarding these tables:

- ☛ The values for the number of subnets per network assume that the all-zeroes and all-ones subnets are allowed. [If not, you must subtract 2 from those figures](#); this also means that the option using only one bit for the subnet ID becomes invalid, and the subnet address formulas no longer work as shown.
- ☛ The number of hosts per subnet **does** exclude the all-zeroes and all-ones cases, so it is two to the power of the number of host ID bits, less two.
- ☛ The first row of each table shows the “default” case where the number of subnet bits is zero, and thus the subnet mask is the [default subnet mask for the class](#).
- ☛ In the subnet mask for all options but the default, I have highlighted the portion of the subnet mask corresponding to the subnet ID, for clarity. This has been done for each individual bit of the binary mask, and for each octet in the dotted decimal representation of the mask where part of the subnet ID is found.
- ☛ You will see that not all of the divisions make a great deal of sense in the real world... though you might be surprised. For example, at first glance it seems silly to think that we might want to assign 14 bits of a Class B host ID to the subnet ID and leave 2 bits for the host ID—what sort of real network has 16,384 subnets with 2 hosts on each? Yet some larger Internet service companies may indeed require thousands of tiny subnets when setting up connections between routers, or between their core network and their customers.
- ☛ The subnet address formulas in the last column of each table show the address for subnet #N (numbering from zero up to one less than the maximum number of subnets). [See the end of step #4 in the step-by-step subnetting section](#) for a full explanation of how these formulas work.

## Class A

**Table 53: Subnetting Summary Table For Class A Networks (Page 1 of 2)**

# of Subnet ID Bit	# of Host ID Bits	# of Subnets Per Network	# of Hosts Per Subnet	Subnet Mask (Binary / Dotted Decimal)	Subnet Mask (Slash/CIDR Notation)	Subnet Address #N Formula (N=0, 1, ... # of Subnets-1)

### IP Variable Length Subnet Masking (VLSM)

Conventional [Subnet masking](#) replaces the two-level IP addressing scheme with a more flexible three-level method. Since it lets network administrators assign IP addresses to hosts based on how they are connected in physical networks, subnetting is a real breakthrough for those maintaining large IP networks. It has its own weaknesses though, and still has room for improvement. The main weakness of conventional subnetting is in fact that the subnet ID represents only *one* additional hierarchical level in how IP addresses are interpreted and used for routing.

### ***The Problem With Single-Level Subnetting***

It may seem “greedy” to look at subnetting and say “what, only *one* additional level”? ☺ However, in large networks, the need to divide our entire network into only one level of subnetworks doesn't represent the best use of our IP address block. Furthermore, we have already seen that since the subnet ID is the same length throughout the network, we can have problems if we have subnetworks with very different numbers of hosts on them—the subnet ID must be chosen based on whichever subnet has the greatest number of hosts, even if most of subnets have far fewer. This is inefficient even in small networks, and can result in the need to use extra addressing blocks while wasting many of the addresses in each block.

---

For example, consider a relatively small company with a Class C network, 201.45.222.0/24. They have six subnetworks in their network. The first four subnets (S1, S2, S3 and S4) are relatively small, containing only 10 hosts each. However, one of them (S5) is for their production floor and has 50 hosts, and the last (S6) is their development and engineering group, which has 100 hosts.

The total number of hosts needed is thus 196. Without subnetting, we have enough hosts in our Class C network to handle them all. However, when we try to subnet, we have a big problem. In order to have six subnets we need to use 3 bits for the subnet ID. This leaves only 5 bits for the host ID, which means every subnet has the identical capacity of 30 hosts, as shown in [Figure 70](#). This is enough for the smaller subnets but not enough for the larger ones. The only solution with conventional subnetting, other than shuffling the physical subnets, is to get another Class C block for the two big subnets and use the original for the four small ones. But this is expensive, and means wasting hundreds of IP addresses!

**Class C (/24) Network (254 Hosts)**

**Figure 70: Class C (/24) Network Split Into Eight Conventional Subnets**

With traditional subnetting, all subnets must be the same size, which creates problems when there are some subnets that are much larger than others. Contrast to [Figure 71](#).

### ***The Solution: Variable Length Subnet Masking***

The solution to this situation is an enhancement to the basic subnet addressing scheme called *Variable Length Subnet Masking (VLSM)*. VLSM seems complicated at first, but is easy to comprehend if you understand basic subnetting. The idea is that you subnet the network, and then subnet the subnets just the way you originally subnetted the network. In

---

fact, you can do this multiple times, creating subnets of subnets of subnets, as many times as you need (subject to how many bits you have in the host ID of your address block). It is possible to choose to apply this multiple-level splitting to only some of the subnets, allowing you to selectively cut the "IP address pie" so that some of the slices are bigger than others. This means that our example company could create six subnets to match the needs of its networks, as shown in [Figure 71](#).

**Figure 71: Class C (/24) Network Split Using Variable Length Subnet Masking (VLSM)**

Using VLSM, an organization can divide its IP network multiple times, to create subnets that much better match the size requirements of its physical networks. Contrast to [Figure 70](#).

**Key Concept:** *Variable Length Subnet Masking (VLSM)* is a technique where subnetting is performed multiple times in iteration, to allow a network to be divided into a hierarchy of subnetworks that vary in size. This allows an organization to much better match the size of its subnets to the requirements of its networks.

### ***An Example: Multiple-Level Subnetting Using VLSM***

VLSM subnetting is done the same way as regular subnetting; it is just more complex because of the extra levels of subnetting hierarchy. You do an initial subnetting of the network into large subnets, and then further break down one or more of the subnets as required. You add bits to the subnet mask for each of the "sub-subnets" and "sub-sub-

---

subnets" to reflect their smaller size. In VLSM, the [slash notation of classless addressing](#) is commonly used instead of binary subnet masks—VLSM is very much like [CIDR](#) in how it works—so that's what I will use.

**Note:** Before proceeding to the VLSM example that follows, a suggestion: if you aren't feeling comfortable with how basic subnetting works, you probably want to read through [the section on practical subnetting](#) first. Trust me. 😊

---

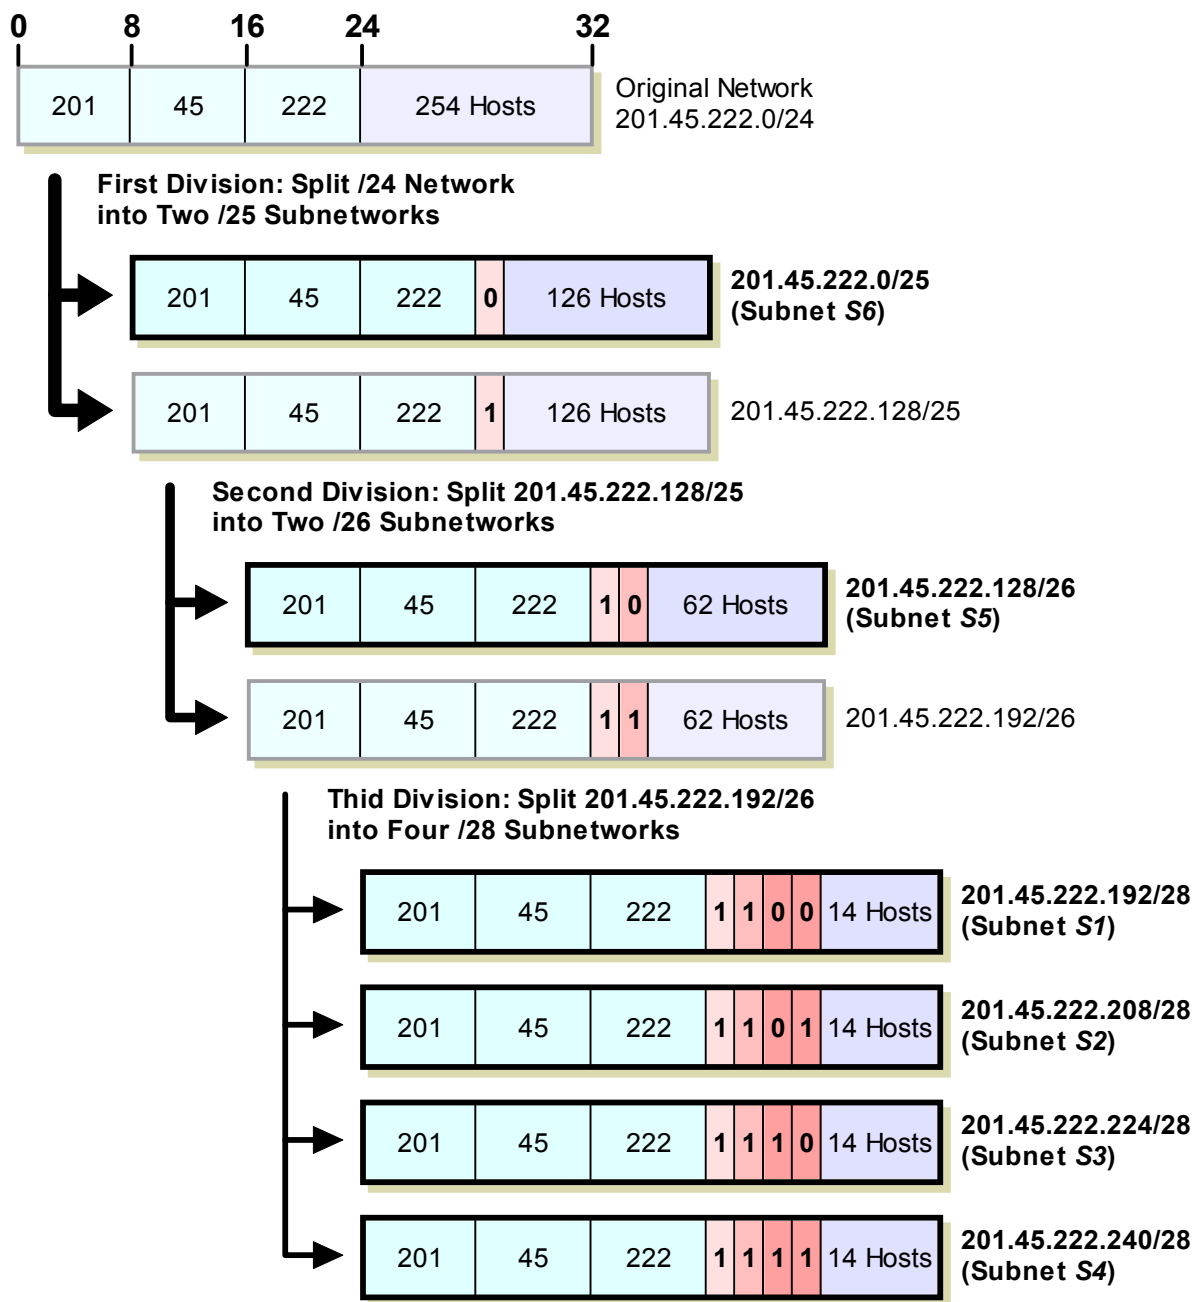

Let's take our example above again and see how we can make everything fit using VLSM. We start with our Class C network, 201.45.222.0/24. We then do three subnettings as follows (see [Figure 72](#) for an illustration of the process):

1. We first do an initial subnetting by using one bit for the subnet ID, leaving us 7 bits for the host ID. This gives us two subnets: 201.45.222.0/25 and 201.45.222.128/25. Each of these can have a maximum of 126 hosts. We set aside the first of these for subnet S6 and its 100 hosts.
2. We take the second subnet, 201.45.222.128/25, and subnet it further into two sub-subnets. We do this by taking one bit from the 7 bits left in the host ID. This gives us the sub-subnets 201.45.222.128/26 and 201.45.222.192/26, each of which can have 62 hosts. We set aside the first of these for subnet S5 and its 50 hosts.
3. We take the second sub-subnet, 201.45.222.192/26, and subnet it further into four sub-sub-subnets. We take 2 bits from the 6 that are left in the host ID. This gives us four sub-sub-subnets that each can have a maximum of 14 hosts. These are used for S1, S2, S3 and S4.

Okay, I *did* get to pick the numbers in this example so that they work out just perfectly, but you get the picture. VLSM greatly improves both the flexibility and the efficiency of subnetting. In order to use it, routers that support VLSM-capable routing protocols must be employed. VLSM also requires more care in how routing tables are constructed to ensure that there is no ambiguity in how to interpret an address in the network.

As I said before, VLSM is similar in concept to the way [classless addressing and routing \(CIDR\)](#) is performed. The difference between VLSM and CIDR is primarily one of focus. VLSM deals with subnets of a single network in a private organization. CIDR takes the concept we just saw in VLSM to the Internet as a whole, by changing how organizational networks are allocated by replacing the single-level “classful” hierarchy with a multiple-layer hierarchy.

**Figure 72: Variable Length Subnet Masking (VLSM) Example**

This diagram illustrates the example described in the text, of a Class C (/24) network divided using three hierarchical levels. It is first divided into two subnets; one subnet is divided into two *sub-subnets*; and one sub-subnet is divided into four *sub-sub-subnets*. The resulting six subnets are shown with thick black borders, and have a maximum capacity of 126, 62, 14, 14, 14 and 14 hosts.

---

## **IP Subnetting: Practical Subnet Design and Address Determination Example**

When educators ask students what they consider to be the most confusing aspect in learning about networking, many say that it is IP address subnetting. While subnetting isn't all that difficult in concept, it can be a bit mind-boggling in part due to the manipulations of binary numbers required. Many people understand the ideas behind subnetting but find it hard to follow the actual steps required to subnet a network.

For this reason, even though I [explained the concepts behind subnetting in detail in the previous section](#), I felt it would be valuable to have another section that provides a step-by-step look at how to perform custom subnetting. This section divides subnetting into five relatively straight-forward stages that cover determining requirements, making the design decision of how many bits to use for subnet ID and host ID, and then determining important numbers such as the subnet mask, subnet addresses and host addresses.

My focus in this section is on showing the practical “how” of subnetting. The topics here work through two examples using a Class B and a Class C sample network to show you how subnetting is done, and I am explicit in showing how everything is calculated. This means the section is a bit “number-heavy”. Also, I try not to duplicate conceptual issues covered in the previous section, though a certain amount of overlap does occur. Overall, if you are not familiar with how subnetting works at all, you will want to [read that section first](#). I do refer to topics in that section where appropriate, especially the [summary tables](#). Incidentally, I only cover conventional subnetting here, not [VLSM](#).

This section may serve as a useful refresher or summary of subnetting for someone who is already familiar with the basics but just wants to review the steps performed in subnetting. Again, always bear in mind that subnetting is based on the older “[classful](#)” IP addressing [scheme](#), and today's Internet is [classless](#), using [CIDR](#).

**Background Information:** If you are not familiar with binary numbers, binary-to-decimal conversion and masking, and you didn't take my advice in preceding sections to brush up on these concepts using the [background explanation of computational math](#), you *really* want to do that now.

---

**Note:** If in reading this section you find yourself wanting to do binary-to-decimal conversions or binary math, remember that most versions of Windows (and many other operating systems) have a calculator program that incorporates scientific functions.

---

---

## **IP Subnetting Step #1: Requirements Analysis**

When you are building or upgrading a network as a whole, the first step isn't buying hardware, or figuring out protocols, or even design. It's *requirements analysis*, the process of determining what it is the network needs to do. Without this foundation, you risk implementing a network that may perfectly match your design—but not meet the needs of your organization. The exact same rule applies to subnetting as well. Before we look at the gory details of host addresses and subnet masks, we must decide how to subnet the network. To do that, we must understand the requirements of the network.

### ***Key Subnetting Requirements***

Analyzing the requirements of the network for subnetting isn't difficult, because there are only a few issues that we need to consider. Since requirements analysis is usually done by asking questions, here's a list of the most important questions in analyzing subnetting requirements:

- ① What class is our IP address block?
- ② How many physical subnets are on the network today? (A “physical subnet” generally refers to a broadcast domain on a LAN; a set of hosts on a physical network bounded by routers.)
- ③ Do we anticipate adding any more physical networks in the near future, and if so, how many?
- ④ How many hosts do we have in the largest of our subnets today?
- ⑤ How many hosts do we anticipate having in the largest subnet in the near future?

The first question is important because everything in subnetting is based around dividing up a [Class A, Class B or Class C network](#), so we need to know which we are dealing with. If we are in the process of designing a network from scratch and don't have a Class A, B or C block yet, then we will determine which we need based on the approximate size of the organization. After that, we need to determine two key numbers: how many physical subnets we have, and the maximum number of hosts per subnet.

### ***Assessing Future Needs During Requirements Analysis***

We need to analyze the requirements above not only for the present network, but for the *near future* as well. The current values for these two numbers represent how the network needs to be designed today. However, designing only for the present is not a good idea.

Suppose we have exactly four subnetworks in our network now. In theory, we could use only two bits for the subnet ID, since  $2^2$  is 4. However, if our company is growing rapidly, this would be a poor choice. When we need to add a fifth subnet we'd have a problem!

Similarly, consider the growth in the number of hosts in a subnet. If the current largest subnet has 60 hosts, you don't want 6a bits for the host ID, because that limits you to 62 hosts. You can divide large subnets into smaller ones, but this may just mean unnecessarily additional work.

---

So, what is the “near future”? The term is necessarily vague, because it depends on how far into the future the organization wants to look. On the one hand, planning for several years' growth can make sense, if you have enough IP addresses to do it. On the other, you don't want to plan too far out, since changes in the short term may cause you to completely redesign your network anyway.

**Key Concept:** To successfully subnet a network, you must begin by learning what the requirements of the network will be. The most important parameters to determine are the number of subnets required and the maximum number of hosts needed per subnet. Numbers should be based not just on present needs but requirements in the near future.

---

## **IP Subnetting Step #2: The Key Design Trade-off: Partitioning Network Address Host Bits**

After we complete our brief [requirements analysis](#), we should know the two critical parameters that we must have in order to subnet our network: the number of subnets required for the network, and the maximum number of hosts per subnetwork. In using these figures to design our subnetted network, we will be faced with the key design decision in subnetting: how to divide the 8, 16 or 24 bits in the “classful” host ID into subnet ID and host ID.

### ***Deciding How Many Bits to Use for the Subnet ID and Host ID***

Put another way, we need to decide how many bits to “steal” from the host ID to use for the subnet ID. As I introduced in [the topic on custom subnet masks](#), the fundamental trade-off in choosing this number is as follows:

- ☉ Each bit taken from the host ID for the subnet ID doubles the number of subnets that are possible in the network.
- ☉ Each bit taken from the host ID for the subnet ID (approximately) halves the number of hosts that are possible within each subnet on the network.

There are six possible ways this decision can be made for a Class C network, as illustrated in [Figure 73](#).

The relationship between the bits and the number of subnets and hosts is as follows:

- ☉ The number of subnets allowed in the network is two to the power of the number of subnet ID bits.
- ☉ The number of hosts allowed per subnet is two to the power of the number of host ID bits, less two.

We subtract two from the number of hosts in each subnet to exclude the “[special meaning cases](#)” where the host ID is all zeroes or all ones. As I explained in [the topic on custom subnetting](#), this exclusion was originally also applied to the subnet ID, but is no longer in newer systems.

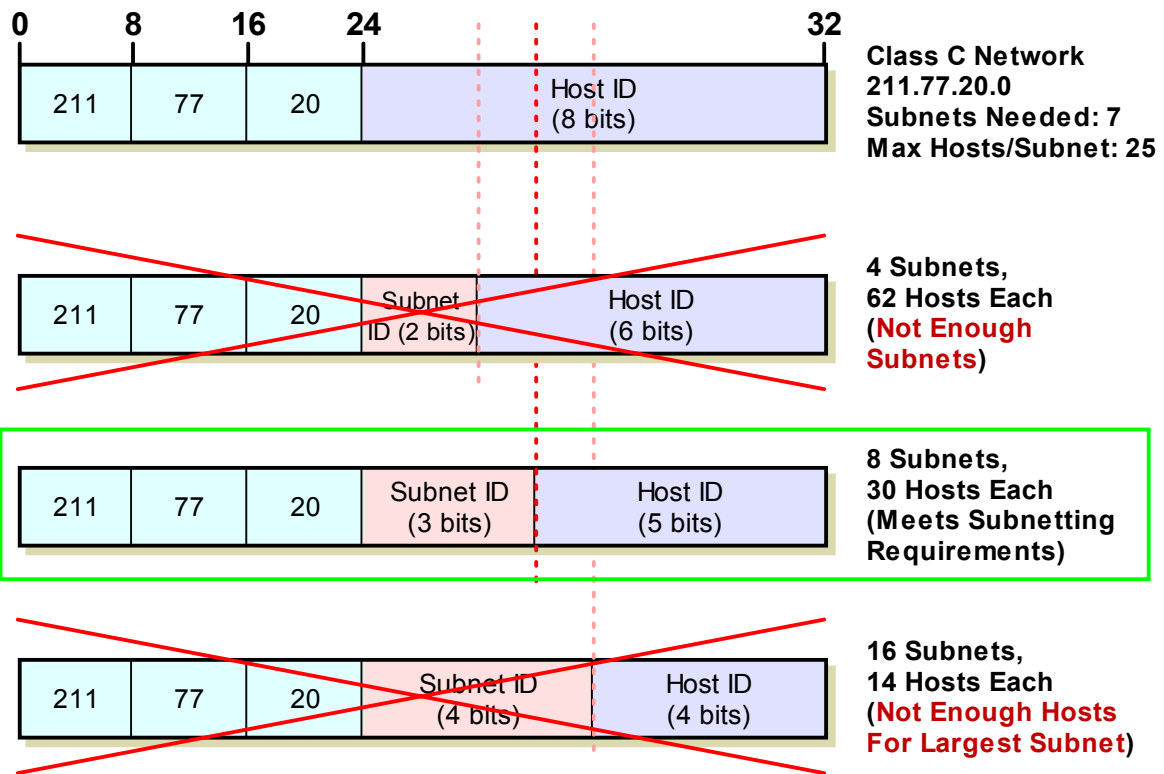

**Figure 73: Subnetting Design Trade-Off For Class C Networks**

Now, to choose how many bits to use for the subnet we could use *trial and error*. By this I mean we could try to first calculate the number of subnets and hosts when we use one bit for the subnet ID and leave the rest for the host ID. We could then try with two bits for the subnet ID, and then try with three and so on. This would be silly, however; it's time consuming and makes it hard for us to choose the best option. There's an easier method: we can use the [subnetting summary tables](#). They let us look at all our options and usually see immediately the best one for us.

### ***Class C Subnetting Design Example***

Let's take an example. Suppose we have a Class C network, base address 211.77.20.0, with a total of 7 subnets. The maximum number of hosts per subnet is 25. Looking at the subnetting summary table for Class C, the answer is instantly clear: we need 3 bits for the subnet ID. Why? This allows us 8 subnets and 30 hosts per subnet. If we try to choose 2 bits, we can't define enough subnets (only 4). As [Figure 74](#) shows, if we choose 4 bits for the subnet ID, then we can only have 14 hosts per subnet.

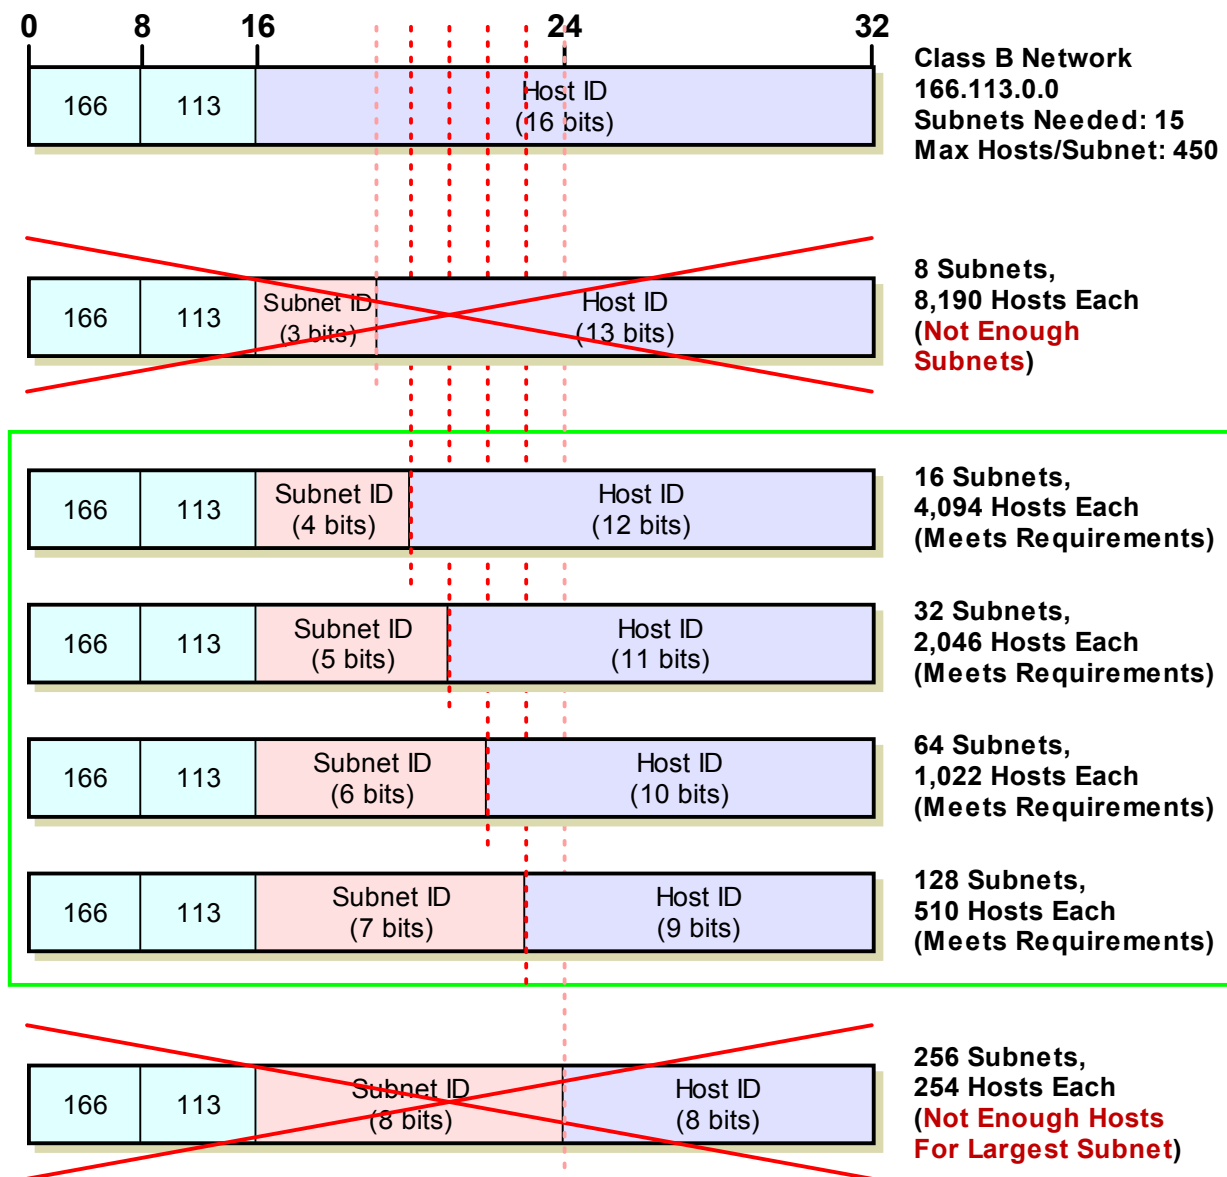

**Figure 74: Example Class C Subnetting: An “Easy Decision”**

In this particular example, where 7 subnets are needed and 25 hosts are needed for the largest subnet, there is only one choice of subnet ID size that meets the requirements.

## Class B Subnetting Design Example

In some cases, especially with larger networks, we may have multiple choices. Consider a more interesting example, the larger Class B network 166.113.0.0, where we have a total of 15 subnets and the largest has 450 hosts. Examining the subnet summary table for Class B suggests four acceptable options, as shown in [Figure 75](#).

**Figure 75: Example Class B Subnetting: A More Difficult Decision**

This Class B network needs at least 15 subnets and must allow up to 450 host per subnet. Three subnet ID bits is too few, and 8 means only 254 hosts per subnet, which is insufficient, but there are four acceptable options, so we must choose wisely. ☺

---

In all four of these, the number of subnets is equal to 15 or greater, and the number of hosts per subnet is over 450. So, which option should we choose? Usually, we want to pick something *in the middle*. If we use 4 bits for the subnet ID, this gives us only a maximum of 16 subnets, which limits growth in the number of subnets, since we already have 15. The same applies to the choice of 7 bits for the subnet ID, since we already have 450 hosts in one subnet now, and that limits us to 510. Thus, we probably want either 5 or 6 bits here. If we expect more growth in the number of hosts in the largest subnet, we'd choose 5 bits; if we expect more growth in the number of subnets, we'd choose 6 bits. If unsure, it's probably best to assume more growth in the number of hosts per subnet, so here we would choose 5 bits.

The converse problem may also occur: you may be in a position where there are no rows in the table that will match. For example, if our Class C example has 35 hosts in the largest subnet instead of 25, we are out of luck: there is no combination of subnet ID and host ID size that works. The same is true in our Class B example if we had 4,500 hosts in that big subnet instead of 450. In this situation we must either divide the large subnet into a smaller one, use more than one IP address block, or upgrade to a larger block.

**Key Concept:** If there is more than one combination of subnet ID and host ID sizes that will meet requirements, try to choose a “middle-of-the-road” option that best anticipates future growth requirements. If no combination meets the requirements, the requirements have to change!

---

### **IP Subnetting Step #3: Determining The Custom Subnet Mask**

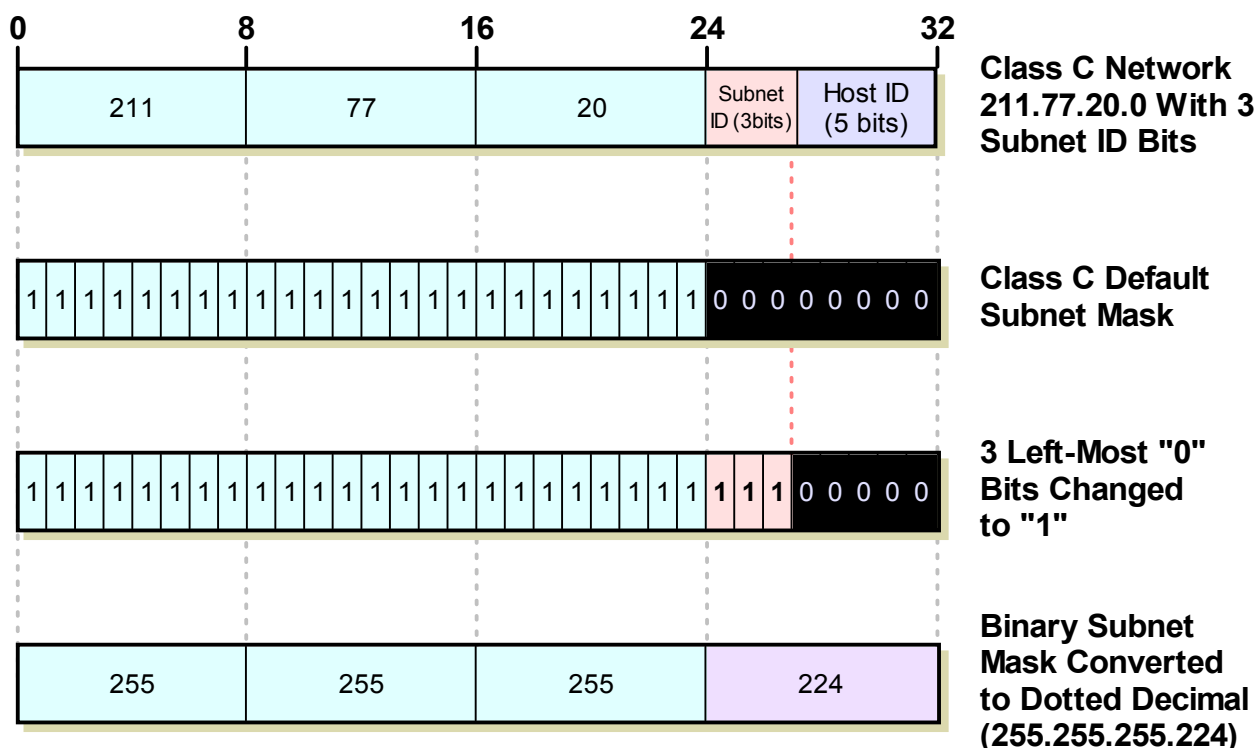

Once we have decided how many bits to use for the subnet ID and how many to leave for the host ID, we can determine the [custom subnet mask](#) for our network. Now, don't go running for cover on me. ☺ A lot of people's eyes glaze over at mention of the subnet mask, but it's really quite simple to figure out once we have done our homework in making the design decision we did in [Step #2](#). In fact, there are two ways of doing this; one is less work than the other, but they're both quite easy. I was going to call them the “hard” way and the “easy” way, but instead, I'll call them “easy” and “easier”.

#### ***Calculating The Custom Subnet Mask***

Let's start with the “easy” method, in which we determine the subnet mask in binary form from the information we already have about our network, and then convert the mask to decimal. To refresh your memory and guide the process, remember this: the [subnet mask](#) is a 32-bit binary number where a 1 represents each bit that is part of the network ID or subnet ID, and a 0 represents each bit of the host ID.

#### **Class C Custom Subnet Mask Calculation Example**

Refer back to the Class C example in the previous topic. We decided to use 3 bits for the subnet ID, leaving 5 bits for the host ID. Here are the steps we will follow to determine the custom subnet mask for this network (illustrated in [Figure 76](#)):

**Figure 76: Determining The Custom Subnet Mask for A Class C Network**

1. **Determine Default Subnet Mask:** Each of Classes A, B and C has a [default subnet mask](#), which is the subnet mask for the network prior to subnetting. It has a 1 for each network ID bit and a 0 for each host ID bit. For Class C, the subnet mask is 255.255.255.0. In binary, this is:

11111111 11111111 11111111 00000000

2. **Change Left-Most Zeroes To Ones For Subnet Bits:** We have decided to use 3 bits for the subnet ID. The subnet mask has to have a 1 for each of the network ID or subnet ID bits. The network ID bits are already 1 from the default subnet mask, so, we change the 3 **left-most** 0 bits in the default subnet mask from a 0 to 1, shown highlighted below. This results in the following custom subnet mask for our network:

11111111 11111111 11111111 **111**00000

3. **Convert Subnet Mask To Dotted Decimal Notation:** We take each of the octets in the subnet mask and convert it to decimal. The result is our custom subnet mask in the form we usually see it: 255.255.255.224.
4. **Express Subnet Mask In "Slash Notation":** Alternately, we can express the subnet mask in "slash notation". This is just a slash followed by the number of ones in the subnet mask. 255.255.255.224 is equivalent to "/27".

## Class B Custom Subnet Mask Calculation Example

Now, let's do the same example with our Class B network (166.113.0.0) with 5 bits for the subnet ID (with a bit less narration this time; see [Figure 77](#)):

**Figure 77: Determining The Custom Subnet Mask for A Class B Network**

- Determine Default Subnet Mask:** For Class B, the subnet mask is 255.255.0.0. In binary, this is:  
11111111 11111111 00000000 00000000
- Change Left-Most Zeroes To Ones For Subnet Bits:** We have decided to use 5 bits for the subnet ID, so, we change the 5 left-most 0 bits from a 0 to 1, shown highlighted below, to give us our binary custom subnet mask:  
11111111 11111111 **11111**000 00000000
- Convert Subnet Mask To Dotted Decimal Notation:** We take each of the octets in the subnet mask and convert it to decimal, to give us a custom subnet mask of 255.255.**248**.0
- Express Subnet Mask In "Slash Notation":** We can express the subnet mask 255.255.248.0 as "/21", since it is 21 ones followed by 11 zeroes. In other words, its prefix length is 21.

---

## Determining The Custom Subnet Mask Using Subnetting Tables

Now, what could be easier than that? Well, you could simply [refer to the subnetting summary tables](#). Find the table for the appropriate class, and then find the row that you selected in the previous step that matches the number of subnet ID bits you want to use. You can see the matching subnet mask right there.

(Hey, it's good to know how to do it yourself! You may not always have tables to refer to!)

## IP Subnetting Step #4: Determining Subnet Identifiers and Subnet Addresses

The network ID assigned to our network applies to the entire network. This includes all subnets and all hosts in all subnets. Each subnet, however, needs to be identified with a unique *subnet identifier* or *subnet ID*, so it can be differentiated from the other subnets in the network. This is of course the purpose of the subnet ID bits that we took from the host ID bits [in subnetting](#). After we have identified each subnet we need to determine the address of each subnet, so we can use this in assigning hosts specific IP addresses.

This is another step in subnetting that is not really hard to understand or do. The key to understanding how to determine [subnet IDs and subnet addresses](#) is to always work in binary form, and then convert to decimal later. We will also look at a “shortcut” for determining addresses in decimal directly, which is faster but less conceptually simple.

Let's go directly to our examples to see how subnet IDs and addresses are determined. We number the subnets starting with 0, and then going to 1, 2, 3 and so on, up to the highest subnet ID that we need.

**Note:** I assume in this description that we will be using the all-zeroes and all-ones subnet numbers. In the original RFC 950 subnetting system, those two subnets are not used, which changes most of the calculations below. [See here for an explanation](#).

---

We determine the subnet IDs and addresses as follows

1. **Subnet ID:** This is just the subnet number, and can be expressed in either binary or decimal form.
2. **Subnet Address:** This is the address formed by taking the address of the network as a whole, and substituting the (binary) subnet ID in for the subnet ID bits. We need to do this in binary, but only for the octets where there are subnet ID bits; the ones where there are only network ID bits or only host ID bits are left alone.

Seem complicated? Let's go back to our examples and we'll see that it's really not.

---

## Class C Subnet ID and Address Determination Example

Recall our Class C network, 211.77.20.0. The network address in binary is:

11010011 01001101 00010100 00000000

We are subnetting using 3 bits for the subnet ID, leaving 5 bits for the host ID. Now let's see the network address with the subnet bits in bold:

11010011 01001101 00010100 **000**00000

These are the bits we substitute with the subnet ID for each subnet. Notice that since the first three octets contain network ID bits, and the network ID is the same for every subnet, they never change. We don't even really need to look at them in binary form, though for clarity we will do so.

Here's how we determine the subnet IDs and addresses, again, starting with 0 (see [Figure 78](#)):

0. Subnet #0 has a subnet ID of 0, or 000 in binary. To find the address, we start with the network address in binary, and substitute "000" for the subnet ID bits. Well gee, those bits are already all zero! What this means is that the address for subnet #0 is the same as the address for the network as a whole: 211.77.20.0.

This is always the case: subnet #0 always has the same address as the network.

1. Subnet #1 has a subnet ID of 1 in decimal or 001 in binary. To find the address we substitute "001" for the subnet ID bits, to yield the following:

11010011 01001101 00010100 **001**00000

Converting to decimal, we get 211.77.20.32.

2. Subnet #2 has a subnet ID of 2, or 010 in binary. To find its address we substitute "010" for the subnet ID bits, to give:

11010011 01001101 00010100 **010**00000

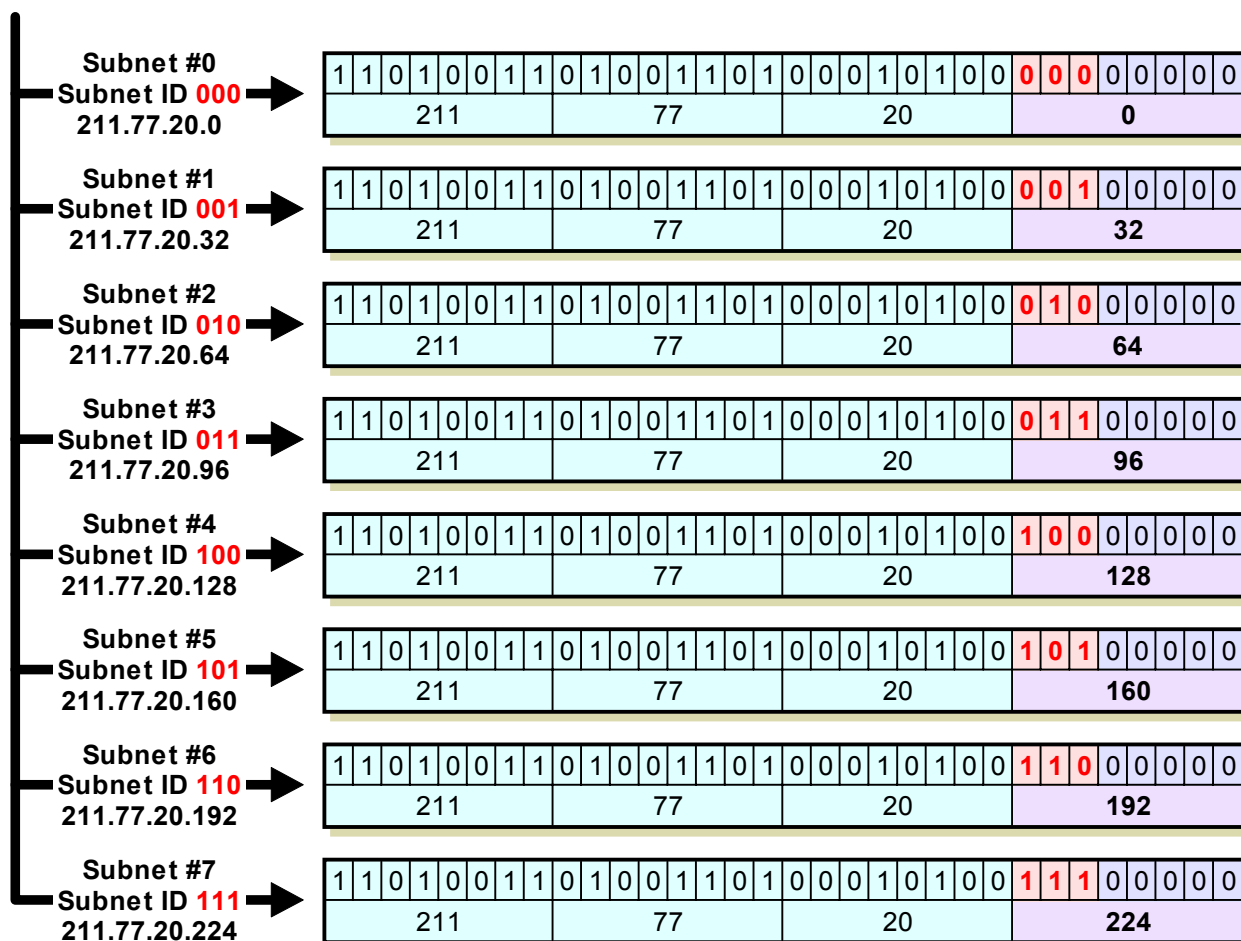

Which is 211.77.20.64 in binary.

3. Subnet #3 has a subnet ID of 011. As we can see the first three octets of the address are always 211.77.20. The last octet here is "**011**00000", which is 96 in decimal, so the whole address is 211.77.20.96.

Starting to see a pattern here? Yep, the address of any subnet can be found by adding 32 to the last octet of the previous subnet. This pattern occurs for all subnetting choices; the increment depends on how many bits we are using for the subnet ID. Here, the increment is 32, which is  $2^5$ ; 5 is the number of host ID bits left after we took 3 subnet ID bits.

4. Subnet #4 is 100, address is 211.77.20.128.
5. Subnet #5 is 101, address is 211.77.20.160.
6. Subnet #6 is 110, address is 211.77.20.192.
7. Subnet #7 is 111, address is 211.77.20.224.

**Figure 78: Determining Subnet Addresses For A Class C Network**

This diagram shows each of the 8 possible subnets created when we use 3 bits for the subnet ID in a Class C network. The binary subnet ID is simply substituted for the subnet bits, and the resulting 32-bit number converted to dotted decimal form.

**Key Concept:** The subnet addresses in a subnetted network are always evenly spaced numerically, with the spacing depending on the number of subnet ID bits.

---

We only needed seven subnets in our example, #0 through #6. Subnet #7 would be a spare. Notice that the last subnet has the same last octet as the subnet mask for our network? That's because we substituted "111" for the subnet ID bits, [just as we did when we calculated the subnet mask](#).

### ***Class B Subnet ID and Address Determination Example***

Let's look at our other example now, Class B network 166.113.0.0. In binary this is:

0100110 01110001 00000000 00000000

We are using 5 bits for the subnet ID, leaving 11 host ID bits. The network address with the subnet ID bits highlighted is:

0100110 01110001 00000000 00000000

Here, only the third octet will ever change for the different subnets. The first two will always be "166.113" and the last octet will always be zero. There are 32 possible subnets; I'll list the first few so you can see the pattern (refer to [Figure 79](#) as well):

0. Subnet #0 has a subnet ID of 00000. This means the address will be 166.113.0.0, the network address, as we would expect.
1. Subnet #1 has a subnet ID of 00001. The address becomes:

10100110 01110001 00001000 00000000

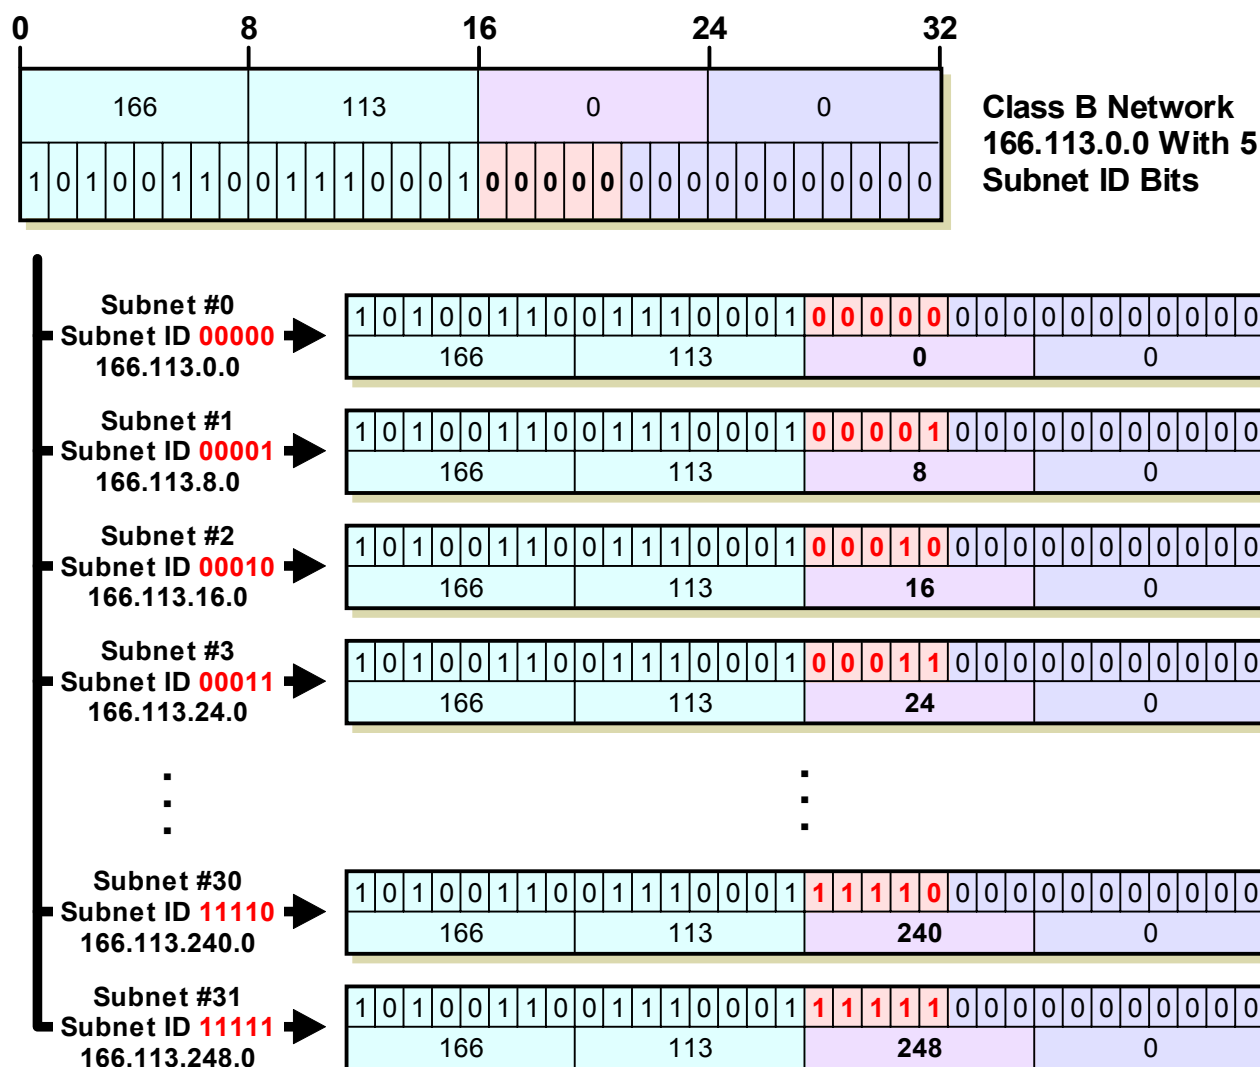

This is 116.113.8.0 in decimal.

2. Subnet #2 has a subnet ID of 00010, giving an address of 116.113.00010000.0 or 116.113.16.0.
3. Subnet #3 has a subnet ID of 00011 and a subnet address of 116.113.24.0.

Again, the pattern here is obvious: you add 8 to the third octet to get successive addresses. The last subnet here is #31, which has a subnet address of 116.113.248.0, which has the same third and fourth octets as our subnet mask of 255.255.248.0.

### ***Using Subnet Address Formulas to Calculate Subnet Addresses***

Since the subnet addresses form a pattern, and the pattern depends on the number of subnet ID bits, it is possible to express the subnet addresses using a single formula for each subnetting option. I have shown these formulas for each of Classes A, B and C in the [subnetting summary tables](#). The formulas can be used to directly calculate the address of subnet #N, where N is numbered from 0 up to one less than the total number of subnets, as we have done above.

**Figure 79: Determining Subnet Addresses For A Class B Network**

This is the same as [Figure 78](#), but for a Class B network with 5 subnet ID bits (I have not shown all 32 subnets, for obvious reasons!)

### Basic Subnet Formula Calculations

In these formulas, the network ID bits are shown as “x.”, or “x.y.” or “x.y.z.” for the three classes. This just means that the subnet addresses have as those octets whatever the numbers are in those octets for the network address. In our examples, “x.y” would be “166.113” for our Class B network, and “x.y.z” would be “211.77.20” for our Class C.

When the number of subnet bits is 8 or less, the formula is relatively simple, and a calculation is done for only one octet, as a multiplication of N, such as “N\*4” or “N\*32”. This is usually the case, since the number of subnets is usually less than 256, and it's the case with both of our examples.

---

In our Class C network with 3 subnet ID bits, the formula from the table is “x.y.z.N\*32”. For this network, all subnets are of the form “211.77.20.N\*32”, with N going from 0 to 7. So, subnet #5 is 211.77.20.(5\*32), which is 211.77.20.160, as we saw before. Similarly, in our Class B network with 5 subnet ID bits, the formula is x.y.N\*8.0. In this case “x.y” is 166.113. Subnet #26 would have the address 166.113.(26\*8).0, or 166.113.208.0.

This is pretty simple stuff, and make the formulas a good short-cut for quickly determining subnet addresses, especially when there are many subnets. They can also be used in a spreadsheet. The only place that using the formulas requires a bit of care is when the number of subnet bits is 9 or more. This means the subnet identifier crosses an octet boundary, and this causes the formula to become more complex. So consider the rest of this topic optional, and [skip it](#) if you don't want to complicate your brain. ☺

### Subnet Formula Calculations With More Than 8 Subnet Bits

When the number of subnet bits is greater than 8, some of the octets are of the form “N divided by an integer”, such as “N/8”. This is an *integer division*, which means “divide N by 8, keep the integer part and drop the fractional part or *remainder*”. Other octets are calculated based on the *modulo* of N, shown as “N%8”. This is the exact opposite: it means, “divide N by 8, drop the integer and keep the remainder”. For example, 33/5 in integer math is 6 (6 with a remainder of 3, drop the remainder, or alternately, 6.6, drop the fraction). 33%5 is 3 (6 with a remainder of 3, drop the 6, keep the remainder).

Let's take as an example our Class B network and suppose that for some strange reason we decided to use 10 bits for the subnet ID instead of 5. In this case, the formula is “x.y.N/4.(N%4)\*64”. Subnet #23 in this case would have the address “166.113.23/4.(23%4)\*64”. The 23/4 becomes just 5 (the fractional.75 is dropped). 23 modulo 4 is 3, which is multiplied by 64 to get 192. So the subnet address is “166.113.5.192”. Subnet #709 would be “166.113.709/4.(709%4)\*64, which is 166.113.177.64.

### Subnet Formula Calculations With More Than 16 Subnet Bits

Okay, now for the real fun. If you subnet a Class A address using more than 16 bits for the subnet ID, you are crossing *two* octet boundaries, and the formulas become very ... interesting, involving both integer division *and* modulo. Suppose we were in charge of Class A address 21.0.0.0 and choose to subnet it. However, we sat down to do this after having had a few stiff ones at the office holiday party, so our judgment is a bit impaired. We decide that it would be a great idea to choose 21 bits for our subnet ID, since we like the number 21. This gives us a couple million subnets.

The formula for subnet addresses in this case, is “x.N/8192.(N/32)%256.(N%32)\*8”. Yikes. Well, this is a bit involved—so much so that it might be easier to just take a subnet number and do it in binary, the long way. But let's take an example and see how it works, for, say, subnet #987654. The first octet is of course 21. The second octet is 987654/8192, integer division. This is 120. The third octet is (987654/32)%256. The result of the division is 30864 (we drop the fraction). Then, we take 30864%256, which yields a remainder of 144. The fourth octet is (987654%32)\*8. This is 6\*8 or 48. So subnet address #987654 is 21.120.144.48.

---

(Don't drink and drive. Don't drink and subnet either. ☺)

### **IP Subnetting Step #5: Determining Host Addresses For Each Subnet**

Once we know the addresses of each of the subnets in our network, we use these addresses as the basis for assigning IP addresses to the individual hosts in each subnet. We start by associating a subnet base address with each physical network (since at least in theory, our subnets correspond to our physical networks). We then sequentially assign hosts particular IP addresses within the subnet (or in a different manner, if we prefer!)

Determining host addresses is really quite simple, once we know the subnet address. All we do is substitute the numbers 1, 2, 3... and so on for the host ID bits in the subnet address. We must do this in binary of course, and then convert the address to decimal form. Again, we can do some “short-cutting” once the rather obvious pattern of how to assign addresses emerges. We'll look at those later in the topic.

#### ***Class C Host Address Determination Example***

Let's start with our Class C example again, 211.77.20.0, which we divided into 8 subnets using 3 subnet bits. Here's how the address appears with the subnet bits shown highlighted, and the host ID bits shown highlighted and underlined.:

11010011 01001101 00010100 00000000

The first subnet is subnet #0, which has all zeroes for those subnet bits, and thus the same address as the network as a whole: 211.77.20.0. We substitute the numbers 1, 2, 3 and so on for the underlined bits to get the host IDs. (Remember that we don't start with 0 here because for the host ID, the all-zero and all-one binary patterns have special meaning). So it goes like this:

1. The first host address has the number 1 for the host ID, or “00001” in binary. So, it is:

11010011 01001101 00010100 00000001

In decimal, this is 211.77.20.1.

2. The second host address has the number 2 for the host ID, or “00010” in binary. Its binary value is:

11010011 01001101 00010100 00000010

In decimal, this is 211.77.20.2

I'm sure you get the picture already; the third host will be 211.77.20.3, the fourth 211.77.20.4 and so on. There is a maximum of 30 hosts in each subnet, as we saw before. So, the last host in this subnet will be found by substituting 30 (11110 in binary) for the host ID bits, resulting in a decimal address of 211.77.20.30.

---

We can do the same thing for each of the other subnets; the only thing that changes is the values in the subnet ID bits. Let's take for example, subnet #6. It has "110" for the subnet bits instead of "000". So, its subnet base address is 211.77.20.192, or:

11010011 01001101 00010100 **11000000**

We assign hosts to this subnet by substituting 00001, then 00010, then 00011 for the host ID bits as before:

1. The first host address is:

11010011 01001101 00010100 **11000001**

Or 211.77.20.193.

2. The second host address is:

11010011 01001101 00010100 **11000010**

Or 211.77.20.194.

And so on, all the way up to the last host in the subnet, which is 211.77.20.222. [Figure 80](#) shows graphically how subnet and host addresses are calculated for this sample network.

One more address we may wish to calculate is the broadcast address for the subnet. This of course is one of the [special cases](#), found by substituting all ones for the host ID. For subnet #0, this would be 211.77.20.31. For subnet #6, it would be 211.77.20.223. That's pretty much all there is to it.

### ***Class B Host Address Determination Example***

We can do the same thing for our Class B network, naturally. The address of that network is 166.113.0.0. Now, say we want to define the hosts that go in subnet #13. We substitute 13 in binary (01101) for the subnet ID bits, to get the following subnet address, shown with the subnet ID bits highlighted and the host ID bits highlighted and underlined:

10100110 01110001 **01101000 00000000**

This is the subnet address 166.113.104.0. Now, we have 11 bits of host ID, so we can have a maximum of 2,046 hosts. The first is found by substituting "000 00000001" for the host ID bits, to give an address of 166.113.104.1. The second host is 166.113.104.2, and so on. The last is found by substituting "111 11111110", to give an address of 166.113.111.254. Note that since the host ID bits extend over two octets, two octets change as we increment the host ID, unlike our Class C example. The broadcast address is 166.113.111.255.

**Key Concept:** In a subnetted network, the address of host #H within subnet number #S is found by plugging in the binary value of **S** for the network's subnet ID bits, and the binary value of **H** for subnet's host ID bits.

---

**Figure 80: Determining Host Addresses For A Class C Network**

This diagram shows how both subnet addresses and host addresses are determined in a two-step process. The subnet addresses are found by substituting subnet ID values (shown in red) for the subnet ID bits of the network. Then, for any given subnet address, we can determine a host address by substituting a host number (shown in blue) for the host ID bits within that subnet. So, for example, host #2 in subnet #6 has “110” for the subnet ID and “00010” for the host ID, resulting in a final octet value of “11000010” or 194.

---

## "Shortcuts" For Quickly Computing Host Addresses

As you can see, defining the host IDs is really quite straight-forward. If you can substitute bits and convert to decimal, you have all you need to know. You can also see that as was the case with defining the subnet addresses, there are patterns that you can use in defining host IDs and understanding how they work. These generally define ways that we can more quickly determine certain host addresses by working directly in decimal instead of bothering with binary substitutions. This is a bit more complex conceptually, so only proceed if you are feeling a bit brave.

The following are some of the "shortcuts" you can use in determining host IP addresses in a subnet environment:

- ☉ **First Host Address:** *The first host address is always the subnet address with the last octet incremented by 1.* So, in our class C example, subnet #3's base address is 211.77.20.96. The first host address in subnet #3 is thus 211.77.20.97.
- ☉ **Subsequent Host Addresses:** After you find the first host address, to get the next one you just add one to the last octet of the previous address. If this makes the last octet 256 (which can happen only if there are more than 8 host ID bits) you "wrap around" this to zero and increment the third octet.
- ☉ **Directly Calculating Host Addresses:** If the number of host ID bits is 8 or less, you can find host #N's address by adding "N" to the last octet's decimal value. For example, in our class C example, subnet #3's base address is 211.77.20.96. Therefore, host #23 in this subnet has an address of 211.77.20.119.

If there are more than 8 bits in the host ID, this only works for the first 255 hosts, after which you have to "wrap around" and increase the value of the third octet. Consider again subnet #13 in our Class B example, which has a base address of 166.113.104.0. Host #214 on this subnet has address 166.113.104.0, but host #314 isn't 166.113.104.314. It is 166.113.105.58 (host #255 is 166.113.104.255, then host #256 is 166.113.105.0, and we count up 58 more (314-256) to get to #314, 166.113.105.58).

- ☉ **Range Of Host Addresses:** The range of hosts for any subnet is determined as follows:
  - ☉ **First Address:** Base address of subnet with last octet incremented by one.
  - ☉ **Last Address:** Base address of *next subnet after this one*, less two in the last octet (which may require changing a "0" in the last octet to "254" and reducing the value of the third octet by 1).

For example, consider subnet #17 in our Class B example. Its subnet address is 166.113.136.0. The address of subnet #18 is 166.113.144.0. So, the range of hosts for subnet #17 is 166.113.136.1 to 166.113.143.254.

- ☉ **Broadcast Address:** *The broadcast address for a subnet is always one less than the base address of the subsequent subnet.* Or alternately, one more than the last "real" host address of the subnet. So, for subnet #17 in our Class B example, the broadcast address is 166.113.143.255.

Did I just confuse you? Well, remember, these are shortcuts and sometimes when you take a shortcut you get lost. ☺ Just kidding, it's really not that hard once you play around with it a bit.

---

In closing, remember the following quick summary when working with IP addresses in a subnet environment:

1. The network ID is the same for all hosts in all subnets, and all subnets in the network.
2. The subnet ID is the same for all hosts in each subnet, but unique to each subnet in the network.
3. The host ID is unique within each subnet. Each subnet has the same set of host IDs.
4. Subnetting is fun!

---

## **IP Classless Addressing: Classless Inter-Domain Routing (CIDR) / "Supernetting"**

As the early Internet began to grow dramatically, [three main problems arose with the original "classful" addressing scheme](#). These difficulties were addressed partially through [subnet addressing](#), which provides more flexibility for the administrators of individual networks on an internet. Subnetting, however, doesn't really tackle the problems in general terms. Some of these issues remain due to the use of classes even with subnets.

While development began on [IP version 6](#) and its [roomy 128-bit addressing system](#) in the mid-1990s, it was recognized that it would take many years before widespread deployment of IPv6 would be possible. In order to extend the life of IP version 4 until the newer IP version 6 could be completed, it was necessary to take a new approach to addressing IPv4 devices. This new system calls for eliminating the notion of address classes entirely, creating a new *classless addressing* scheme sometimes called *Classless Inter-Domain Routing (CIDR)*.

In this section I describe modern classless IP addressing. I begin with an overview of the concepts behind classless addressing and the idea behind "supernetting", including why it was created and what its advantages and disadvantages are. I then define CIDR and describe how the system works in more detail, including the notation used for address blocks. I list each of the CIDR address block sizes and show how they relate to the older class A, B and C networks. I conclude with an example of CIDR addressing, which is similar to the practical subnetting section prior to this one, but focused on CIDR and a bit more condensed.

**Background Information:** Classless IP addressing represents the latest evolution of IP addressing, following on the heels of subnetting and the original "classful" addressing system described in preceding sections. Understanding classless IP addressing and routing requires at least some familiarity with these older IP addressing methods. If you have come to this section without reading the preceding sections on ["classful" addressing](#) and [subnetting](#), I strongly advise reviewing them first. If you understand subnetting but aren't familiar with how Variable Length Subnet Masking (VLSM) works, reading [the topic on VLSM](#) is a good idea, since CIDR is similar to VLSM in many ways.

---

### **IP Classless Addressing and "Supernetting" Overview, Motivation, Advantages and Disadvantages**

[Subnet addressing](#) was an important development in the evolution of IP addressing, because it solved some important issues with the conventional, two-level class-based addressing scheme. Subnetting's contribution to ease in IP addressing was allowing each network to have its own two-level hierarchy, giving the administrator of each network the equivalent of an "internet within the Internet".

---

When we looked at [the advantages of subnetting](#), we saw that one was that subnetting was local within each organization, and “invisible” to other organizations. This is an advantage in that it lets each organization tailor its network without other groups having to worry about the details of how this is done. Unfortunately, this “invisibility” also represents a key **disadvantage** of subnetted “classful” addressing: it cannot correct the fundamental inefficiencies associated with that type of addressing, because organizations are still assigned address blocks based on classes.

### ***The Main Problem With “Classful” Addressing***

A key weakness of regular subnetting is low “granularity”. A Class B address block contains a very large number of addresses (65,534) but a Class C block has only a relatively small number (254). There are many thousands of “medium-sized” organizations who need more than 254 IP addresses, but a small percentage of these need 65,534 or anything even close to it. (The lack of a good match to a medium-sized organization with 5,000 hosts is illustrated in [Figure 64](#).) When setting up their networks, these companies and groups would tend to request Class B address blocks and not Class C blocks because they need more than 254, without considering how many of the 65,000-odd addresses they really would use.

Now, due to how the classes of the older system were designed, there are over 2 million Class C address blocks, but only 16,384 Class Bs. While 16,384 seems like a lot at first glance, there are millions of organizations and corporations around the world. Class B allocations were being consumed at a rapid pace, while the smaller Class C networks were relatively unused.

The [folks handing out Internet addresses](#) needed a way to better utilize the address space so it would not run out before the transition to IP version 6. Subnetting didn't help a great deal with this problem. Why? Because it only works **within** the “classful” address blocks. If an organization needing 2,000 IP addresses requests a Class B block, they could use subnetting to more efficiently manage their block. However, subnetting could do nothing about the fact that this organization would never use over 62,000 of the addresses in its block—about 97% of their allocated address space.

The only solution to this would be to convince—or at worst case, force—companies to use many smaller Class C blocks instead of “wasting” the bulk of a Class B assignment. Many organizations resisted this due to the complexity involved, and this caused the other main problem that subnetting didn't correct: the growth of Internet routing tables. Replacing one Class B network with 10 Class Cs means ten times as many entries for routers to keep track of.

### ***A Better Solution: Eliminate Address Classes***

It was clear that as long as there were only three sizes of networks, the allocation efficiency problem could never be properly rectified. The solution was to get rid of the classes completely, in favor of a *classless* allocation scheme. This system would solve both of the main problems with “classful” addressing: inefficient address space use, and the exponential growth of routing tables.

---

This system was developed in the early 1990s and formalized in 1993 in RFCs 1517, 1518, 1519 and 1520. The technology was called *Classless Inter-Domain Routing (CIDR)*. Despite this name, the scheme deals with both addressing and routing matters, since they are inextricably linked.

The idea behind CIDR is to adapt the concept of subnetting a single network to the entire internet. In essence, then, classless addressing means that instead of breaking a particular network into subnets, we can aggregate networks into larger “supernets”. CIDR is sometimes called *supernetting* for this reason: it applies the principles of subnetting to larger networks. It is this aggregation of networks into supernets that allowed CIDR to resolve the problem of growing Internet routing tables.

Of course, if we are going to apply subnetting concepts to the entire internet, we need to be able to have subnets of different sizes. After all, that's one of our primary goals in eliminating the classes. So, more accurately, CIDR is an internet-wide application of not regular one-level subnetting, but of [Variable Length Subnet Masking \(VLSM\)](#). Just as VLSM lets us split a network as many times as we want to create subnets, “sub-subnets” and “sub-sub-subnets”, CIDR lets us do this with the entire Internet, as many times as needed.

**Key Concept:** Classless Inter-Domain Routing (CIDR) is a system of IP addressing and routing that solves the many problems of “classful” addressing by eliminating fixed address classes in favor of a flexible, multiple-level, hierarchical structure of networks of varying size.

---

### ***The Many Benefits of Classless Addressing and Routing***

CIDR provides numerous advantages over the “classful” addressing scheme, whether or not subnetting is used:

- ☉ **Efficient Address Space Allocation:** Instead of allocating addresses in fixed-size blocks of low granularity, under CIDR addresses are allocated in sizes of any binary multiple. So, a company that needs 5,000 addresses can be assigned a block of 8,190 instead of 65,534, as shown in [Figure 81](#). Or, to think of it another way, the equivalent of a single Class B network can be shared amongst 8 companies that each need 8,190 or fewer IP addresses.
- ☉ **Elimination of Class Imbalances:** There are no more class A, B and C networks, so there is no problem with some portions of the address space being widely used while others are neglected.
- ☉ **Efficient Routing Entries:** CIDR's multiple-level hierarchical structure allows a small number of routing entries to represent a large number of networks. Network descriptions can be “aggregated” and represented by a single entry. Since CIDR is hierarchical, the detail of lower-level, smaller networks can be hidden from routers that move traffic between large groups of networks. [This is discussed more completely in the section on IP routing issues.](#)

- 
- ☉ **No Separate Subnetting Method:** CIDR implements the concepts of subnetting within the internet itself. An organization can use the same method used on the Internet to subdivide its internal network into subnets of arbitrary complexity without needing a separate subnetting mechanism.

**Figure 81: Classless Addressing (CIDR) Solves The “Granularity Problem”**

Figure 64 illustrated the primary problem with “classful” addressing: the great distance between the size of Class B and Class C networks. CIDR solves this issue by allowing any number of bits to be used for the network ID. In the case of an organization with 5,000 hosts, a /19 network with 8,190 hosts can be assigned. This reduces the address space for such an organization by about 95%.

### ***The Main Disadvantage of CIDR: Complexity***

Since the main benefit of “classful” addressing was its simplicity, it's no surprise that the main drawback of CIDR is its greater complexity. One issue is that it is no longer possible to determine by looking at the first octet to determine how many bits of an IP address represent the network ID and how many the host ID. A bit more care needs to be used in setting up routers as well, to make sure that routing is accomplished correctly.

---

## **IP "Supernetting": Classless Inter-Domain Routing (CIDR) Hierarchical Addressing and Notation**

When we first looked at IP addressing, we saw that IP addresses are designed to be [divided into a network identifier and host identifier](#). Then, when subnets were introduced, we “stole” bits from the host ID to create a subnet ID, giving the IP address a total of [three hierarchical levels](#). With [VLSM](#), we further subnetted the subnets, taking more bits from the host ID to give us a multiple-level hierarchy with “sub-subnets”, “sub-sub-subnets” and so forth.

In a classless environment, we completely change how we look at IP addresses, by applying VLSM concepts not just to one network, but to the entire Internet. In essence, the Internet becomes just one giant network that is “subnetted” into a number of large blocks. Some of these large blocks are then broken down into smaller blocks, which can in turn be broken down further. This breaking down can occur multiple times, allowing us to split the “pie” of Internet addresses into slices of many different sizes, to suit the needs of organizations.

As the name implies, classless addressing completely eliminates the prior notions of classes. There are no more Class A, B, C blocks that are divided by the first few bits of the address. Instead, under CIDR, all Internet blocks can be of arbitrary size. Instead of having all networks use 8 (Class A), 16 (Class B) or 24 (Class C) bits for the network ID, we can have large networks with, say, 13 bits for the network ID (leaving 19 bits for the host ID), or very small ones that use 28 bits for the network ID (only 4 bits for the host ID). The size of the network is still based on the binary power of the number of host ID bits, of course.

Recall that when we used subnetting, we had a problem: subnetting could be done by taking any number of available host ID bits, so how would devices know where the line was between the subnet ID and host ID? The same problem occurs under CIDR. There are no classes, so we can't tell anything by looking at the first few bits of an IP address. Since addresses can have the dividing point between host ID and network ID occur anywhere, we need additional information in order to interpret IP addresses properly. Under CIDR, of course, this impacts not only addresses within an organization but in the entire Internet, since there are no classes and each network can be a different size.

### ***CIDR ("Slash") Notation***

Just as subnetting required the use of a [subnet mask](#) to show which bits belong to the network ID or subnet ID and which to the host ID, CIDR uses a subnet mask to show where the line is drawn between host ID and network ID. However, for simplicity, under CIDR we don't usually work with 32-bit binary subnet masks. Instead, we use *slash notation*, more properly called *CIDR notation*. In this method, we show the size of the network, sometimes called the *prefix length*, by following an IP address by an integer that tells us how many bits are used for the network ID (prefix).

**Key Concept:** Since there are no address classes in CIDR, one cannot tell the size of the network ID of an address from the address alone. In CIDR, the length of the prefix (network ID) is indicated by placing it following a slash after the address. This is called *CIDR notation* or *slash notation*.

For example, consider the network specification 184.13.152.0/22. The “22” means this network has 22 bits for the network ID and 10 bits for the host ID. This is equivalent to specifying a network with an address of 184.13.152.0 and a subnet mask of 255.255.252.0, as you can see in [Figure 82](#). This sample network provides a total of 1,022 hosts ( $2^{10}$  minus 2). [The table in the following topic](#) shows all the different possible network sizes that can be configured under CIDR.

**Figure 82: CIDR (“Slash”) Notation and Its Subnet Mask Equivalent**

A classless network is normally specified in CIDR or “slash” notation, such as this example: 184.13.152.0/22. Here, the “/22” means the first 22 bits of the address are the network ID. The equivalent subnet mask can be calculated by creating a 32-bit number with 22 ones followed by 10 zeroes.

**Note:** You may recall my mentioning that under “classful” subnetting, [the bits used for the subnet ID did not need to be contiguous](#). Even though to avoid confusion this was rarely if ever used, non-contiguous subnet ID bits were possible. Under CIDR, the requirement for contiguous subnet ID bits has been made official—you could not use slash notation otherwise.

---

## ***“Supernetting”: Subnetting the Internet***

In theory, then, what CIDR does is provide the [central address-assignment authority](#) with the flexibility to hand out address blocks of different sizes to organizations based on their need. However, when CIDR was developed, a shift was made in the method by which public IP addresses were assigned. Having everyone in the world attempt to get addresses from one organization wasn’t the best method. It was necessary under the “classful” scheme because the hierarchy was only two levels deep: IANA handed out network IDs to everyone, who then assigned host IDs (or subnetted).

Under CIDR we have many hierarchical levels: we split big blocks into smaller blocks and then still-smaller blocks, and so on. It makes sense to manage blocks in a similar hierarchical manner as well. So, what happens is that IANA/ICANN divides addresses into large blocks, which it distributes to the four *regional Internet registries (RIRs)*: APNIC, ARIN, LACNIC and RIPE NCC. These then further divide the address blocks and distribute them to lower-level national Internet registries (NIRs), local Internet registries (LIRs) and/or individual organizations such as Internet Service Providers (ISPs). This is all explained in [the background topic on Internet authorities and registries](#).

ISPs can then divide these blocks into smaller ones that they allocate to their customers. These customers are sometimes smaller ISPs themselves, which repeat the process. They split their blocks into pieces of different sizes and allocate them to their customers, some of whom are even smaller ISPs and some of whom are “end users”. The number of times this can occur is limited only by how many addresses are in the original block.

It’s also worth noting that while CIDR is based on subnetting concepts, subnetting itself is not used in CIDR—or at least, not in the way it is used under “classful” addressing. There is no explicit subnetting using a subnet ID within CIDR: all IP addresses are interpreted only as having a network ID and a host ID. An organization does the equivalent of subnetting by dividing its own network into subnetworks using the same general method that ISPs do. This probably seems a bit confusing. [Later in this section I have provided a detailed example](#) of how hierarchical address block assignment and splitting works under CIDR.

## ***Common Features of “Classful” and Classless Addressing***

Note that there are a few aspects of addressing that were defined under the “classful” scheme that don’t change under CIDR:

- 
- ☉ **Private Address Blocks:** Certain blocks of addresses are still reserved for private network addressing. These addresses are not directly routed on the Internet, but can be used in conjunction with [Network Address Translation \(NAT\)](#) to allow IP hosts without public addresses to access the Internet.
  - ☉ **Addresses With Special Meanings:** [The special meanings assigned to certain network ID and host ID patterns](#) are the same as before. This is also why we still must subtract two from the number of hosts in each network: for the all-zeroes case that refers to the network as a whole, and the all-ones address used for broadcast.
  - ☉ **Loopback Addresses:** The network 127.0.0.0 is still reserved for [loopback functionality](#). (In CIDR it is given the notation 127.0.0.0/8).

Finally, note that use of classless addressing requires hardware and software designed to handle it. If the hardware and software are still assuming that they are operating in a “classful” environment, they will not properly interpret addresses. Since CIDR has now been around for over a decade, this is usually not a problem with modern systems.

### **IP Classless Addressing Block Sizes and “Classful” Network Equivalents**

Since CIDR allows us to divide IP addresses into network ID and host ID along any bit boundary, it permits the creation of dozens different sizes of networks. As with subnetting, the size of network is a [trade-off between the number of bits used for the network ID and the number used for the host ID](#). Unlike conventional subnetting, where a single choice is made for all subnets, CIDR allows many levels of hierarchical division of the Internet, so many sizes of networks exist simultaneously. Larger networks are created and subdivided into smaller ones, as we saw in the previous topic.

Since many people are used to looking at IP address blocks in terms of their “classful” sizes, it is common to express CIDR address blocks in terms of their “classful” equivalents. First of all, it should be simple at this point to see that a CIDR “/8” network is equal in size to a Class A network; a “/16” is equivalent to a Class B; a “/24” is equivalent to a Class C. This is of course because Class A networks use 8 bits for the network ID, Class Bs use 16, and Class Cs use 24. However, remember that these CIDR equivalents do not need to have any [particular ranges for their first octets](#) as in the “classful” scheme.

Each time we reduce the prefix length, we are defining a network about double the size of the one with the higher number, since we have increased the number of bits in the host ID by one. So, a “/15” network is equal in size to two “/16”s.

[Table 56](#) shows each of the possible theoretical ways to divide the 32 bits of an IP address into network ID and host ID bits under CIDR. For each, I have shown the number of hosts in each network, and the way a network of each size is represented in both slash notation and as a conventional subnet mask. I have also shown the equivalent number of Class A, Class B and Class C networks for each.

A few things to remember in looking at this table:

- Some of the entries shown are more theoretical than practical, and are included merely for completeness. This is particularly the case with the larger networks. For example, I doubt anyone ever actually works with a /1 or /2 size CIDR network; there would only be two of the former and four of the latter encompassing the entire IP address space! Most of the time you will be working with smaller networks, /16 and below.
- Under normal circumstances, you cannot have a /31 or /32 CIDR network since they would have zero valid host IDs. (There is a special case: /31 networks can be used for point-to-point links, where it is obvious who the intended recipient is of each transmission, and where broadcasts are not necessary. This is described in RFC 3021.)
- In the columns showing the number of equivalent Class A, B and C networks I have only shown numbers in the range of 1/256th to 256 for simplicity. Obviously, a /6 network, in addition to being equal in size to 4 Class A networks, also equals 1,024 Class Bs and 262,144 Class C networks, but few people would bother referring to a /6 as being 262,144 Class Cs.

**Table 56: CIDR Address Blocks and “Classful” Address Equivalents (Page 1 of 2)**

# of Bits For Network ID	# of Bits For Host ID	# of Hosts Per Network	Prefix Length in Slash Notation	Equivalent Subnet Mask	# of Equivalent “Classful” Addressing Networks		
					Class A	Class B	Class C
1	31	2,147,483,646	/1	128.0.0.0	128	—	—
2	30	1,073,741,822	/2	192.0.0.0	64	—	—
3	29	536,870,910	/3	224.0.0.0	32	—	—

30	2	2	/30	255.255.255.252	—	—	1/64

### **IP CIDR Addressing Example**

The multiple hierarchical levels of CIDR make the technology seem rather complicated. However, understanding how CIDR works really is not that difficult, assuming you already know how subnetting is done. In particular, [if you know how VLSM functions](#), you basically already know how CIDR does, since they are pretty much the same thing. They differ only in the way that the hierarchical division of networks is accomplished, and the terminology.

To show how CIDR works better, let's take an example that will illustrate the power of classless addressing: its ability to selectively subdivide a large block of addresses into smaller ones that suit the needs of various organizations. Since address allocation in CIDR typically starts with larger blocks owned by larger Internet Service Providers (ISPs), let's start there as well.

Suppose we have an ISP that is just starting up. It's not a “major” ISP, but a moderate-sized one with only a few customers, so it needs only a relatively small allocation. It begins with the block 71.94.0.0/15. The “/15” on the end of the block address tells us that this is a block of addresses where the first 15 bits are the network ID and the last 17 the host ID. Of course, this block was obtained from a larger ISP, carved from a larger block of addresses by that ISP. For example, 71.94.0.0/15 would be equal to half of the address block 71.92.0.0/14, a quarter of the block 71.88.0.0/13, and so on.

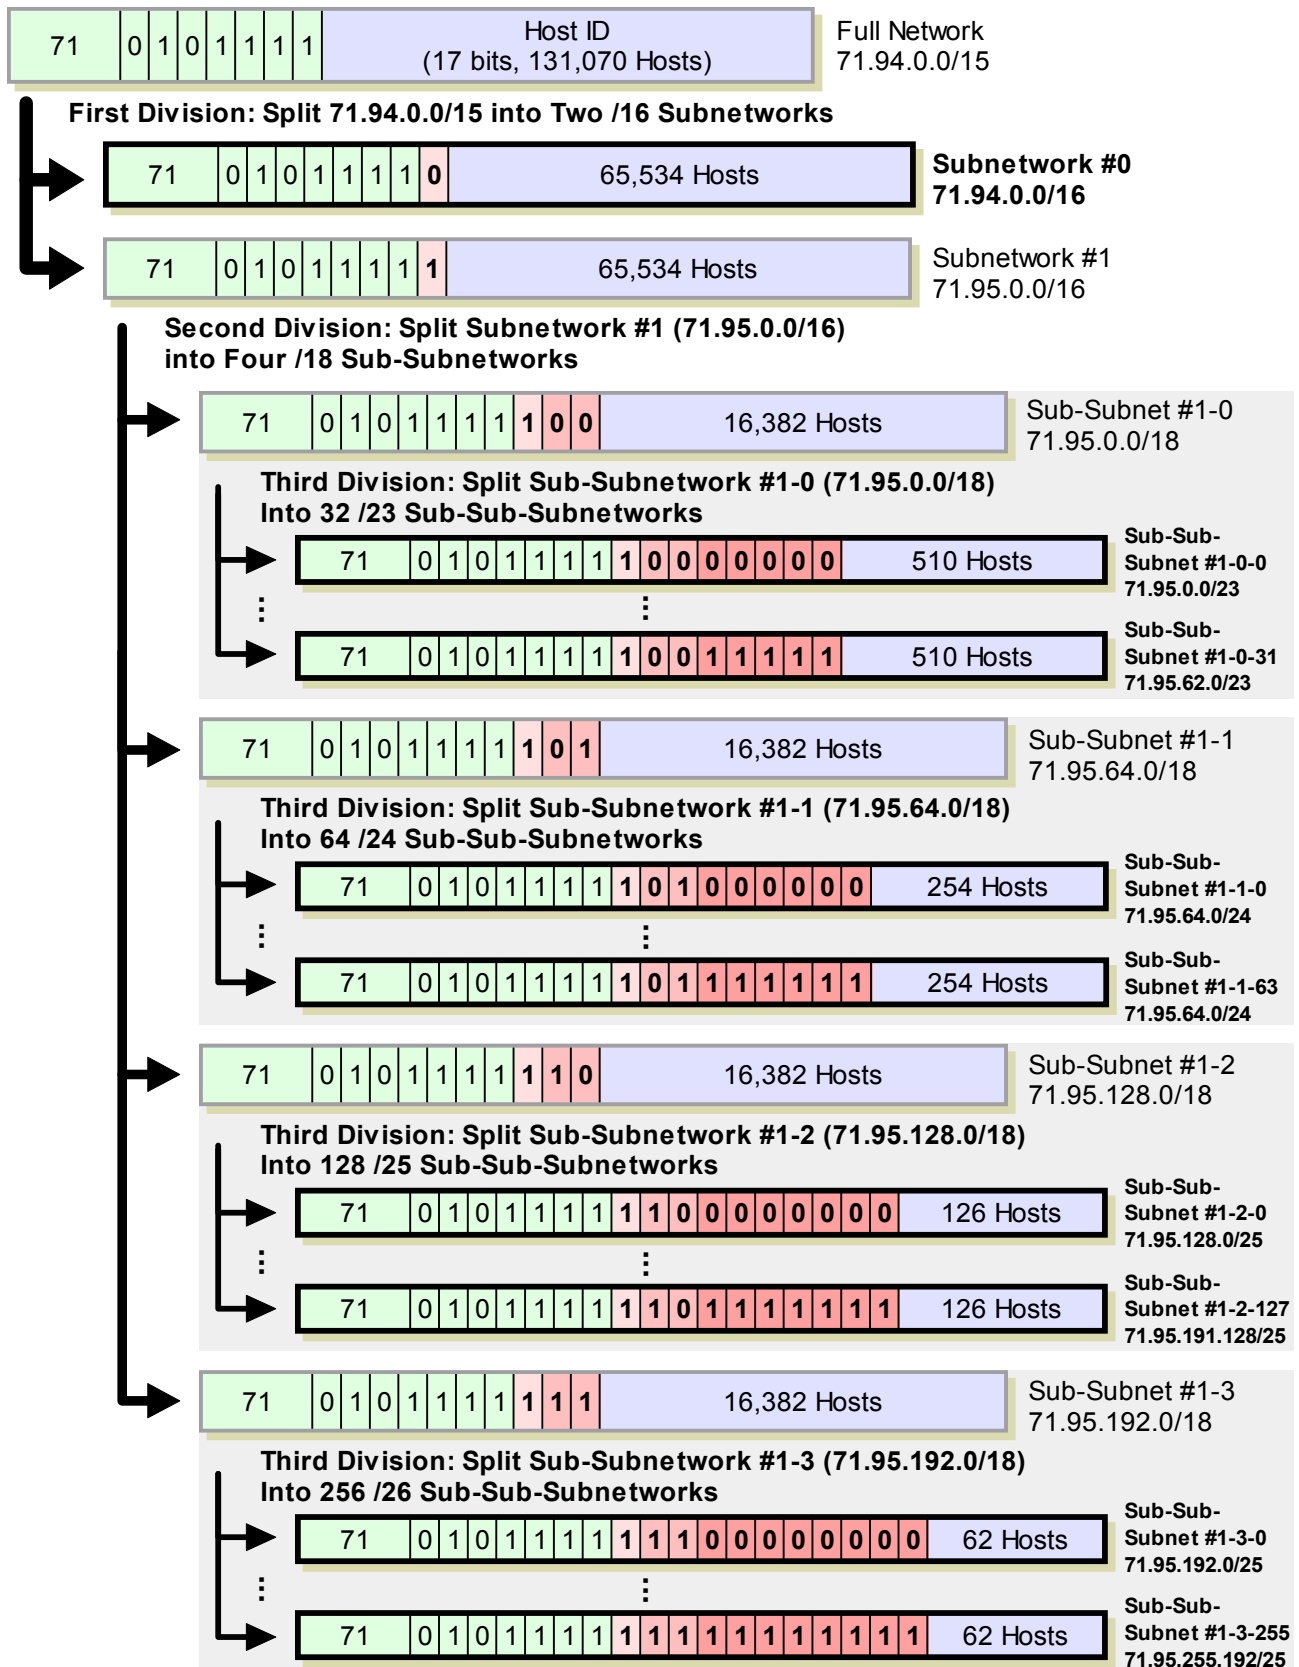

**Figure 83: Example Hierarchical Division Of A /15 CIDR Address Block**

This diagram shows one method by which an ISP with a relatively large /15 address block (131,070 hosts) might choose to hierarchically divide it. In this case it is first divided in half into two /16 blocks. One is reserved, while the other is divided into four /18 blocks. Each of those is divided into blocks of a different size, to allow allocation to organizations requiring up to 62, 126, 254 or 510 hosts respectively.

Our ISP's block is equal in size to two Class Bs and has a total of 131,070 possible host addresses. This ISP can choose to divide this block in a variety of ways, depending on the needs of its clients and its own internal use. However, this ISP is just starting up, so it is not even sure of what its ultimate needs will be. Let's say it expects to resell about half of its address space to other ISPs, but isn't sure what sizes they will need yet. Of the other half, it plans to split it into four different sizes of blocks to match the needs of different-sized organizations.

To imagine how the ISP divides its address space, we can consider the analogy of cutting up a pie. The ISP will first "cut the pie in half" and reserve one half for its future ISP customers. It will then cut the other half into some large pieces and some small pieces. This is illustrated in [Figure 83](#). (Okay, it's a square pie. I wanted to show the individual small blocks to scale. Sue me. ☺)

The actual process of division might follow this progression (illustrated in [Figure 84](#)).:

**Figure 84: Hierarchical Address Division Using Classless Addressing (CIDR)**

---

## ***First Level of Division***

The “pie” is initially cut down the middle by using the single left-most host ID bit as an extra network bit. Let's see our network address block, 71.94.0.0/15 in binary, with the left-most host ID bit shown highlighted:

01000111 0101111**0** 00000000 00000000

To make the split, we make one network equal to this binary network address with the highlighted bit remaining zero, and the other one with it changed to a one. This creates two subnetworks—not subnets as in the “classful” sense of the word, but portions of the original network—which I have numbered based on the numeric value of what is substituted into the new network ID bits:

Subnetwork #0: 01000111 0101111**0** 00000000 00000000

Subnetwork #1: 01000111 0101111**1** 00000000 00000000

Since bit #16 is now also part of the network address, these are “/16” networks, the size of a “classful” Class B network. So, the subnetworks are:

Subnetwork #0: 71.94.0.0/16

Subnetwork #1: 71.95.0.0/16

You'll notice that the “#0” subnetwork has the same IP address as the larger network it came from; this is always true of the subnetwork 0 in a network.

## ***Second Level of Division***

Let's say we set aside subnetwork #0 above for future ISP allocations. We then choose to divide the second subnetwork, into four. These we will then further subdivide into different sizes to meet our customer needs. To divide into four groups we need two more bits from the host ID of subnetwork #1, shown highlighted and underlined next to the original subnet bit:

01000111 0101111**1 00**0000000 00000000

---

These two bits are replaced by the patterns 00, 01, 10 and 11 to get four sub-subnetworks. They will be “/18” networks of course, since we took two extra bits from the host ID of a “/16”:

Sub-subnetwork #1-0: 01000111 01011111 **1 00**000000 00000000  
(71.95.0.0/18)

Sub-subnetwork #1-1: 01000111 01011111 **1 01**000000 00000000  
(71.95.64.0/18)

Sub-subnetwork #1-2: 01000111 01011111 **1 10**000000 00000000  
(71.95.128.0/18)

Sub-subnetwork #1-3: 01000111 01011111 **1 11**000000 00000000  
(71.95.192.0/18)

Each of these has 16,382 addresses.

### ***Third Level of Division***

We now take each of the four /18 networks above and further subdivide it. We want to make each of these contain a number of blocks of different sizes corresponding to our potential customers. One way to do this would be as follows:

- ☛ **Larger Organizations:** Customers needing up to 510 addresses require a /23 network. We divide sub-subnetwork #1-0, 71.95.0.0/18 by taking five bits from the host ID field:

01000111 01011111 **1 00000000** 00000000

We substitute into these five bits 00000, 00001, 00010 and so on, giving us 32 different /23 networks in this block, each containing 9 bits for the host ID, for 510 hosts. The first will be sub-sub-subnetwork #1-0-0, 71.95.0.0/23; the second sub-sub-subnetwork #1-0-1, 71.95.2.0/23; the last will be sub-sub-subnetwork #1-0-31: 71.95.62.0/23.

- ☛ **Medium-Sized Organizations:** For customers needing up to 254 addresses, we divide sub-subnetwork #1-1, 71.95.64.0/18, by taking six bits from the host ID field:

01000111 01011111 **1 01000000** 00000000

This gives us 64 different /24 networks. The first will be sub-sub-subnetwork #1-1-0, 71.95.64.0/24, the second sub-sub-subnetwork #1-1-1, 71.95.65.0/24, and so on.

- ☛ **Smaller Organizations:** For customers with up to 126 hosts, we divide sub-subnetwork #1-2, 71.95.128.0/18, by taking seven bits from the host ID field:

01000111 01011111 **1 10000000 0**0000000

Seven bits allow 128 of these /25 networks within our /18 block. The first will be 71.95.128.0/25, the second 71.95.128.128/25, the third 71.95.129.0/25, and so on.

- 
- ☉ **Very Small Organizations:** For customers with up to 60 hosts, we divide sub-subnetwork #1-3, 71.95.192.0/18, by taking eight bits from the host ID field:

01000111 01011111 **11000000** 00000000

This gives us 256 different /26 networks within our /18 block. The first will be 71.95.192.0/26, the second 71.95.192.64/26, and so on.

### ***Other Alternatives for Dividing the Network***

Above all else, CIDR is about flexibility—this is only one of many different ways to slice up this pie (sheet of brownies, whatever!) The ISP might decide that creating four different sizes of customer networks in advance was not the right way to go. They might instead just take the tack of dividing the pie in half, dividing it in half again, and so on, as many times as needed to create “pie slices” of the right size. Alternately, if most of their customers need around 50, 100, 200 or 500 hosts, the example above might be the easiest to administer.

It would still be possible for the ISP to further divide any of the smaller blocks further if they needed. They could split a /26 sub-sub-subnetwork into four /28 sub-sub-sub-subnetworks for very small customers, for example. Also, an individual customer of this ISP could do the same thing, dividing their own block to suit the internal structure of their network.

---

## IP Datagram Encapsulation and Formatting

The primary job of the Internet Protocol is the delivery of data between devices over an internetwork. On its journey between two hosts in an internet, this data may travel across many physical networks. To help ensure that the data is sent and received properly, it is *encapsulated* within a message called an *IP datagram*. This datagram includes several fields that help manage the operation of IP and ensure that data gets where it needs to go.

In this section I take a look at how the Internet Protocol takes data passed to it from higher layers and packages it for transmission. I begin with a general discussion of IP datagrams and encapsulation. I then describe the general format of IP datagrams, including the fields used in the IP header and how they are interpreted. I also include a brief discussion of IP datagram options and their use.

**Background Information:** this section assumes at least passing familiarity with [IP addressing concepts](#). It also makes reference to [the section on datagram fragmentation and reassembly](#).

---

**Note:** IP datagrams are sometimes called *IP packets*. Whether “datagram” or “packet” is the preferred term seems to depend on whom you ask; even the standards don’t use one term exclusively. On the other hand, I have seen IP datagrams called *IP frames*, and that’s definitely not correct! [The topic on messages and names](#) in the fundamentals chapter describes these terms more completely.

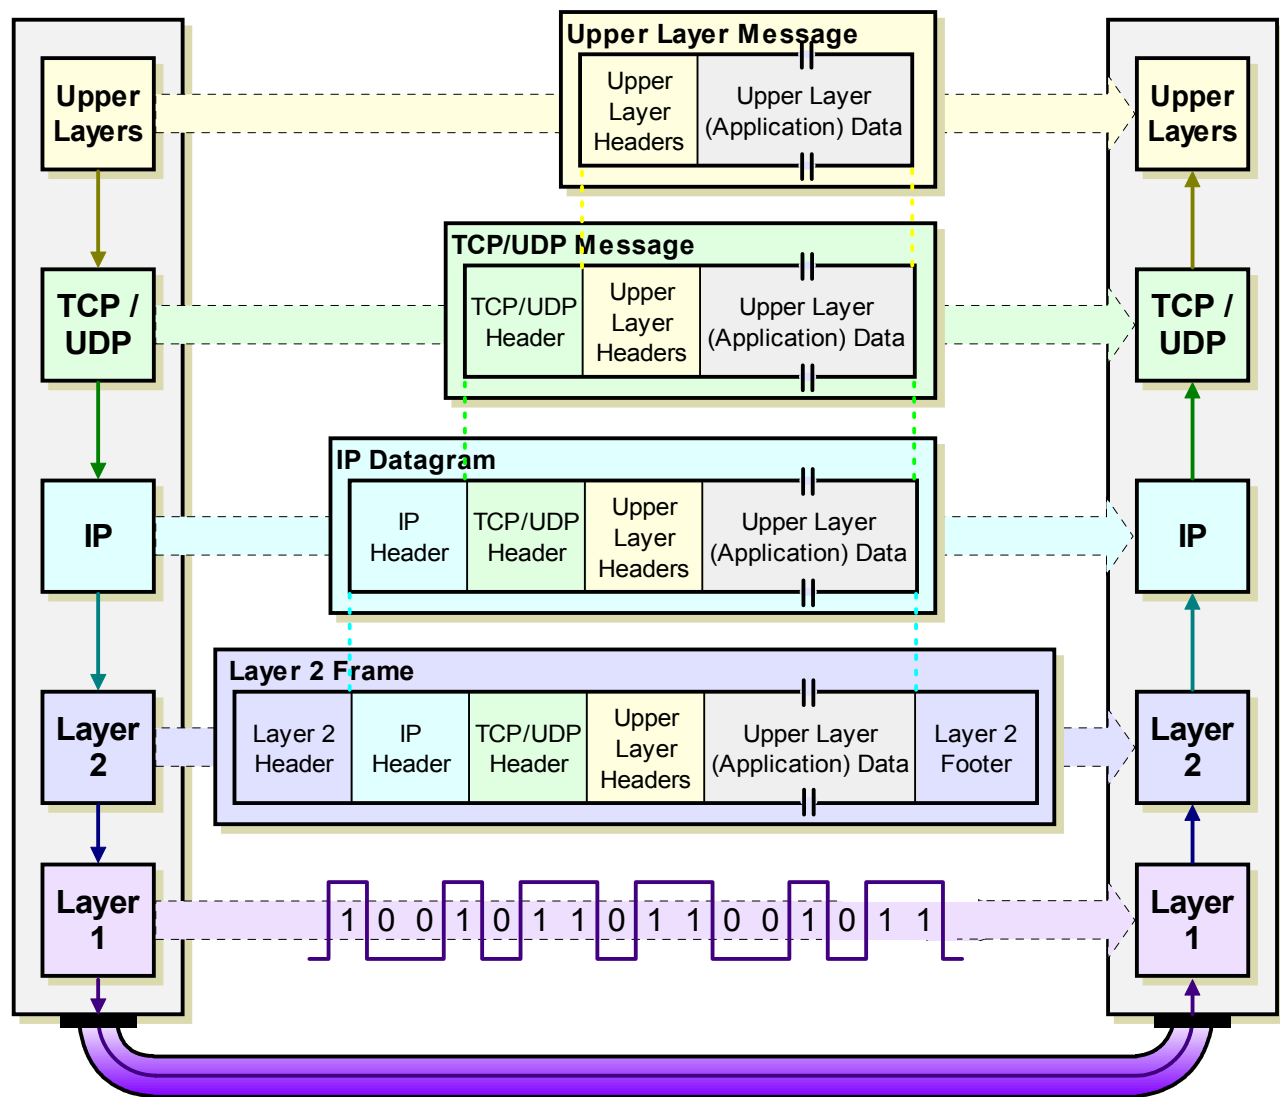

---

## IP Datagram Encapsulation

In [the chapter describing the OSI Reference Model](#), I looked at several ways that protocols at various layers in a networking protocol stack interact with each other. One of the most important concepts in inter-protocol operation is that of *encapsulation*. Most data originates within the higher layers of the OSI model. The protocols at these layers pass the data down to lower layers for transmission, usually in the form of discrete messages. Upon receipt, each lower-level protocol takes the entire contents of the message received and encapsulates it into its own message format, adding a header and possibly a footer that contain important control information. [Encapsulation is explained in general terms in a separate topic](#).

A good analogy for how encapsulation works is a comparison to sending a letter enclosed in an envelope. You might write a letter and put it in a white envelope with a name and address, but if you gave it to a courier for overnight delivery, they would take that envelope and put it in a larger delivery envelope. ([I actually have written a complete description of this sort of analogy](#), if you are interested.)

Due to the prominence of TCP/IP, the Internet Protocol is one of the most important places where data encapsulation occurs on a modern network. Data is passed to IP typically from one of the two main transport layer protocols: TCP or UDP. This data is already in the form of a TCP or UDP message with TCP or UDP headers. This is then encapsulated into the body of an IP message, usually called an *IP datagram* or *IP packet*. Encapsulation and formatting of an IP datagram is also sometimes called *packaging*—again, the implied comparison to an envelope is obvious. The process is shown in [Figure 85](#).

**Figure 85: IP Datagram Encapsulation**

This is an adaptation of [Figure 15](#), the very similar drawing for the OSI Reference Model as a whole, showing specifically how data encapsulation is accomplished in TCP/IP. As you can see, an upper layer message is packaged into a TCP or UDP message. This then becomes the payload of an IP datagram, which is shown here simply with one header (things can get a bit more complex than this.) The IP datagram is then passed down to layer 2 where it is in turn encapsulated into some sort of LAN, WAN or WLAN frame, then converted to bits and transmitted at the physical layer.

---

If the message to be transmitted is too large for the size of the underlying network, it may first be [fragmented](#). This is analogous to splitting up a large delivery into multiple smaller envelopes or boxes. In this case, each IP datagram carries only part of the higher-layer message. The receiving device must [reassemble the message](#) from the IP datagrams. So, a datagram doesn't always carry a full higher-layer message; it may hold only part of one.

The IP datagram is somewhat similar in concept to a frame used in Ethernet or another data link layer. The important difference, of course, is that IP datagrams are designed to facilitate transmission across an **internetwork**, while data link layer frames are used only for direct delivery within a physical network. The fields included in the IP header are used to manage internetwork datagram delivery. This includes key information for delivery such as the address of the destination device, identification of the type of frame, and control bits. [The header follows a specific format described in the following topic.](#)

After data is encapsulated into an IP datagram, it is passed down to the data link layer for transmission across the current “hop” of the internetwork. There, it is of course further encapsulated, IP header and all, into a data link layer frame such as an Ethernet frame. An IP datagram may be encapsulated into many such data link layer frames [as it is routed across the internetwork](#); on each hop the IP datagram is removed from the data link layer frame and then repackaged into a new one for the next hop. The IP datagram, however, is not changed (except for some control fields) until it reaches its final destination.

## **IP Datagram General Format**

Data transmitted over an internet using IP is carried in messages called *IP datagrams*. Like all network protocol messages, IP uses a specific format for its datagrams. We are of course looking here at [IP version 4](#) and so we will examine the IPv4 datagram format, which was defined in RFC 791 along with the rest of IPv4.

The IPv4 datagram is conceptually divided into two pieces: the *header* and the *payload*. The header contains addressing and control fields, while the payload carries the actual data to be sent over the internetwork. Unlike some message formats, IP datagrams do not have a footer following the payload.

Even though IP is a relatively simple, connectionless, “unreliable” protocol, the IPv4 header carries a fair bit of information, which makes it rather large. At a minimum, it is 20 bytes long, and with options can be significantly longer. The IP datagram format is described in [Table 57](#) and illustrated in [Figure 86](#).

**Table 57: Internet Protocol Version 4 (IPv4) Datagram Format (Page 1 of 3)**

Field Name	Size (bytes)	Description												
<b>Version</b>	1/2 (4 bits)	<b>Version:</b> Identifies the version of IP used to generate the datagram. For IPv4, this is of course the number 4. The purpose of this field is to ensure compatibility between devices that may be running different versions of IP. In general, a device running an older version of IP will reject datagrams created by newer implementations, under the assumption that the older version may not be able to interpret the newer datagram correctly.												
<b>IHL</b>	1/2 (4 bits)	<b>Internet Header Length (IHL):</b> Specifies the length of the IP header, in 32-bit words. This includes the length of any options fields and padding. The normal value of this field when no options are used is 5 (5 32-bit words = 5*4 = 20 bytes). Contrast to the longer <i>Total Length</i> field below.												
<b>TOS</b>	1	<b>Type Of Service (TOS):</b> A field designed to carry information to provide quality of service features, such as prioritized delivery, for IP datagrams. It was never widely used as originally defined, and its meaning has been subsequently redefined for use by a technique called <i>Differentiated Services (DS)</i> . See below for more information.												
<b>TL</b>	2	<b>Total Length (TL):</b> Specifies the total length of the IP datagram, in bytes. Since this field is 16 bits wide, the maximum length of an IP datagram is 65,535 bytes, though most are much smaller.												
<b>Identification</b>	2	<b>Identification:</b> This field contains a 16-bit value that is common to each of the fragments belonging to a particular message; for datagrams originally sent unfragmented it is still filled in, so it can be used if the datagram must be fragmented by a router during delivery. This field is used by the recipient to reassemble messages without accidentally mixing fragments from different messages. This is needed because fragments may arrive from multiple messages mixed together, since IP datagrams can be received out of order from any device. <a href="#">See the discussion of IP message fragmentation.</a>												
<b>Flags</b>	3/8 (3 bits)	<p><b>Flags:</b> Three control flags, two of which are used to manage fragmentation (as described in <a href="#">the topic on fragmentation</a>), and one that is reserved:</p> <table> <tr> <th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr> <tr> <td><b>Reserved</b></td><td>1/8 (1 bit)</td><td><b>Reserved:</b> Not used.</td></tr> <tr> <td><b>DF</b></td><td>1/8 (1 bit)</td><td><b>Don't Fragment:</b> When set to 1, specifies that the datagram should not be fragmented. Since the fragmentation process is generally "invisible" to higher layers, most protocols don't care about this and don't set this flag. It is, however, used for testing the maximum transmission unit (MTU) of a link.</td></tr> <tr> <td><b>MF</b></td><td>1/8 (1 bit)</td><td><b>More Fragments:</b> When set to 0, indicates the last fragment in a message; when set to 1, indicates that more fragments are yet to come in the fragmented message. If no fragmentation is used for a message, then of course there is only one "fragment" (the whole message), and this flag is 0. If fragmentation is used, all fragments but the last set this flag to 1 so the recipient knows when all fragments have been sent.</td></tr> </table>	Subfield Name	Size (bytes)	Description	<b>Reserved</b>	1/8 (1 bit)	<b>Reserved:</b> Not used.	<b>DF</b>	1/8 (1 bit)	<b>Don't Fragment:</b> When set to 1, specifies that the datagram should not be fragmented. Since the fragmentation process is generally "invisible" to higher layers, most protocols don't care about this and don't set this flag. It is, however, used for testing the maximum transmission unit (MTU) of a link.	<b>MF</b>	1/8 (1 bit)	<b>More Fragments:</b> When set to 0, indicates the last fragment in a message; when set to 1, indicates that more fragments are yet to come in the fragmented message. If no fragmentation is used for a message, then of course there is only one "fragment" (the whole message), and this flag is 0. If fragmentation is used, all fragments but the last set this flag to 1 so the recipient knows when all fragments have been sent.
Subfield Name	Size (bytes)	Description												
<b>Reserved</b>	1/8 (1 bit)	<b>Reserved:</b> Not used.												
<b>DF</b>	1/8 (1 bit)	<b>Don't Fragment:</b> When set to 1, specifies that the datagram should not be fragmented. Since the fragmentation process is generally "invisible" to higher layers, most protocols don't care about this and don't set this flag. It is, however, used for testing the maximum transmission unit (MTU) of a link.												
<b>MF</b>	1/8 (1 bit)	<b>More Fragments:</b> When set to 0, indicates the last fragment in a message; when set to 1, indicates that more fragments are yet to come in the fragmented message. If no fragmentation is used for a message, then of course there is only one "fragment" (the whole message), and this flag is 0. If fragmentation is used, all fragments but the last set this flag to 1 so the recipient knows when all fragments have been sent.												

**Table 57: Internet Protocol Version 4 (IPv4) Datagram Format (Page 2 of 3)**

Field Name	Size (bytes)	Description																																	
<b>Fragment Offset</b>	1 5/8 (13 bits)	<b>Fragment Offset:</b> When fragmentation of a message occurs, this field specifies the offset, or position, in the overall message where the data in this fragment goes. It is specified in units of 8 bytes (64 bits). The first fragment has an offset of 0. Again, <a href="#">see the discussion of fragmentation</a> for a description of how the field is used.																																	
<b>TTL</b>	1	<b>Time To Live (TTL):</b> Short version: Specifies how long the datagram is allowed to “live” on the network, in terms of router hops. Each router decrements the value of the TTL field (reduces it by one) prior to transmitting it. If the TTL field drops to zero, the datagram is assumed to have taken too long a route and is discarded.  See below for the longer explanation of <i>TTL</i> .																																	
<b>Protocol</b>	1	<p><b>Protocol:</b> Identifies the higher-layer protocol (generally either a transport layer protocol or encapsulated network layer protocol) carried in the datagram. The values of this field were originally defined by the IETF “Assigned Numbers” standard, RFC 1700, and are now maintained by the <a href="#">Internet Assigned Numbers Authority (IANA)</a>:</p> <table border="1"> <thead> <tr> <th>Value (Hexadecimal)</th><th>Value (Decimal)</th><th>Protocol</th></tr> </thead> <tbody> <tr> <td>00</td><td>0</td><td>Reserved</td></tr> <tr> <td>01</td><td>1</td><td>ICMP</td></tr> <tr> <td>02</td><td>2</td><td>IGMP</td></tr> <tr> <td>03</td><td>3</td><td>GGP</td></tr> <tr> <td>04</td><td>4</td><td>IP-in-IP Encapsulation</td></tr> <tr> <td>06</td><td>6</td><td>TCP</td></tr> <tr> <td>08</td><td>8</td><td>EGP</td></tr> <tr> <td>11</td><td>17</td><td>UDP</td></tr> <tr> <td>32</td><td>50</td><td>Encapsulating Security Payload (ESP) Extension Header</td></tr> <tr> <td>33</td><td>51</td><td>Authentication Header (AH) Extension Header</td></tr> </tbody> </table> <p>Note that the last two entries are used when <a href="#">IPSec</a> inserts additional headers into the datagram: the <a href="#">AH</a> or <a href="#">ESP</a> headers.</p>	Value (Hexadecimal)	Value (Decimal)	Protocol	00	0	Reserved	01	1	ICMP	02	2	IGMP	03	3	GGP	04	4	IP-in-IP Encapsulation	06	6	TCP	08	8	EGP	11	17	UDP	32	50	Encapsulating Security Payload (ESP) Extension Header	33	51	Authentication Header (AH) Extension Header
Value (Hexadecimal)	Value (Decimal)	Protocol																																	
00	0	Reserved																																	
01	1	ICMP																																	
02	2	IGMP																																	
03	3	GGP																																	
04	4	IP-in-IP Encapsulation																																	
06	6	TCP																																	
08	8	EGP																																	
11	17	UDP																																	
32	50	Encapsulating Security Payload (ESP) Extension Header																																	
33	51	Authentication Header (AH) Extension Header																																	
<b>Header Checksum</b>	2	<b>Header Checksum:</b> A checksum computed over the header to provide basic protection against corruption in transmission. This is not the more complex CRC code typically used by data link layer technologies such as Ethernet; it's just a 16-bit checksum. It is calculated by dividing the header bytes into words (a word is two bytes) and then adding them together. The data is not checksummed, only the header. At each hop the device receiving the datagram does the same checksum calculation and on a mismatch, discards the datagram as damaged.																																	

**Table 57: Internet Protocol Version 4 (IPv4) Datagram Format (Page 3 of 3)**

Field Name	Size (bytes)	Description
<b>Source Address</b>	4	<b>Source Address:</b> The 32-bit IP address of the originator of the datagram. Note that even though intermediate devices such as routers may handle the datagram, they do not normally put their address into this field—it is always the device that originally sent the datagram.
<b>Destination Address</b>	4	<b>Destination Address:</b> The 32-bit IP address of the intended recipient of the datagram. Again, even though devices such as routers may be the intermediate targets of the datagram, this field is always for the ultimate destination.
<b>Options</b>	Variable	<b>Options:</b> One or more of several types of options may be included after the standard headers in certain IP datagrams. I discuss them in <a href="#">the topic that follows this one</a> .
<b>Padding</b>	Variable	<b>Padding:</b> If one or more options are included, and the number of bits used for them is not a multiple of 32, enough zero bits are added to “pad out” the header to a multiple of 32 bits (4 bytes).
<b>Data</b>	Variable	<b>Data:</b> The data to be transmitted in the datagram, either an entire higher-layer message or a fragment of one.

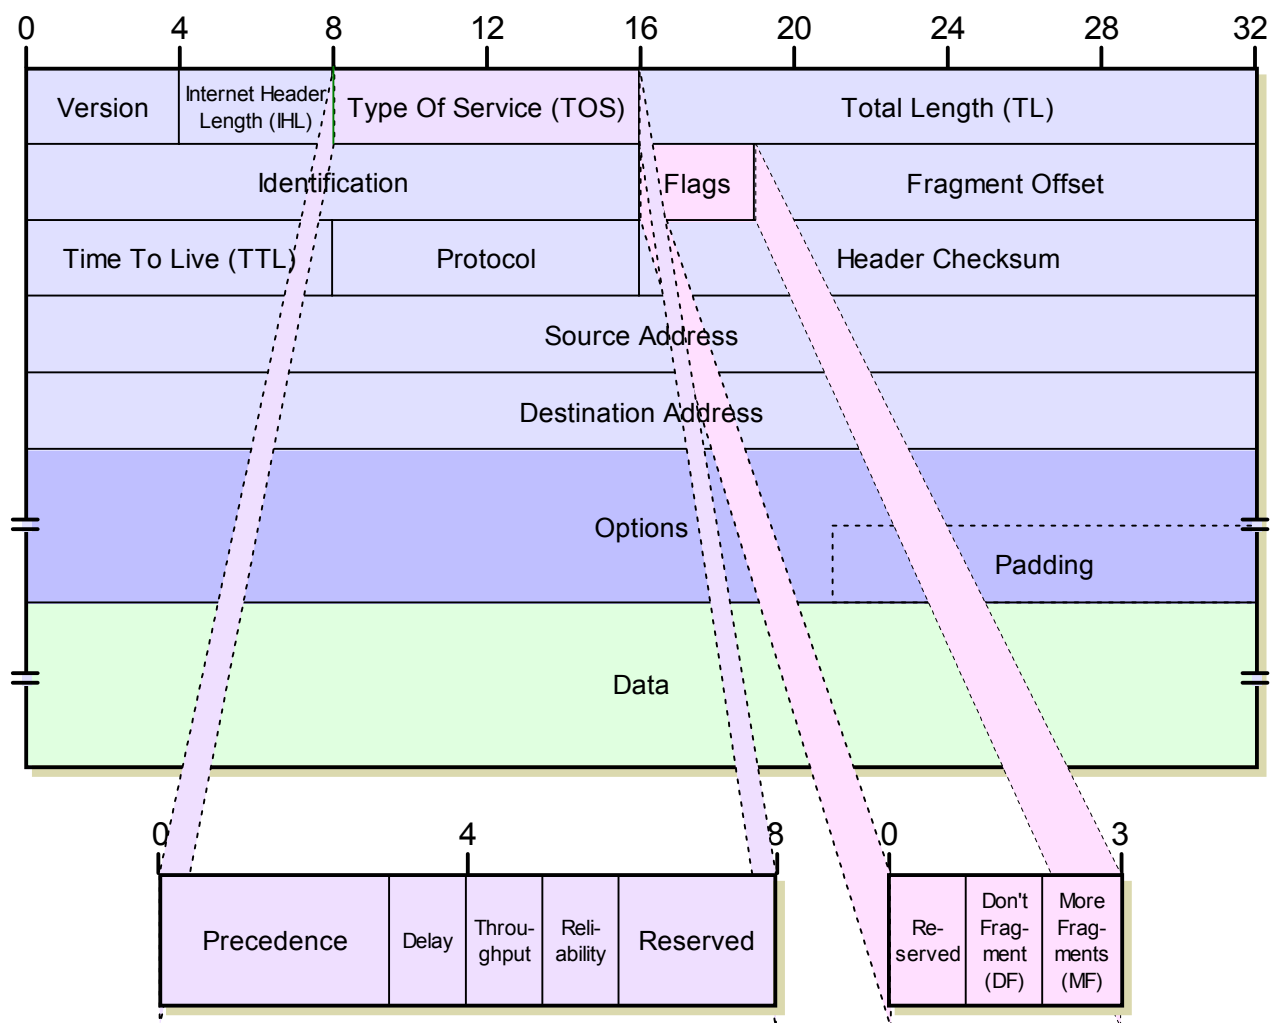

That’s a pretty big table, because the IP datagram format is pretty important and has a lot of fields that need explaining. To keep it from being even longer, I decided to move a couple of the more complex descriptions out of the table.

### ***Time To Live (TTL) Field***

Since IP datagrams are sent from router to router as they travel across an internetwork, it is possible that a situation could result where a datagram gets passed from router A to router B to router C and then back to router A. Router loops are not supposed to happen, and rarely do, but are possible.

To ensure that datagrams don’t circle around endlessly, the *TTL* field was intended to be filled in with a time value (in seconds) when a datagram was originally sent. Routers would decrease the time value periodically, and if it ever hit zero, the datagram would be destroyed. This was also intended to be used to ensure that time-critical datagrams wouldn’t linger past the point where they would be “stale”.

In practice, this field is not used in exactly this manner. Routers today are fast and usually take far less than a second to forward a datagram; measuring the time that a datagram “lives” would be impractical. Instead, this field is used as a “maximum hop count” for the datagram. Each time a router processes a datagram, it reduces the value of the *TTL* field by one. If doing this results in the field being zero, the datagram is said to have expired. It is dropped, and usually an ICMP *Time Exceeded* message is sent to inform the originator of the message that this happened.

**Figure 86: Internet Protocol Version 4 (IPv4) Datagram Format**

This diagram shows graphically the all-important IPv4 datagram format. The first 20 bytes are the fixed IP header, followed by an optional *Options* section, and a variable-length *Data* area. Note that the *Type Of Service* field is shown as originally defined in the IPv4 standard.

The *TTL* field is one of the primary mechanisms by which networks are protected from router loops (see [the description of ICMP Time Exceeded messages](#) for more on how *TTL* helps IP handle router loops.)

### ***Type Of Service (TOS) Field***

This one-byte field was originally intended to provide certain [quality of service](#) features for IP datagram delivery. It allowed IP datagrams to be tagged with information indicating not only their precedence, but the preferred manner in which they should be delivered. It was divided into a number of subfields, as shown in [Table 58](#) (and [Figure 86](#)).

The lack of quality of service features has been considered a weakness of IP for a long time. But as we can see in [Table 58](#), these features were built into IP from the start. What's going on here? The answer is that even though this field was defined in the standard back in the early 1980s, it was not widely used by hardware and software. For years, it was just passed around with all zeroes in the bits and mostly ignored.

**Table 58: Original Definition Of IPv4 Type Of Service (TOS) Field**

Subfield Name	Size (bytes)	Description																		
<b>Precedence</b>	3/8 (3 bits)	<p><b>Precedence:</b> A field indicating the priority of the datagram. There were eight defined values, from lowest to highest priority:</p> <table><tr><th>Precedence Value</th><th>Priority Level</th></tr><tr><td>000</td><td>Routine</td></tr><tr><td>001</td><td>Priority</td></tr><tr><td>010</td><td>Immediate</td></tr><tr><td>011</td><td>Flash</td></tr><tr><td>100</td><td>Flash Override</td></tr><tr><td>101</td><td>CRITIC/ECP</td></tr><tr><td>110</td><td>Internetwork Control</td></tr><tr><td>111</td><td>Network Control</td></tr></table>	Precedence Value	Priority Level	000	Routine	001	Priority	010	Immediate	011	Flash	100	Flash Override	101	CRITIC/ECP	110	Internetwork Control	111	Network Control
Precedence Value	Priority Level																			
000	Routine																			
001	Priority																			
010	Immediate																			
011	Flash																			
100	Flash Override																			
101	CRITIC/ECP																			
110	Internetwork Control																			
111	Network Control																			
<b>D</b>	1/8 (1 bit)	<b>Delay:</b> Set to 0 to request “normal” delay in delivery; set to 1 if low delay delivery is requested.																		
<b>T</b>	1/8 (1 bit)	<b>Throughput:</b> Set to 0 to request “normal” delivery throughput; set to 1 if higher throughput delivery is requested.																		
<b>R</b>	1/8 (1 bit)	<b>Reliability:</b> Set to 0 to request “normal” reliability in delivery; set to 1 if higher reliability delivery is requested.																		
<b>Reserved</b>	2/8 (2 bits)	<b>Reserved:</b> Not used.																		

The [IETF](#), seeing the field unused, attempted to revive its use. In 1998, RFC 2474 redefines the first six bits of the *TOS* field to support a technique called *Differentiated Services (DS)*. Under DS, the values in the *TOS* field are called *codepoints* and are associated with different service levels. This starts to get rather complicated, so refer to RFC 2474 if you want all the details.

Understanding the IP datagram format is an important part of troubleshooting IP networks. Be sure to see the following topic on options for more information on how IP options are used in datagrams, and the [topic on fragmenting](#) for some more context on the use of fragmentation-related fields such as *Identification*, *Fragment Offset*, and *More Fragments*.

---

## **IP Datagram Options and Option Format**

All IP datagrams must include the [standard 20-byte header](#), which contains key information such as the source and destination address of the datagram, fragmentation control parameters, length information and more. In addition to these invariable fields, the creators of IPv4 included the ability to add *options* that provide additional flexibility in how IP handles datagrams. Use of these options is, of course, optional. ☺ However, all devices that handle IP datagrams must be capable of properly reading and handling them.

The IP datagram may contain zero, one or more options, which makes the total length of the *Options* field in the IP header variable. Each of the options can be either a single byte long, or multiple bytes in length, depending on how much information the option needs to convey. When more than one option is included they are just concatenated together and put into the *Options* field as a whole. Since the IP header must be a multiple of 32 bits, a *Padding* field is included if the number of bits in all options together is not a multiple of 32 bits.

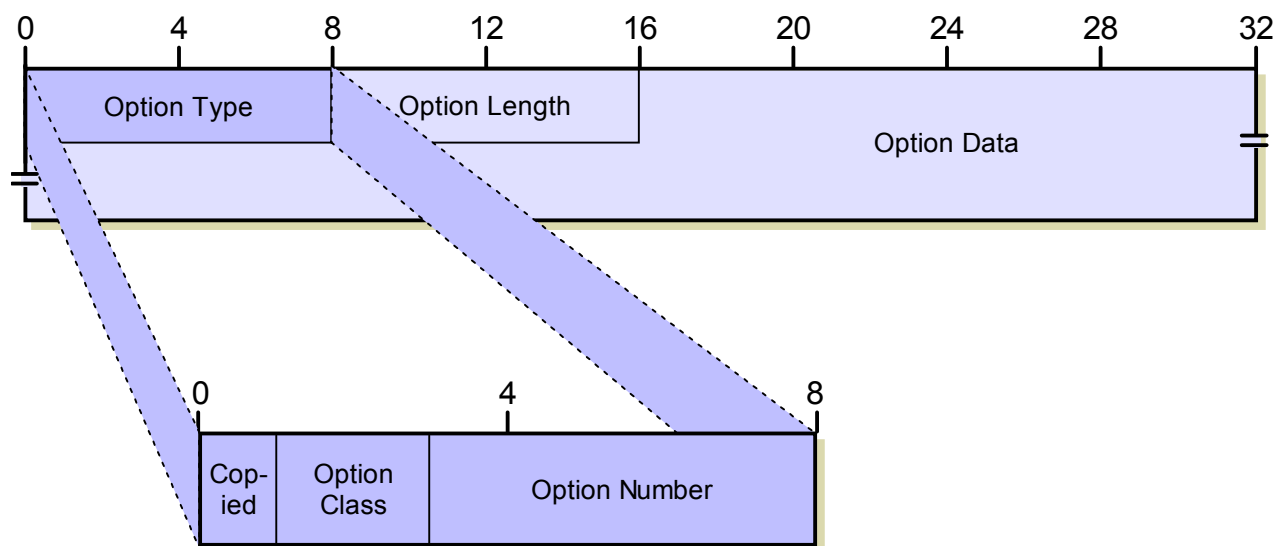

---

## IP Option Format

Each IP option has its own subfield format, generally structured as shown in [Table 59](#) and [Figure 87](#).

**Table 59: Internet Protocol Version 4 (IPv4) Option Format**

Subfield Name	Size (bytes)	Description												
Option Type	1	<b>Option Type:</b> This 8-bit field is divided into three “sub-subfields”. For a few options, the option number in this subfield tells the recipient all it needs to know; the option number is itself the message being sent by the option. If so, the <i>Option Type</i> field appears by itself. Other options include the <i>Option Length</i> and <i>Option Data</i> subfields. The <i>Option Type</i> subfield format is:												
		<table><tr><th>Sub-Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr><tr><td><i>Copied</i></td><td>1/8 1 bit)</td><td><b>Copied Flag:</b> This bit is set to 1 if the option is intended to be copied into all fragments when a datagram is fragmented; it is cleared to 0 if the option should not be copied into fragments.</td></tr><tr><td><i>Option Class</i></td><td>2/8 (2 bits)</td><td><b>Option Class:</b> Specifies one of four potential values that indicate the general category into which the option belongs. In fact, only two of the values are used: 0 is for <i>Control</i> options, and 2 for <i>Debugging and Measurement</i>.</td></tr><tr><td><i>Option Number</i></td><td>5/8 (5 bits)</td><td><b>Option Number:</b> Specifies the kind of option. 32 different values can be specified for each of the two option classes. Of these, a few are more commonly employed. See below for more information on the specific options.</td></tr></table>	Sub-Subfield Name	Size (bytes)	Description	<i>Copied</i>	1/8 1 bit)	<b>Copied Flag:</b> This bit is set to 1 if the option is intended to be copied into all fragments when a datagram is fragmented; it is cleared to 0 if the option should not be copied into fragments.	<i>Option Class</i>	2/8 (2 bits)	<b>Option Class:</b> Specifies one of four potential values that indicate the general category into which the option belongs. In fact, only two of the values are used: 0 is for <i>Control</i> options, and 2 for <i>Debugging and Measurement</i> .	<i>Option Number</i>	5/8 (5 bits)	<b>Option Number:</b> Specifies the kind of option. 32 different values can be specified for each of the two option classes. Of these, a few are more commonly employed. See below for more information on the specific options.
		Sub-Subfield Name	Size (bytes)	Description										
		<i>Copied</i>	1/8 1 bit)	<b>Copied Flag:</b> This bit is set to 1 if the option is intended to be copied into all fragments when a datagram is fragmented; it is cleared to 0 if the option should not be copied into fragments.										
		<i>Option Class</i>	2/8 (2 bits)	<b>Option Class:</b> Specifies one of four potential values that indicate the general category into which the option belongs. In fact, only two of the values are used: 0 is for <i>Control</i> options, and 2 for <i>Debugging and Measurement</i> .										
<i>Option Number</i>	5/8 (5 bits)	<b>Option Number:</b> Specifies the kind of option. 32 different values can be specified for each of the two option classes. Of these, a few are more commonly employed. See below for more information on the specific options.												
Option Length	0 or 1	<b>Option Length:</b> For variable-length options, indicates the size of the entire option, including all three subfields shown here, in bytes.												
Option Data	0 or Variable	<b>Option Data:</b> For variable-length options, contains data to be sent as part of the option.												

**Figure 87: Internet Protocol Version 4 (IPv4) Option Format**

This diagram shows the full field format for an IPv4 option. Note that a few simple options may consist of only the *Option Type* subfield, with the *Option Length* and *Option Data* subfields omitted.

## IP Options

Table 60 lists the most common IPv4 options, showing the option class, option number and length for each (a length of 1 indicating an option that consists of only an Option Type field), and providing a brief description of how each is used.

**Table 60: Internet Protocol Version 4 (IPv4) Options (Page 1 of 2)**

Option Class	Option Number	Length (bytes)	Option Name	Description
0	0	1	<i>End Of Options List</i>	An option containing just a single zero byte, used to mark the end of a list of options.
0	1	1	<i>No Operation</i>	A “dummy option” used as “internal padding” to align certain options on a 32-bit boundary when required.
0	2	11	<i>Security</i>	An option provided for the military to indicate the security classification of IP datagrams.
0	3	Variable	<i>Loose Source Route</i>	One of two options for source routing of IP datagrams. See below for an explanation.

**Table 60: Internet Protocol Version 4 (IPv4) Options (Page 2 of 2)**

Option Class	Option Number	Length (bytes)	Option Name	Description
0	7	Variable	<i>Record Route</i>	<p>This option allows the route used by a datagram to be recorded within the header for the datagram itself. If a source device sends a datagram with this option in it, each router that “handles” the datagram adds its IP address to this option. The recipient can then extract the list of IP addresses to see the route taken by the datagram.</p> <p>Note that the length of this option is set by the originating device. It cannot be enlarged as the datagram is routed, and if it “fills up” before it arrives at its destination, only a partial route will be recorded.</p>
0	9	Variable	<i>Strict Source Route</i>	One of two options for source routing of IP datagrams. See below for an explanation.
2	4	Variable	<i>Timestamp</i>	<p>This option is similar to the <i>Record Route</i> option. However, instead of each device that handles the datagram inserting its IP address into the option, it puts in a timestamp, so the recipient can see how long it took for the datagram to travel between routers.</p> <p>As with the <i>Record Route</i> option, the length of this option is set by the originating device and cannot be enlarged by intermediate devices.</p>
2	18	12	<i>Traceroute</i>	Used in the enhanced implementation of the <a href="#">traceroute utility</a> , as described in RFC 1393. Also see <a href="#">the topic on the ICMP Traceroute messages</a> .

**Key Concept:** Each IPv4 datagram has a 20-byte mandatory header, and may also include one or more *options*. Each option has its own field format, and most are variable in size.

### ***IP Options and Source Routing***

Normally, IP datagrams are routed without any specific instructions from devices regarding the path a datagram should take from the source to the destination. [It's the job of routers](#), using routing protocols, to figure out those details. In some cases, however, it may be advantageous to have the source of a datagram specify the route a datagram takes through the network. This is called *source routing*.

There are two IP options that support source routing. In each, the option includes a list of IP addresses specifying the routers that must be used, to reach the destination. When *strict* source routing is used, this means that the path specified in the option must be used

---

exactly, in sequence, with no other routers permitted to handle the datagram at all. In contrast, *loose* source routing specifies a list of IP addresses that must be followed in sequence, but having intervening hops in between the devices on the list is allowed.

For full details on the exact structure used by each option type, please refer to RFC 791.

---

## IP Datagram Size, Maximum Transmission Unit (MTU), Fragmentation and Reassembly

IP's main responsibility is to deliver data between internetworked devices. As we saw in [the preceding section](#), this requires that data received from higher layers be encapsulated into IP datagrams for transmission. These datagrams are then passed down to the data link layer where they are sent over physical network links.

In order for this to work properly, each datagram must be small enough to fit within the frame format of the underlying technology. If the message is bigger than the maximum frame size of the underlying network, it may be necessary to break up an IP message into several datagrams, a process called *fragmentation*. The datagrams are then sent individually and *reassembled* into the original message.

The Internet Protocol is designed to manage datagram size, and to allow fragmentation and reassembly in a seamless manner. In this section I explore issues related to managing the size of IP datagrams. I start with an overview of datagram size issues and the important concept of a network's maximum transmission unit (MTU), discussing why fragmentation is necessary. I then describe the process by which IP messages to be transmitted are fragmented by the source device and possibly routers along the path to the destination, and then outline how they are reassembled by the recipient.

**Background Information:** Explaining fragmentation and reassembly requires some understanding of the basic format of IP datagrams and some of the fields they contain. If you haven't yet read [the topic describing IP datagram general format](#) you may wish to review it before proceeding here.

---

## IP Datagram Size, the Maximum Transmission Unit (MTU), and Fragmentation Overview

As the core network layer protocol of the TCP/IP protocol suite, IP is designed to implement potentially large internetworks of devices. When we work with IP we get used to the concept of hosts being able to send information back and forth even though they may be quite far away and the data may need to travel across many devices between them. Even though we can usually consider the TCP/IP internet to be like a large, abstract “virtual network” of devices, we must always remember that underneath the network layer, data always travels across one or more physical networks. The implementation of the Internet Protocol must take this reality into account as well.

In order to send messages using IP we [encapsulate the higher-layer data into IP datagrams](#). These datagrams must then be sent down to the data link layer, where they are further encapsulated into the frames of whatever technology is going to be used to physically convey them, either directly to their destination, or indirectly to the next intermediate step in their journey to their intended recipient. The data link layer implementation puts the entire IP datagram into the data portion (the payload) of its frame format, just as IP puts

---

transport layer messages, transport headers and all, into its IP *Data* field. This immediately presents us with a potential issue: matching the size of the IP datagram to the size of the underlying data link layer frame size.

### ***Matching IP Datagram Size to Underlying Network Frame Size***

The underlying network that a device uses to connect to other devices could be LAN connection like Ethernet or Token Ring, a wireless LAN link such as 802.11, or a dialup, DSL, T-1 or other WAN connection. Each physical network will generally use its own frame format, and each format has a limit on how much data can be sent in a single frame. If the IP datagram is too large for the data link layer frame format's payload section, we have a problem!

For example, consider an FDDI. The maximum size of the data field in FDDI is around 4,470, depending on whether or not SNAP is used. This means FDDI can handle an IP datagram of up to 4,470 bytes. In contrast, a regular Ethernet frame uses a frame format that limits the size of the payload it sends to 1,500 bytes. This means Ethernet can't deal with IP datagrams greater than 1,500 bytes in size.

Now, remember that in sending a datagram across an internetwork, it may pass across more than one physical network. To access a site on the Internet, for example, we typically send a request through our local router, which then connects to other routers that eventually relay the request to the Internet site. Each hop as the datagram is forwarded may use a different physical network, with a different maximum underlying frame size.

The whole idea behind a network layer protocol is to implement this concept of a “virtual network” where devices talk even though they are far away. This means that higher layers shouldn't need to worry about details like the size limits of underlying data link layer technologies. However, someone has to worry about it. This task falls to the Internet Protocol.

### ***Maximum Transmission Unit (MTU) and Datagram Fragmentation***

The IP implementation of all devices on an IP internet needs to be aware of the capacity of the technology used by that implementation for its immediate data link layer connection to other devices. This limit is called the *maximum transmission unit (MTU)* of the network. This term is also sometimes seen as the *maximum transfer unit*.

If an IP layer receives a message to be sent across the internetwork, it looks at the size of the message and then computes how large the IP datagram would be after the addition of the 20 or more bytes needed for the IP header. If the total length is greater than the MTU of the underlying network, the IP layer will fragment the message into multiple IP fragments. So, if a host is connected using an Ethernet LAN to its local network, it may use an MTU of 1,500 for IP datagrams, and will fragment anything larger. [Figure 88](#) shows an example of differing MTUs and fragmentation.

---

**Key Concept:** The size of the largest IP datagram that can be transmitted over a physical network is called that network's *maximum transmission unit (MTU)*. If a datagram is passed from a network with a high MTU to one with a low MTU, it must be *fragmented* to fit the network with the smaller MTU.

---

Since some physical networks on the path between devices may have a smaller MTU than others, it may be necessary to fragment more than once. For example, suppose the source device wants to send an IP message 12,000 bytes long. Its local connection has an MTU of 3,300 bytes. It will have to divide this message into four fragments for transmission: three that are about 3,300 bytes long and a fourth remnant about 2,100 bytes long. (I'm oversimplifying by ignoring the extra headers required; [the next topic includes the full details of the fragmentation process.](#))

**Figure 88: IP Maximum Transmission Unit (MTU) and Fragmentation**

In this simple example, Device A is sending to Device B over a small internetwork consisting of one router and two physical links. The link from A to the router has an MTU of 3,300 bytes, but from the router to B it is only 1,300 bytes. Thus, any IP datagrams over 1,300 bytes will need to be fragmented.

### ***Multiple-Stage Fragmentation***

While the fragments above are in transit, they may need to pass over a hop between two routers where the physical network's MTU is only 1,300 bytes. In this case, each of the fragments will again need to be fragmented. The 3,300 byte fragments will end up in three pieces each (two of about 1,300 bytes and one of around 700 bytes) and the final 2,100-byte fragment will become a 1300-byte and 800-byte fragment. So instead of having four fragments, we will end up with eleven ( $3 \times 3 + 1 \times 2$ )! This is illustrated in [Figure 89](#).

### ***Internet Minimum MTU: 576 Bytes***

Each router must be able to fragment as needed to handle IP datagrams up to the size of the largest MTU used by networks to which they attach. Routers are also required, as a minimum, to handle an MTU of at least 576 bytes. This value is specified in RFC 791, and was chosen to allow a “reasonable sized” data block of at least 512 bytes, plus room for the standard IP header and options. Since it is the minimum size specified in the IP standard, 576 bytes has become a common default MTU value used for IP datagrams. Even if a host is connected over a local network with an MTU larger than 576, it may choose to use an MTU value of 576 anyway, to ensure that no further fragmentation will be required by intermediate routers.

**Figure 89: IPv4 Datagram Fragmentation**

This example shows illustrates a two-step fragmentation of a large IP datagram. The boxes represent datagrams or datagram fragments and are shown to scale. The original datagram is 12,000 bytes in size, represented by the large gray box. To transmit this data over the first local link, Device A splits it into four fragments, shown at left in four primary colors. The first router must fragment each of these into smaller fragments to send them over the 1,300-byte MTU link, as shown on the bottom. Note that the second router does *not* reassemble the 1,300-byte fragments, even though its link to Device B has an MTU of 3,300 bytes. (Figure 90 shows the process by which the fragments in this example are created.)

Note that while intermediate routers may further fragment an already-fragmented IP message, intermediate devices do not reassemble fragments. Reassembly is done only by the recipient device. This has some advantages and some disadvantages, as we will see when we examine [the reassembly process](#).

---

## ***MTU Path Discovery***

When trying to send a great deal of data, efficiency in message transmissions becomes important. The larger each IP datagram we send, the smaller the percentage of bytes wasted for overhead such as header fields. This means that ideally, we want to use as large an MTU as possible without fragmentation occurring.

Determining the optimal MTU to use for a route between two devices requires knowing the MTU of every link on that route—information that the end-points of the connection simply don't have. They can determine the MTU of the overall route, however, using a clever technique called *path MTU discovery*. I call this technique “clever” because it does not use any special feature designed for the particular purpose of determining a route's MTU, but rather an error reporting mechanism built into TCP/IP [Internet Control Message Protocol \(ICMP\)](#).

One of the message types defined in ICMPv4 is the [Destination Unreachable message](#), which is returned under various conditions where an IP datagram cannot be delivered. One of these situations is when a datagram is sent that is too large to be forwarded by a router over a physical link *but* which has its *Don't Fragment (DF)* flag set to prevent fragmentation. In this case, the datagram must be discarded and a *Destination Unreachable* message sent back to the source. A device can exploit this capability by testing the path with datagrams of different sizes, to see how large they must be before they are rejected.

The source node typically sends a datagram that has the MTU of its local physical link, since that represents an upper bound on the MTU of any path to or from that device. If this goes through without any errors, it knows it can use that value for future datagrams to that destination. If it gets back any *Destination Unreachable - Fragmentation Needed and DF Set* messages, this means some other link between it and the destination has a smaller MTU. It tries again using a smaller datagram size, and continues until it finds the largest MTU that can be used on the path.

## **IP Message Fragmentation Process**

When an IP datagram is too large for the [maximum transmission unit \(MTU\)](#) of the underlying data link layer technology used for the next leg of its journey, it must be *fragmented* before it can be sent across the network. The higher-layer message to be transmitted is not sent in a single IP datagram but rather broken down into pieces called *fragments* that are sent separately. In some cases, the fragments themselves may need to be fragmented further.

## ***Fragmentation Issues and Concerns***

Fragmentation is necessary to implement a network-layer internet that is independent of lower layer details, but introduces significant complexity to IP. Remember that IP is an unreliable, connectionless protocol. IP datagrams can take any of several routes on their way from the source to the destination, and some may not even make it to the destination at all. When we fragment a message we make a single datagram into many, which introduces several new issues to be concerned with:

- 
- ☉ **Sequencing and Placement:** The fragments will typically be sent in sequential order from the beginning of the message to the end, but they won't necessarily show up in the order in which they were sent. The receiving device must be able to determine the sequence of the fragments to reassemble them in the correct order. In fact, some implementations send the last fragment first, so the receiving device will immediately know the full size of the original complete datagram. This makes keeping track of the order of segments even more essential.
  - ☉ **Separation of Fragmented Messages:** A source device may need to send more than one fragmented message at a time; or, it may send multiple datagrams that are fragmented en route. This means the destination may be receiving multiple sets of fragments that must be put back together. Imagine a box into which the pieces from two, three or more jigsaw puzzles have been mixed and you understand this issue.
  - ☉ **Completion:** The destination device has to be able to tell when it has received all of the fragments so it knows when to start reassembly (or when to give up if it didn't get all the pieces).

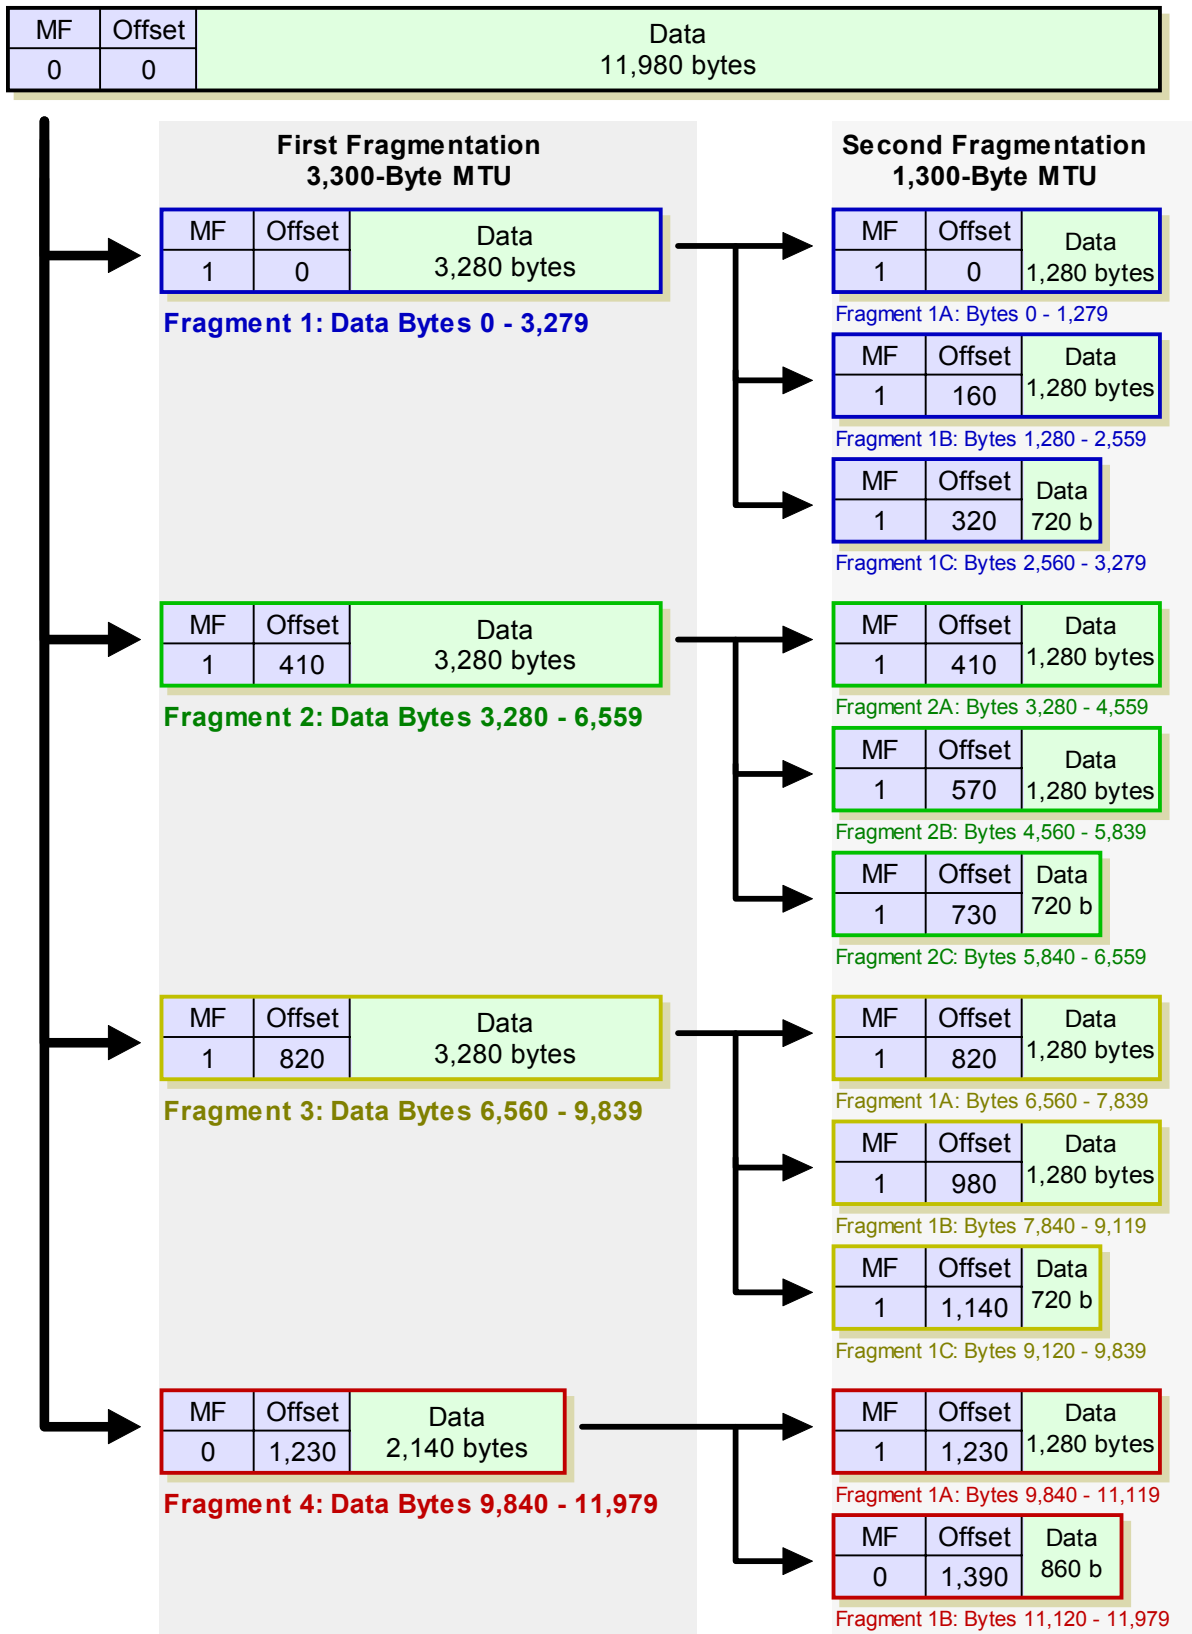

To address these concerns and allow the proper reassembly of the fragmented message, IP includes several fields in the [IP format header](#) that convey information from the source to the destination about the fragments. Some of these contain a common value for all the fragments of the message, while others are different for each fragment.

### ***The IP Fragmentation Process: An Example***

The device performing the fragmentation follows a specific algorithm to divide the message into fragments for transmission. The exact implementation of the fragmentation process depends on the device. Let's take the same example from the previous topic, an IP message 12,000 bytes wide (including the 20-byte IP header) that needs to be sent over a link with an MTU of 3,300. Here's a typical method by which this fragmentation might be performed (you may find the illustration in [Figure 90](#) helpful):

1. **Create First Fragment:** The first fragment is created by taking the first 3,300 bytes of the 12,000-byte IP datagram. This includes the original header, which becomes the IP header of the first fragment (with certain fields changed as described below). So, 3,280 bytes of data are in the first fragment. This leaves 8,700 bytes to encapsulate (11,980 minus 3,280).
2. **Create Second Fragment:** The next 3,280 bytes of data are taken from the 8,700 bytes that remain after the first fragment was built, and paired with a new header to create fragment #2. This leaves 5,420 bytes.
3. **Create Third Fragment:** The third fragment is created from the next 3,280 bytes of data, with a 20-byte header. This leaves 2,140 bytes of data.
4. **Create Fourth Fragment:** The remaining 2,140 bytes are placed into the fourth fragment, with a 20-byte header of course.

I want to emphasize two important points here. First, IP fragmentation does **not** work by fully encapsulating the original IP message into the *Data* fields of the fragments. If this were done, the first 20 bytes of the *Data* field of the first fragment would contain the original IP header. This technique is used by some other protocols, such as the [PPP Multilink Protocol](#), but not by IP. The original IP header is “transformed” into the IP header of the first fragment.

**Figure 90: IPv4 Datagram Fragmentation Process**

In this diagram, the *MF* and *Fragment Offset* fields of each fragment are shown for reference. The *Data* fields are shown to scale (the length of each is proportional to the number of bytes in the fragment.)

---

Second, note that the total number of bytes transmitted increases: we are sending 12,060 bytes (3,300 times three plus 2,160) instead of 12,000. The extra 60 bytes are from the additional headers in the second, third and fourth fragments. (The increase in size could theoretically be even larger if the headers contain options.)

### ***Fragmentation-Related IP Datagram Header Fields***

When a sending device or router fragments a datagram, it must provide information that will allow the receiving device to be able to identify the fragments and reassemble them into the datagram that was originally sent. This information is recorded by the fragmenting device in a number of fields in the IP datagram header.

#### ***Total Length***

After fragmenting, this field indicates the length of each fragment, not the length of the overall message. Normally, the fragment size is selected to match the MTU value in bytes. However, fragments must have a length that is a multiple of 8, to allow proper offset specification (see below). The last fragment will usually be shorter than the others because it will contain a “leftover” piece, unless the message length happens to be an exact multiple of the fragment size.

#### ***Identification***

To solve the “many jigsaw puzzles in a box” problem, a unique identifier is assigned to each message being fragmented. Consider this like writing a different number on the bottom of each piece of a jigsaw puzzle before tossing it into the box. This value is placed in the *Identification* field in the IP header of each fragment sent. The *Identification* field is 16 bits wide, so a total of 65,536 different identifiers can be used.

Obviously, we want to make sure that each message sent between the same source and destination that is being fragmented has a different identifier. The source can decide how it generates unique identifiers. This may be done through something as simple as a counter that is incremented each time a new set of fragments is created.

#### ***More Fragments***

This flag is set to a 1 for all fragments except the last one, which has it set to 0. When the fragment with a value of 0 in the *More Fragments* flag is seen, the destination knows it has received the last fragment of the message.

#### ***Fragment Offset***

This field solves the problem of sequencing fragments by indicating to the recipient device where in the overall message each particular fragment should be placed. The field is 13 bits wide, so the offset can be from 0 to 8191. Fragments are specified in units of 8 bytes, which is why fragment length must be a multiple of 8. Uncoincidentally,  $8191 * 8$  is 65,528, just about the maximum size allowed for an IP datagram.

---

Let's take the same example from above. The first fragment would have a *Fragment Offset* of 0. The second would have an offset of 410 (3,280 divided by 8). The third would have an offset of 820 (6,560 divided by 8). The fourth would have an offset of 1230.

**Key Concept:** When an MTU requirement forces a datagram to be fragmented, it is split into several smaller IP datagrams, each containing part of the original. The header of the original datagram is changed into the header of the first fragment, and new headers are created for the other fragments. Each is set to the same *Identification* value to mark them as part of the same original datagram. The *Fragment Offset* of each is set to the location where the fragment belongs in the original. The *More Fragments* field is set to 1 for all fragments but the last, to let the recipient know when it has received all the fragments.

---

### ***IP Header Flags Related to Fragmentation***

In addition to the fields above, there are a couple of flags in the IP header related to fragmentation.

#### **The Copied Flag**

If a datagram containing options must be fragmented, some of the options may be copied to each of the fragments. This is controlled by the *Copied* flag in each option field.

#### **The Don't Fragment Flag**

This flag can be set to 1 by a transmitting device to specify that a datagram not be fragmented in transit. This may be used in certain circumstances where the entire message must be delivered intact as pieces may not make sense. It may also be used if the destination device has a limited IP implementation and can't reassemble fragments, and is also used for testing the [maximum transmission unit \(MTU\)](#) of a link. Normally, however, devices don't care about fragmentation and this field is left at zero.

What happens if a router encounters a datagram too large to pass over the next physical network but with the *Don't Fragment* bit set to 1? It can't fragment the datagram and it can't pass it along either, so it is "stuck". It will generally drop the datagram, and then send back a special [ICMP Destination Unreachable error message](#): "Fragmentation Needed and *Don't Fragment* Bit Set". This is used in MTU Path Discovery as described in the preceding section.

### **IP Message Reassembly Process**

When a datagram is fragmented, either by the originating device or by one or more routers transmitting the datagram, it becomes multiple fragment datagrams. The destination of the overall message must collect these fragments and then *reassemble* them into the original message. Reassembly is accomplished by using the special information in the fields we saw in the preceding topic to help us "put the jigsaw puzzle back together again".

---

## Asymmetry of Fragmentation and Reassembly

It's important to understand that while reassembly is the complement to fragmentation, the two processes are not symmetric. A primary differentiation between the two is that while intermediate routers can fragment a single datagram or further fragment a datagram that is already a fragment, intermediate devices do not perform reassembly. This is done only by the ultimate destination of the IP message. So, if a datagram at an intermediate router on one side of a physical network with an MTU of 1,300 causes fragmentation of a 3,300 byte datagram, the router on the other end of this 1,300 MTU link will *not* restore the 3,000 byte datagram to its original state. It will send all the 1,300 byte fragments on down the internet, as shown in [Figure 89](#).

There are a number of reasons why the decision was made to implement IP reassembly this way. Perhaps the most important one is that fragments can take different routes to get from the source to destination, so any given router may not see all the fragments in a message. Another reason is that having routers need to worry about reassembling fragments would increase their complexity. Finally, as we will see, reassembly of a message requires that we wait for all fragments before sending on the reassembled message. Having routers do this would slow routing down. Since routers don't reassemble they can immediately forward all fragments on to the ultimate recipient.

However, there are drawbacks to this design as well. One is that it results in more smaller fragments traveling over longer routes than if intermediate reassembly occurred. This increases the chances of a fragment going missing and the entire message being discarded. Another is a potential inefficiency in the utilization of data link layer frame capacity. In the example above, the 1,300-byte fragments would not be reassembled back into a 3,300 byte datagram at the end of the 1,000-MTU link. If the next link after that one also had an MTU of 3,300, we would have to send three frames, each encapsulating a 1,300-byte fragment, instead of a single larger frame, which is slightly slower.

**Key Concept:** In IPv4, fragmentation can be performed by a router between the source and destination of an IP datagram, but reassembly is only done by the destination device.

---

## The Reassembly Process

As we saw in looking at [how fragmentation works](#), it involves a fair bit of complexity. Several IP header fields are filled in when a message is fragmented to give the receiving device the information it requires to properly reassemble the fragments. The receiving device follows a procedure to keep track of the fragments as they are received and build up its copy of the total received message from the source device. Most of its efforts are geared around dealing with the potential difficulties associated with IP being an unreliable protocol.

The details of implementation of the reassembly process are specific to each device, but generally include the following functions:

- 
- ☉ **Fragment Recognition and Fragmented Message Identification:** The recipient knows it has received a message fragment the first time it sees a datagram with the *More Fragments* bit set to one or the *Fragment Offset* a value other than zero. It identifies the message based on: the source and destination IP addresses; the protocol specified in the header; and the *Identification* field generated by the sender.
  - ☉ **Buffer Initialization:** The receiving device initializes a buffer where it can store the fragments of the message as they are received. It keeps track of which portions of this buffer have been filled with received fragments, perhaps using a special table. By doing this, it knows when the buffer is partially filled with received fragments and when it is completely full.
  - ☉ **Timer Initialization:** The receiving device sets up a timer for reassembly of the message. Since it is possible that some fragments may never show up, this timer ensures that the device will not wait “forever” trying to reassemble the message.
  - ☉ **Fragment Receipt and Processing:** Whenever a fragment of this message arrives (as indicated by it having the same source and destination addresses, protocol and *Identification* as the first fragment), the fragment is processed. It is inserted into the message buffer in the location indicated by its *Fragment Offset* field. The device also makes note of the fact that this portion of the message has been received.

Reassembly is finished when the entire buffer has been filled and the fragment with the *More Fragments* bit set to zero is received, indicating that it is the last fragment of the datagram. The reassembled datagram is then processed like a normal, unfragmented datagram would be. On the other hand, if the timer for the reassembly expires with any of the fragments missing, the message cannot be reconstructed. The fragments are discarded, and an [ICMP Time Exceeded message](#) generated. Since IP is unreliable, it relies on higher layer protocols such as TCP to determine that the message was not properly received and then retransmit it.

---

## **IP Datagram Delivery and Routing**

The essential functions of IP datagram encapsulation and addressing are sometimes compared to putting a letter in an envelope and then writing the address of the recipient on it. Once our IP datagram “envelope” is filled and labelled, it is ready to go, but it's still sitting on our desk. The last of the main functions of IP is to get the envelope from us to our intended recipient. This is the process of datagram *delivery*. When the recipient is not on our local network, this delivery requires that the datagram be *routed* from our network to the one where the destination resides.

In this section I discuss some of the particulars of how IP routes datagrams over an inter-network. I begin with an overview of the process and contrast direct and indirect delivery of data between devices. I discuss the main method used to route datagrams over the internet, and also explain briefly how IP routing tables are built and maintained. I discuss how the move from “classful” to classless addressing using CIDR impacted routing.

**Related Information:** Note that this section is brief and focuses mainly on routing issues that are directly related to how IP works. Routing is a complex and important topic in networking, and you'll find much more information about it in [the section that discusses TCP/IP routing/gateway protocols](#). I have tried not to duplicate that section by putting too much information about the process of routing here.

---

### **IP Datagram Direct Delivery and Indirect Delivery (Routing)**

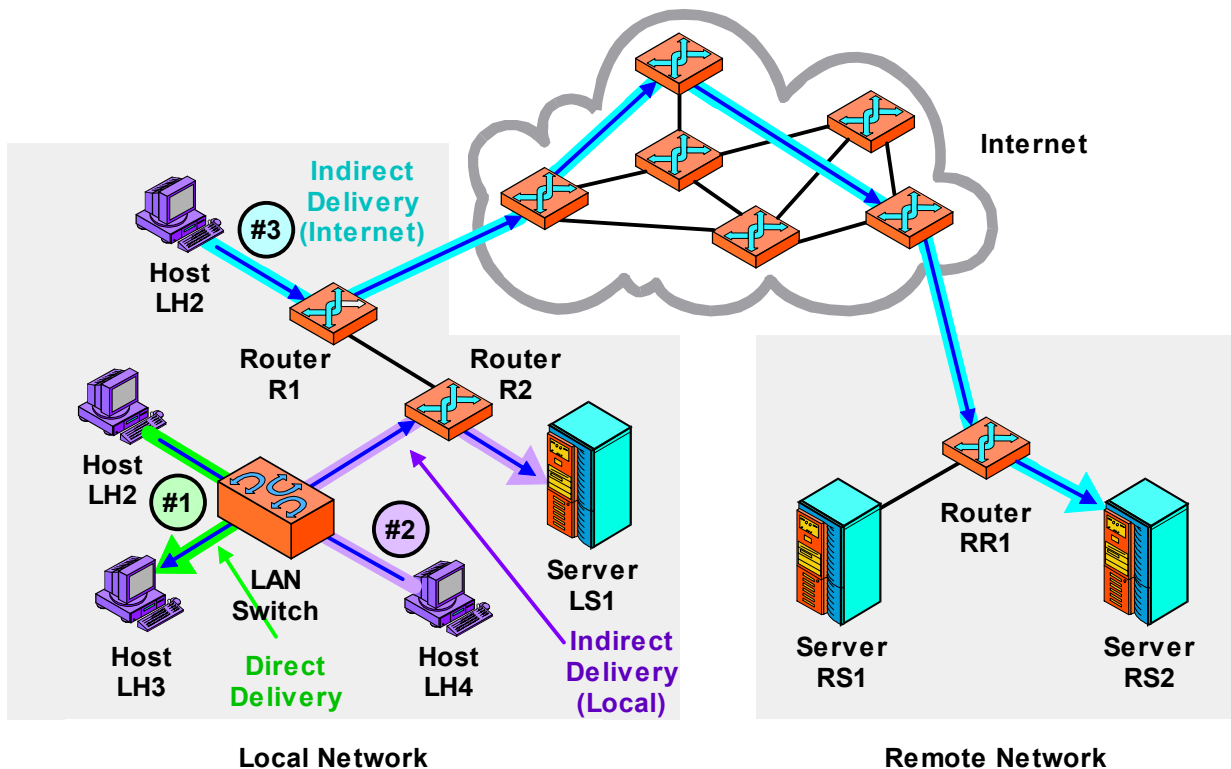

The overall job of the Internet Protocol is to transmit messages from higher layer protocols over an internetwork of devices. These messages must be packaged and addressed, and if necessary fragmented, and then they must be *delivered*. The process of delivery can be either simple or complex, depending on the proximity of the source and destination devices.

#### ***Datagram Delivery Types***

Conceptually, we can divide all IP datagram deliveries into two general types, shown graphically in [Figure 91](#):

- ☉ **Direct Datagram Deliveries:** When datagrams are sent between two devices on the same physical network, it is possible for datagrams to be delivered directly from the source to the destination. Imagine that you want to deliver a letter to a neighbor on your street. You probably wouldn't bother mailing it through the post office; you'd just put the neighbor's name on the envelope and stick it right into his or her mailbox.
- ☉ **Indirect Datagram Deliveries:** When two devices are not on the same physical network, the delivery of datagrams from one to the other is *indirect*. Since the source device can't see the destination on its local network, it must send the datagram through one or more intermediate devices to deliver it. Indirect delivery is analogous to

**Figure 91: Direct and Indirect (Routed) Delivery of IP Datagrams**

This diagram shows three examples of IP datagram delivery. The first transmission (highlighted in green) shows a direct delivery between two devices on the local network. The second (purple) shows indirect delivery within the local network, between a client and server separated by a router. The third shows a more distant indirect delivery, between a client on the local network and a server across the Internet.

mailing a letter to a friend in a different city. You don't deliver it yourself—you put it into the postal system. The letter journeys through postal system, possibly taking several intermediate steps, and ends up in your friend's neighborhood, where a postal carrier puts it into his or her mailbox.

### **Comparing Direct and Indirect Delivery**

Direct delivery is obviously the simpler of these. The source just sends the IP datagram down to its data link layer implementation. The data link layer encapsulates the datagram in a frame that is sent over the physical network directly to the recipient's data link layer, which passes it up to the IP layer.

Indirect delivery is much more complicated, because we can't send the data straight to the recipient. In fact, we usually will not even know where the recipient is, exactly. Sure, we have its address, but we may not know what network it is on, or where that network is relative to our own. (If I told you my address you'd know it's somewhere in Bennington, Vermont, but could you find it?) Like relying on the postal system in the envelope analogy,

---

we must rely on the internetwork itself to indirectly deliver datagrams. And like the postal system, the power of IP is that you don't need to know how to get the letter to its recipient; you just put it into the system.

The devices that accomplish this “magic” of indirect delivery are generally known as *routers*, and indirect delivery is more commonly called *routing*. Like entrusting a letter to your local mail carrier or mailbox, a host that needs to send to a distant device generally sends datagrams to its local router. The router connects to one or more other routers, and they each maintain information about where to send datagrams so that they reach their final destination.

Indirect delivery is almost always required when communicating with distant devices, such as those on the Internet or across a WAN link. However, it may also be needed even to send to a device in the next room of your office, if that device is not connected directly to yours at layer two.

---

**Note:** In the past, routers were often called *gateways*. Today, this term more generally can refer to a device that connects networks in a variety of ways. You will still sometimes hear routers called gateways—especially in the context of terms like “[default gateway](#)”—but since it is ambiguous, the term *router* is preferred.

---

### ***The Relationship Between Datagram Routing and Addressing***

Obviously, each time a datagram must be sent, it is necessary that we determine first of all whether we can deliver it directly or if routing is required. Remember [all those pages and pages of details about IP addressing](#)? Well, this is where the payoff is. The same thing that makes IP addressing sometimes hard to understand—the [division into network ID and host ID bits](#), as well as the [subnet mask](#)—is what allows a device to quickly determine whether or not it is on the same network as its intended recipient:

- ☉ **Conventional “Classful” Addressing:** [We know the class of each address by looking at the first few bits.](#) This tells us which bits of an address are the network ID. If the network ID of the destination is the same as our own, the recipient is on the same network; otherwise, it is not.
- ☉ **Subnetted “Classful” Addressing:** [We use our subnet mask to determine our network ID and subnet ID and that of the destination address.](#) If the network ID and subnet are the same, the recipient is on the same subnet. If only the network ID is the same, the recipient is on a different subnet of the same network. If the network ID is different, the destination is on a different network entirely.
- ☉ **Classless Addressing:** The same basic technique is used as for subnetted “classful” addressing, except that there are no subnets. [We use the “slash number” to determine what part of the address is the network ID](#) and compare the source and destination as before. There are complications here, however, that I discuss more in [the topic on routing in a classless environment](#).

**Key Concept:** The delivery of IP datagrams is divided into two categories: *direct* and *indirect*. Direct delivery is possible when two devices are on the same physical network. When they are not, indirect delivery, more commonly called *routing*, is required to get the datagrams from source to destination. A device can tell which type of delivery is required by looking at the IP address of the destination, in conjunction with supplemental information such as the subnet mask that tells the device what network or subnet it is on.

---

The determination of what type of delivery is required is the first step in the source deciding where to send a datagram. If it realizes the destination is on the same local network it will address the datagram to the recipient directly at the data link layer. Otherwise, it will send the datagram to the data link layer address of one of the routers to which it is connected. The IP address of the datagram will still be that of the ultimate destination. Mapping between IP addresses and data link layer addresses is accomplished using the [TCP/IP Address Resolution Protocol \(ARP\)](#).

I should also clarify one thing regarding the differentiation between direct and indirect delivery. Routing is done in the latter case to get the datagram to the local network of the recipient. After the datagram has been routed to the recipient's physical network, it is sent to the recipient by the recipient's local router. So, you could say that indirect delivery includes direct delivery as its final step.

The next topic discusses IP routing processes and concepts in more detail.

**Note:** Strictly speaking, any process of delivery between a source and destination device can be considered routing, even if they are on the same network. It is common, however, for the process of routing to refer more specifically to indirect delivery as explained above.

---

## **IP Routing Concepts and the Process of Next-Hop Routing**

When a datagram is sent between source and destination devices that are not on the same physical network, [the datagram must be delivered indirectly](#) between the devices, a process called *routing*. It is this ability to route information between devices that may be far away that allows IP to create the equivalent of a virtual internetwork that spans potentially thousands of physical networks, and lets devices even on opposite ends of the globe communicate. The process of routing in general terms is too complex to get into in complete detail here, but I do want to take a brief look at key IP routing concepts.

---

## Overview of IP Routing and Hops

To continue with our [postal system analogy](#), I can send a letter from my home in the United States to someone in, say, India, and the postal systems of both countries will work to deliver the letter to its destination. However, when I drop a letter in the mailbox, it's not like someone shows up, grabs the letter, and hand-delivers it to the right address in India. The letter travels from the mailbox to my local post office. From there, it probably goes to a regional distribution center, and then from there, to a hub for international traffic. It goes to India, perhaps (likely) via an intermediate country. When it gets to India, the Indian postal system uses its own network of offices and facilities to route the letter to its destination. The envelope “hops” from one location to the next until it reaches its destination.

IP routing works in very much the same manner. Even though IP lets devices “connect” over the internetwork using indirect delivery, all of the actual communication of datagrams occurs over physical networks using *routers*. We don't know where exactly the destination device's network is, and we certainly don't have any way to connect directly to each of the thousands of networks out there. Instead, we rely on intermediate devices that are each physically connected to each other in a variety of ways to form a mesh containing millions of paths between networks. To get the datagram where it needs to go, it needs to be handed off from one router to the next, until it gets to the physical network of the destination device. The general term for this is *next-hop routing*. The process is illustrated in [Figure 92](#).

### The Benefits of Next-Hop Routing

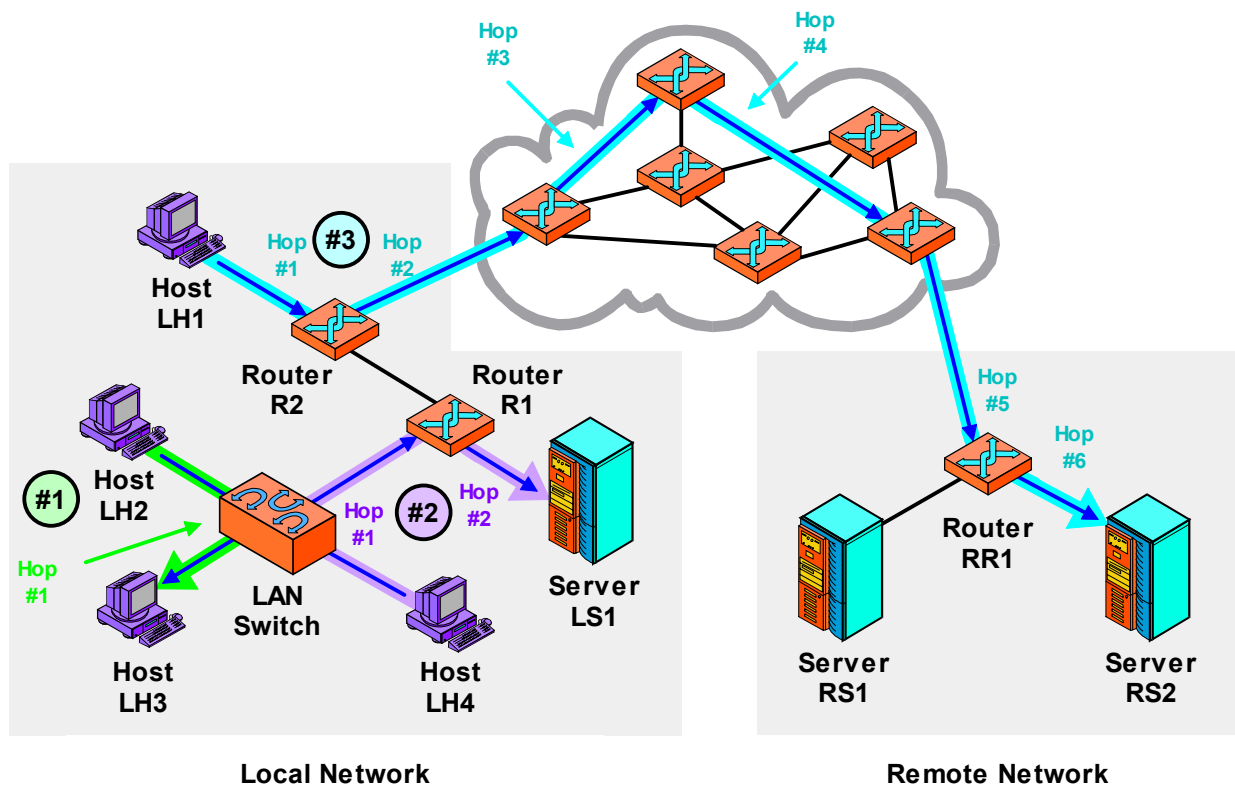

This is a critical concept in how IP works: routing is done on a step-by-step basis, one hop at a time. When we decide to send a datagram to a device on a distant network, we don't know the exact path that the datagram will take; we only have enough information to send it to the correct router to which we are attached. That router, in turn, looks at the IP address of the destination and decides where the datagram should next “hop” to. This process continues until the datagram reaches the destination host's network, when it is delivered.

Next-hop routing may seem at first like a strange way of communicating datagrams over an internetwork. In fact, it is part of what makes IP so powerful. On each step of the journey to any other host, a router only needs to know where the next step for the datagram is. Without this concept, each device and router would need to know what path to take to every other host on the internet, which would be quite impractical.

**Key Concept:** Indirect delivery of IP datagrams is accomplished using a process called *next-hop routing*, where each message is handed from one router to the next until it reaches the network of the destination. The main advantage of this is that each router needs only to know which neighboring router should be the next recipient of a given datagram, rather than needing to know the exact route to every destination network.

---

**Figure 92: IP Datagram Next-Hop Routing**

This is the same diagram as that shown in [Figure 91](#), except this time I have explicitly shown the hops taken by each of the three sample transmissions. The direct delivery of the first (green) transmission has only one hop (remember that the switch doesn't count because it is invisible at layer three). The local indirect delivery passes through one router, so it has two hops. The Internet delivery in this case has six hops; actual Internet routes can be much longer.

### ***Datagram Processing At Each Hop***

As mentioned above, each “hop” in routing consists of traversal of a physical network. After a source sends a datagram to its local router, the data link layer on the router passes it up to the router's IP layer. There, the datagram's header is examined, and the router decides what the next device is to send the datagram to. It then passes it back down to the data link layer to be sent over one of the router's physical network links, typically to another router. The router will either have a record of the physical addresses of the routers to which it is connected, or [it will use ARP to determine these addresses](#).

### ***The Essential Role of Routers in IP Datagram Delivery***

Another key concept related to the principle of next-hop routing is that routers are designed to accomplish routing, not hosts. Most hosts are connected using only one router to the rest of the internet (or Internet). It would be a maintenance nightmare to have to give each host the smarts to know how to route to every other host. Instead, hosts only decide if they are sending locally to their own network, or if they are sending to a non-local network. If the

---

latter, they just send the datagram to their router and say “here, **you** take care of this”. If a host has a connection to more than one router, it only needs to know which router to use for certain sets of distant networks. How routers decide what to do with the datagrams when they receive them from hosts is [the subject of the next topic](#).

## **IP Routes and Routing Tables**

Routers are responsible for forwarding traffic on an IP internetwork. Each router accepts datagrams from a variety of sources, examines the IP address of the destination and decides what the [next hop](#) is that the datagram needs to take to get it that much closer to its final destination. A question then naturally arises: how does a router know where to send different datagrams?

Each router maintains a set of information that provides a mapping between different network IDs and the other routers to which it is connected. This information is contained in a data structure normally called a *routing table*. Each entry in the table, unsurprisingly called a *routing entry*, provides information about one network (or subnetwork, or host). It basically says “if the destination of this datagram is in the following network, the next hop you should take is to the following device”. Each time a datagram is received the router checks its destination IP address against the routing entries in its table to decide where to send the datagram, and then sends it on its next hop.

Obviously, the fewer the entries in this table, the faster the router can decide what to do with datagrams. (This was a big part of the motivation for [classless addressing](#), which aggregates routes into “supernets” to reduce router table size, [as we will see in the next topic](#).) Some routers only have connections to two other devices, so they don't have much of a decision to make. Typically, the router will simply take datagrams coming from one of its interfaces and if necessary, send them out on the other one. For example, consider a small company's router acting as the interface between a network of three hosts and the Internet. Any datagrams sent to the router from a host on this network will need to go over the router's connection to the router at the ISP.

When a router has connections to more than two devices, things become considerably more complex. Some distant networks may be more easily reachable if datagrams are sent using one of the routers than the other. The routing table contains information not only about the networks directly connected to the router, but also information that the router has “learned” about more distant networks.

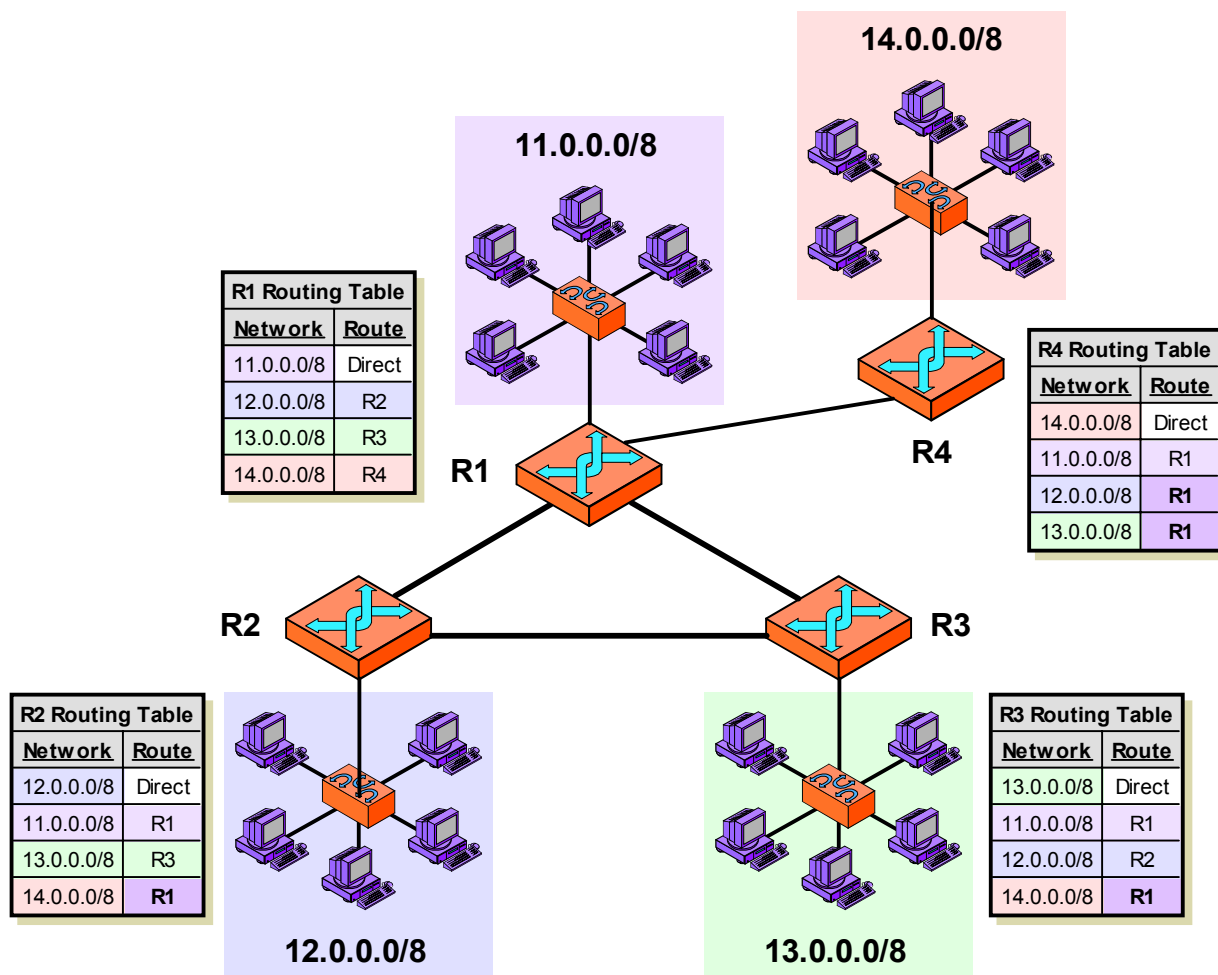

**Key Concept:** A router make decisions about how to route datagrams using its internal *routing table*. The table contains entries specifying to which router datagrams should be sent to reach a particular network.

---

## Routing Tables in an Example Internetwork

Let's consider an example (see [Figure 93](#)) with routers R1, R2 and R3 connected in a “triangle”, so that each router can send directly to the others, as well as to its own local network. Suppose R1's local network is 11.0.0.0/8, R2's is 12.0.0.0/8 and R3's is 13.0.0.0/8. (I'm just trying to keep this simple. ☺) R1 knows that any datagram it sees with 11 as the first octet is on its local network. It will also have a routing entry that says that any IP address starting with “12” should go to R2, and any starting with “13” should go to R3.

**Figure 93: IP Routing and Routing Tables**

This diagram shows a small, simple internetwork consisting of four LANs each served by a router. The routing table for each lists the router to which datagrams for each destination network should be sent, and is color coded to match the colors of the networks. Notice that due to the “triangle”, each of R1, R2 and R3 can send to each other. However, R2 and R3 must send through R1 to deliver to R4, and R4 must use R1 to reach either of the others.

Let's suppose that R1 also connects to another router, R4, which has 14.0.0.0/8 as its local network. R1 will have an entry for this local network. However, R2 and R3 also need to know how to reach 14.0.0.0/8, even though they don't connect to it its router directly. Most

---

likely, they will have an entry that says that any datagrams intended for 14.0.0.0/8 should be sent to R1. R1 will then forward them to R4. Similarly, R4 will send any traffic intended for 12.0.0.0/8 or 13.0.0.0/8 through R1.

### **Route Determination**

Now, imagine that this process is expanded to handle thousands of networks and routers. Not only do routers need to know which of their local connections to use for each network, they want to know, if possible, what is the **best** connection to use for each network. Since routers are interconnected in a mesh there are usually multiple routes between any two devices, but we want to take the best route whenever we can. This may be the shortest route, the least congested, or the route considered optimal based on other criteria.

Determining what routes we should use for different networks turns out to be an important but very complex job. Routers must plan routes and exchange information about routes and networks, which can be done in a variety of ways. This is accomplished in IP using special *IP routing protocols*. It is through these protocols that R2 and R3 would find out that 14.0.0.0/8 exists and that it is connected to them via R1. [I discuss these important “support protocols” in their own section.](#)

**Note:** There is a difference between a **routeable** protocol and a **routing** protocol. IP is a *routeable* protocol, which means its messages (datagrams) can be routed. Examples of *routing* protocols are [RIP](#) or [BGP](#), which are used to exchange routing information between routers.

---

### **IP Routing In A Subnet Or Classless Addressing (CIDR) Environment**

There are three main categories of IP addressing: “classful”, subnetted “classful”, and classless. [As we have already seen](#), the method used for determining whether direct or indirect delivery of a datagram is required is different for each type of addressing. The type of addressing used in the network also impacts how routers decide to forward traffic in an internet.

One of the main reasons why the traditional class-based addressing scheme was created was that it made both addressing and routing relatively simple. We must remember that IPv4 was developed in the late 1970s, when the cheap and powerful computer hardware we take for granted today was still in the realm of science fiction. For the internetwork to function properly, routers had to be able to look at an IP address and quickly decide what to do with it.

“Classful” addressing was intended to make this possible. There was only a two-level hierarchy for the entire internet: network ID and host ID. [Routers could tell by looking at the first four bits](#) which of the bits in any IP address were the network ID and which the host ID. Then they needed only consult their routing tables to find the network ID and see which router was the best route to that network.

---

The addition of subnetting to conventional addressing didn't really change this for the main routers on the internet, because subnetting is internal to the organization. The main routers handling large volumes of traffic on the Internet didn't look at subnets at all; the additional level of hierarchy that subnets represent existed only for the routers within each organization that chose to use subnetting. These routers, when deciding what to do with datagrams within the organization's network, had to extract not only the network ID of IP addresses, but also the subnet ID. This told them which internal physical network to send the datagram to.

### ***Aggregated Routes and their Impact on Routing***

[Classless addressing](#) is formally called *Classless Inter-Domain Routing* or *CIDR*. The name mentions routing and not addressing, and this is evidence that CIDR was introduced in large part to improve the efficiency of routing. This improvement occurs because classless networks use a multiple-level hierarchy. Each network can be broken down into subnetworks, sub-subnetworks, and so on. This means that when we are deciding how to route in a CIDR environment, we can also describe routes in a hierarchical manner. Many smaller networks can be described using a single, higher-level network description that represents them all to routers in the rest of the internet. This technique, sometimes called *route aggregation*, reduces routing table size.

Let's refer back to [the detailed example I gave in the addressing section on CIDR](#). An ISP started with the block 71.94.0.0/15 and subdivided it multiple times to create smaller blocks for itself and its customers. To the customers and users of this block, these smaller blocks must be differentiated; the ISP obviously needs to know how to route traffic to the correct customer. To everyone else on the Internet, however, these details are unimportant in deciding how to route datagrams to anyone in that ISP's block. For example, suppose I am using a host with IP address 211.42.113.5 and I need to send to 71.94.1.43. My local router, and the main routers on the Internet, don't know where in the 71.94.0.0/15 block that address is, and they don't need to know either. They just know that anything with the first 15 bits containing the binary equivalent of 71.94 goes to the router(s) that handle(s) 71.94.0.0/15, which is the aggregated address of the entire block. They let the ISP's routers figure out which of its constituent subnetworks contains 71.94.1.43.

Contrast this to the way it would be in a “classful” environment. Each of the customers of this ISP would probably have one or more Class C address blocks. Each of these would require a separate router entry, and these blocks would have to be known by *all* routers on the Internet. Thus, instead of just one 71.94.0.0/15 entry, there would be dozens or even hundreds of entries for each customer network. In the classless scheme, only one entry exists, for the “parent” ISP.

### ***Potential Ambiguities in Classless Routes***

CIDR provides benefits to routing but also increases complexity. Under CIDR, we cannot determine which bits are the network ID and which the host ID just from the IP address. To make matters worse, we can have networks, subnetworks, sub-subnetworks and so on that all have the same base address!

---

In our example above, 71.94.0.0/15 is the complete network, and subnetwork #0 is 71.94.0.0/16. They have a different prefix length (the number of network ID bits) but the same base address. If a router has more than one match for a network ID in this manner, it must use the match with the longest network identifier first, since it represents a more specific network description..

---

## **IP Multicasting**

The great bulk of TCP/IP communications uses the Internet Protocol to send messages from one source device to one recipient device; this is called *unicast* communications. This is the type of messaging we normally use TCP/IP for; when you use the Internet you are using unicast for pretty much everything. For this reason, most of my discussion of IP has been oriented around describing [unicast messaging](#).

IP does, however, also support the ability to have one device send a message to a set of recipients. This is called *multicasting*. IP multicasting has been “officially” supported since IPv4 was first defined, but has not seen widespread use over the years, due largely to lack of support for multicasting in many hardware devices. Interest in multicasting has increased in recent years, and support for multicasting was made a standard part of the [next generation IP version 6 protocol](#). Therefore, I felt it worthwhile to provide a brief overview of IP multicasting. It's a large and very complex subject, so I will not be getting into it in detail—you'll have to look elsewhere for a full description of IP multicasting. (Sorry, it was either a brief summary or nothing; maybe I'll write more on multicasting in the future.)

The idea behind IP multicasting is to allow a device on an IP internetwork to send datagrams not to just one recipient but to an arbitrary collection of other devices. IP multicasting is modeled after the similar function used in the data link layer to allow a single hardware device to send to various members of a group. Multicasting is relatively easy at the data link layer, however, because all the devices can communicate directly. In contrast, at the network layer, we are connecting together devices that may be quite far away from each other, and must route datagrams between these different networks. This necessarily complicates multicasting when done using IP (except in the special case where we use IP multicasting only between devices on the same data link layer network.)

There are three primary functions that must be performed to implement IP multicasting: addressing, group management, and datagram processing / routing.

### ***Multicast Addressing***

Special addressing must be used for multicasting. These *multicast addresses* identify not single devices but rather *multicast groups* of devices that listen for certain datagrams sent to them. In IPv4, 1/16th of the entire address space was set aside for multicast addresses: the Class D block of the original “[classful](#)” [addressing scheme](#).

Special techniques are used to define the meaning of addresses within this block, and to define a mapping between IP multicast and data link layer multicast addresses. This is all described in [the topic on IP multicast addressing](#); mapping of IP multicast addresses to hardware layer multicast addresses is discussed [in the section on address resolution](#).

### ***Multicast Group Management***

Group management encompasses all of the activities required to set up groups of devices. They must be able to dynamically join groups and leave groups, and information about groups must be propagated around the IP internetwork. To support these activities,

---

additional techniques are required. The *Internet Group Management Protocol (IGMP)* is the chief tool used for this purpose. It defines a message format to allow information about groups and group membership to be sent between devices and routers on the internet.

### ***Multicast Datagram Processing and Routing***

This is probably the most complicated: handling and routing datagrams in a multicast environment. There are several issues here:

- ☉ Since we are sending from one device to many devices, we need to actually create multiple copies of the datagram for delivery, in contrast to the single datagram used in the unicast case. Routers must be able to tell when they need to create these copies.
- ☉ Routers must use special algorithms to determine how to forward multicast datagrams. Since each one can lead to many copies being sent various places, efficiency is important to avoid creating unnecessary volumes of traffic.
- ☉ Routers must be able to handle datagrams sent to a multicast group even if the source is not a group member.

Routing in a multicast environment requires significantly more intelligence on the part of router hardware. Several special protocols, such as the *Distance Vector Multicast Routing Protocol (DVMRP)*, and the multicast version of [OSPF](#), are used to enable routers to forward multicast traffic effectively. These algorithms must balance the need to ensure that every device in a group receives a copy of all datagrams intended for that group, with the need to prevent unnecessary traffic from moving across the internetwork.

**Key Concept:** IP multicasting allows special applications to be developed where one device sends information to more than one other, across a private internet or the global Internet. It is more complex than conventional unicast IP and requires special attention particularly in the areas of addressing and routing.

---

This overview has only scratched the surface of IP multicasting. The complexity involved in handling groups and forwarding messages to multicast groups is one reason why support for the feature has been quite uneven and as a consequence, it is not used widely. Another issue is the demanding nature of multicasting; it uses a great deal of network bandwidth for copies of messages, and also requires more work of already-busy routers.

---

## Internet Protocol Version 6 (IPv6) / IP Next Generation (IPng)

Since 1981, TCP/IP has been built on [version 4 of the Internet Protocol](#). IPv4 was created when the giant, world-wide Internet we take for granted today was just a small experimental network. Considering how much the Internet has grown and changed over the course of two decades, IPv4 has done its job admirably. At the same time, it has been apparent for many years that certain limitations in this venerable protocol would hold back the future growth of both Internet size and services if not addressed.

Due to the key role that IP plays, changing it is no simple feat. It means a substantial modification to the way that nearly everything in TCP/IP operates. However, even though we find change difficult, most of us know that it is necessary. For the last several years, development of a new version of IP has been underway, officially called *Internet Protocol version 6 (IPv6)* and also sometimes referred to as *IP Next Generation* or *IPng*. IPv6 is poised to take over from IPv4, and will be the basis for the Internet of the future.

In this section I provide a detailed description of IP version 6. Since IPv6 is still IP just like IPv4, it performs the same functions: addressing, encapsulation, fragmentation and reassembly, and datagram delivery and routing. For this reason, the subsections and topics in this discussion of IPv6 are patterned after the subsections in the section on IPv4. They include a discussion of IPv6 concepts and issues, coverage of IPv6 addressing and data packaging, and a look at how version 6 does fragmentation, reassembly and routing.

**Background Information:** Since IPv6 represents the evolution of IP, many of its concepts of operation are built upon those introduced in IPv4. To avoid unnecessary duplication, this section has been written with the assumption that the reader is familiar with the operation of IPv4, especially addressing and how datagrams are packaged and delivered. If you have not read [the section on IPv4](#), reviewing it first would be wise, because the description of IPv6 focuses on how it differs from the current IP version.

---

**Related Information:** You may wish to refer to the sections on [ICMP](#) (part of which is ICMPv6—ICMP for IPv6) and the [IPv6 Neighbor Discovery \(ND\) protocol](#), since these are “companions” of sort to IPv6. However, it is not necessary.

---

**Note:** IPv6 is obviously still under development, and as such, writing a section such as this one is like trying to hit a moving target. This is probably why most TCP/IP guides don't say much about IPv6—it keeps changing! I think it is important, so I have described it as defined on the date of publishing. However, since changes are being made to both IPv6 standards and implementation every month, there is a higher probability of information in this particular section being out of date. (I had to make several revisions even prior to publishing the first version of this Guide!)

---

---

## **IPv6 Overview, Changes and Transition**

IPv6 is destined to be the future of the Internet Protocol, and due to IP's critical importance, it will form the basis for the future of TCP/IP and the Internet as well. In fact, it's been under development since the middle of the last decade, and a real IPv6 internetwork has been used for testing for a number of years as well. Despite this, many people don't know much about IPv6, other than it's a newer version of IP. Some have never even heard of it at all! We're going to rectify that, of course—but before we delve into the important changes made in version 6 to how IP addressing, packaging, fragmentation and other functions, let's start with a “bird's eye” view of IPv6.

In this section I provide a brief higher-level overview of IPv6, including a look at how it differs from IPv4 in general terms. I begin with a brief overview of IPv6 and why it was created. I list the major changes made in IPv6 and additions to the protocol from the current version. I also explain some of the difficulties associated with transitioning the enormous global Internet from IPv4 to IPv6.

### **IPv6 Motivation and Overview**

“If it ain't broke, don't fix it.” I consider this one of my favorite pieces of folk wisdom. I generally like to stick with what works, as do most people. And [IP version 4](#) works pretty darned well. It's been around for decades now and has survived the growth of the Internet from a small research network into a globe-spanning powerhouse. So, like a trusty older car that we've operated successfully for years, why should we replace it if it still gets the job done?

Like that older car, we could continue to use IPv4 for the foreseeable future. The question is: *at what cost?* An older car can be kept in good working order if you are willing to devote the time and money it takes to maintain and service it. However, it will still be limited in some of its capabilities. Its reliability may be suspect. It won't have the latest features. With the exception of those who like to work on cars as a hobby, it eventually stops making sense to keep fixing up an older vehicle.

In some ways, this isn't even that great of an analogy. Our highways aren't all that much different than they were in the 1970s, and most other issues related to driving a car haven't changed all that much in the last 25 years either. The choice of updating a vehicle or not is based on practical considerations more than necessity.

In contrast, look at what has happened to the computer and networking worlds in the last 25 years! Today's handheld PCs can do more than the most powerful servers could back then. Networking technologies are 100 or even 1000 times as fast. The number of people connecting to the global Internet has increased by an even larger factor. And the ways that computers communicate have, in many cases, changed dramatically.

IPv4 could be considered in some ways like an older car that has been meticulously maintained and repaired over time. It gets the job done, but its age is starting to show. The main problem with IPv4 is its relatively small [address space](#), a legacy of the decision to use only 32 bits for the IP address. Under the original “classful” addressing allocation scheme,

---

we would have probably already run out of IPv4 addresses by now. Moving to [classless addressing](#) has helped postpone this, as have technologies like [IP Network Address Translation \(NAT\)](#) that allow privately-addressed hosts to access the Internet.

In the end, however, these represent patch jobs and imperfect repairs applied to keep the aging automobile that is IPv4 on the road. The core problem, the 32-bit address space that is too small for the current and future size of the Internet, can only be addressed by moving to a larger address space. This was the primary motivating factor in creating the next version of the Internet Protocol, *IPv6*.

---

**Note:** The reason why the successor to IPv4 is version 6 and not version 5 is because version number 5 was used to refer to an experimental protocol called the *Internet Stream Protocol*, which was never widely deployed. [See the topic on IP history and versions for a full discussion.](#)

---

## ***IPv6 Standards***

IPv6 represents the first major change to the Internet Protocol since IPv4 was formalized in 1981. For many years, its core operation was defined in a series of RFCs published in 1998, RFCs 2460 through 2467. The most notable of these are the main IPv6 standard, RFC 2460 ([Internet Protocol, Version 6 \(IPv6\) Specification](#)), and documents describing the two “helper” protocols for IPv6: RFC 2461, which describes the [IPv6 Neighbor Discovery Protocol](#), and RFC 2463, which describes [ICMP](#) version 6 (ICMPv6) for IPv6.

In addition to these, two documents were also created in 1998 to discuss more about IP addressing: RFC 2373 ([IP Version 6 Addressing Architecture](#)) and RFC 2374 ([An IPv6 Aggregatable Global Unicast Address Format](#)). Due to changes in how IPv6 addressing was to be implemented, these were updated in 2003 by RFC 3513 ([Internet Protocol Version 6 \(IPv6\) Addressing Architecture](#)) and RFC 3587 ([IPv6 Global Unicast Address Format](#)).

Many other RFCs define more specifics of how IPv6 functions, and also describe IPv6-compatible versions of other TCP/IP protocols like [DNS](#) and [DHCP](#). IPv6 is still very much a work in progress with new standards for it being proposed and adopted on a regular basis.

Since IPv6 is the version of IP designed for the next generation of the Internet, it is also sometimes called *IP Next Generation* or *IPng*. Personally, I don't care for this name; it reminds me too much of *Star Trek: The Next Generation*. A great show that my wife and I watch regularly, but still. Regardless of its name, IPv6 or IPng was designed to take TCP/IP and the Internet “where none have gone before”. (Sorry, I **had** to! ☺)

## ***Design Goals of IPv6***

The problem of addressing was the main motivation for creating IPv6. Unfortunately, this has caused many people to think that the address space expansion is the **only** change made in IP, which is definitely not the case. Since making a change to IP is such a big deal,

---

it's something done rarely. It made sense to correct not just the addressing issue but to update the protocol in a number of other respects as well, to ensure its viability. In fact, even the addressing changes in IPv6 go far beyond just adding more bits to IP address fields.

Some of the most important goals in designing IPv6 include:

- ☉ **Larger Address Space:** This is what we discussed earlier. IPv6 had to provide more addresses for the growing Internet.
- ☉ **Better Management of Address Space:** It was desired that IPv6 not only include more addresses, but a more capable way of dividing the address space and using the bits in each address.
- ☉ **Elimination of “Addressing Kludges”:** Technologies like [NAT](#) are effectively “kludges” that make up for the lack of address space in IPv4. IPv6 eliminates the need for NAT and similar work-arounds, allowing every TCP/IP device to have a public address.
- ☉ **Easier TCP/IP Administration:** The designers of IPv6 hoped to resolve some of the current labor-intensive requirements of IPv4, such as the need to configure IP addresses. Even though tools like DHCP eliminate the need to manually configure many hosts, it only partially solves the problem.
- ☉ **Modern Design For Routing:** In contrast to IPv4, which was designed before we all had any idea what the modern Internet would be like, IPv6 was created specifically for efficient routing in our current Internet, and with the flexibility for the future.
- ☉ **Better Support For Multicasting:** Multicasting was an option under IPv4 from the start, but support for it has been slow in coming.
- ☉ **Better Support For Security:** IPv4 was designed at a time when security wasn't much of an issue, because there were a relatively small number of networks on the internet, and their administrators often knew each other. Today, security on the public Internet is a big issue, and the future success of the Internet requires that security concerns be resolved.
- ☉ **Better Support For Mobility:** When IPv4 was created, there really was no concept of mobile IP devices. The problems associated with computers that move between networks led to the need for [Mobile IP](#). IPv6 builds on Mobile IP and provides mobility support within IP itself.

### ***IPv6: The Evolution of IP***

At the same time that IPv6 was intended to address the issues above and many others with traditional IP, we should keep in mind that its changes are *evolutionary*, not *revolutionary*. During the many discussions in the IETF in the 1990s, there were some who said that while we were updating IP, perhaps we should make a complete, radical change to a new type of internetworking protocol completely. The end decision was not to do this, but to define a more capable version of the IP we've been using all along.

---

The reason for this is simple: IP, like our trusted older car, **works**. IPv6 represents an update that strives to add to the best characteristics of IPv4 rather than making everyone start over from scratch with something new and unproven. This design ensures that whatever pain may result from the change from IPv4 to IPv6 can be managed, and hopefully, minimized.

**Key Concept:** The new version of the Internet Protocol is *Internet Protocol Version 6* (IPv6). It was created to correct some of the significant problems of IPv4, especially the looming exhaustion of the IPv4 address space, and to improve the operation of the protocol as a whole, to take TCP/IP in to the future.

---

## **Major Changes And Additions In IPv6**

In the [preceding overview](#), I explained that the primary motivator for creating a new version of IP was to fix the problems with addressing under IPv4. But as we also saw there, numerous other design goals existed for the new protocol as well. Once the decision was made to take the significant step of creating a new version of a protocol as important as IP, it made sense to use the opportunity to make as many improvements as possible.

Of course, there is still the problem of the pain of change to worry about, so each potential change or addition in IPv6 had to have benefits that would outweigh its costs. The resulting design does a good job of providing useful advantages while maintaining most of the core of the original Internet Protocol. The following list provides a summary of the most important changes between IPv4 and IPv6, showing some of the ways that the IPv6 team met the design goals for the new protocol:

- 🕒 **Larger Address Space:** [IPv6 addresses are 128 bits](#) long instead of 32 bits. This expands the address space from around 4 billion addresses to, well, an astronomic number (over 300 trillion trillion trillion addresses).
- 🕒 **Hierarchical Address Space:** One reason why the IPv6 address size was expanded so much was to allow it to be [hierarchically divided](#) to provide a large number of each of many classes of addresses.
- 🕒 **Hierarchical Assignment of Unicast Addresses:** A special [global unicast address format](#) was created to allow addresses to be easily allocated across the entire Internet. It allows for multiple levels of network and subnetwork hierarchies both at the ISP and organizational level. It also permits [generating IP addresses based on underlying hardware interface device IDs](#) such as Ethernet MAC addresses.
- 🕒 **Better Support for Non-Unicast Addressing:** [Support for multicasting is improved](#), and support is added for a new type of addressing: *anycast* addressing. This new kind of addressing basically says “deliver this message to the easiest-to-reach member of this group”, and potentially enables new types of messaging functionality.
- 🕒 **Autoconfiguration and Renumbering:** A provision is included to allow easier [autoconfiguration of hosts and renumbering of the IP addresses in networks and subnetworks](#) as needed. A technique also exists for renumbering router addresses.

- 
- ☛ **New Datagram Format:** The IP datagram format has been redefined and given new capabilities. The main header of each IP datagram has been streamlined, and support added for easily [extending the header](#) for datagrams requiring more control information.
  - ☛ **Support for Quality of Service:** IPv6 datagrams include QoS features, allowing better support for multimedia and other applications requiring quality of service.
  - ☛ **Security Support:** Security support is designed into IPv6 using the [authentication and encryption extension headers](#) and other features.
  - ☛ **Updated Fragmentation and Reassembly Procedures:** The way that [fragmentation and reassembly of datagrams](#) works has been changed in IPv6, to improve efficiency of routing and better reflect the realities of today's networks.
  - ☛ **Modernized Routing Support:** The IPv6 protocol is designed to support modern [routing systems](#), and to allow expansion as the Internet grows.
  - ☛ **Transition Capabilities:** Since it was recognized from the start that going from IPv4 to IPv6 is a big move, support for the IPv4/IPv6 transition has been provided in numerous areas. This includes [a plan for interoperating IPv4 and IPv6 networks](#), [mapping between IPv4 and IPv6 addresses](#) and more.

The rest of the sections on IPv6 provide much more detail on these changes and additions to IP. You'll notice that the majority of these are related to addressing, since that is where the greatest number of important changes have been made in IPv6. Of course, routing and addressing are closely related, and the changes to addressing has had a big impact on routing as well.

Another change that I should mention is that with the introduction of IPv6, several other TCP/IP protocols that deal intimately with IP have also had to be updated. One of these is [ICMP](#), the most important support protocol for IPv4, which has been revised through the creation of ICMPv6 for IPv6. An addition to TCP/IP is the [Neighbor Discovery \(ND\) protocol](#), which performs several functions for IPv6 that were done by [ARP](#) and ICMP in version 4.

## **Transition from IPv4 to IPv6**

The Internet Protocol is the foundation of the TCP/IP protocol suite and the Internet, and thus somewhat comparable to the foundation of a house in terms of its structural importance. Given this, changing IP is somewhat analogous to making a substantial modification to the foundation of your house. Since IP is used to connect together many devices, it is in fact, like changing not just your house, but every house in the world!

How do you change the foundation of a house? Very carefully. The same caution is required with the implementation of IPv6. While to most people IPv6 is something “new”, the reality is that the planning and development of IPv6 has been underway for nearly a full decade, and if we were starting from scratch the protocol would have been ready for action years ago. However, there is a truly enormous installed base of IPv4 hardware and software. This means the folks who develop TCP/IP could not just “flip a switch” and have everyone move over to using IPv6. Instead, a *transition* from IPv4 to IPv6 had to be planned.

---

## IPv4-IPv6 Transition: Differences of Opinion

The transition is already underway, though most people don't know about it. As I said, development of IPv6 itself is pretty much complete, though work continues on refining the protocol and also on development of IPv6-compatible versions of other protocols. The implementation of IPv6 began with the creation of development networks to test IPv6's operation. These were connected together to form an experimental IPv6 internetwork called the *6BONE* (which is a contraction of the phrase "IPv6 backbone".) This internetwork has been in operation for several years.

Experimental networks are well and good, but of course the big issue is transitioning the "real" Internet to IPv6—and here, opinion diverges rather quickly. In one camp are the corporations, organizations and individuals who are quite eager to transition to IPv6 quickly, to gain the many benefits it promises in the areas of addressing, routing and security. Others are taking a much more cautious approach, noting that the dire predictions in the mid-1990s of IPv4's imminent doom have not come to pass, and arguing that we should take our time to make sure IPv6 is going to work on a large scale.

These two groups will continue to play tug-of-war for the next few years, but it seems that the tide is now turning towards those who want to speed up the now-years-long transition. The move towards adoption of IPv6 as a *production* protocol is being spearheaded by a number of groups and organizations. IPv6 has a lot of support in areas outside the United States, many of which are running short of IPv4 addresses due to small allocations relative to their size. One such area is Asia, a region with billions of people, rapidly-growing Internet use and a shortage of IPv4 addresses.

Within the United States, which has the lion's share of IPv4 addresses (due to the Internet having been developed in the U.S.A.), there seems to be a bit less enthusiasm for rapid IPv6 deployment. Even here, however, IPv6 got a major "shot in the arm" in July 2003 when the United States Department of Defense (DoD) announced that starting in October of that year, it would only purchase networking products that included compatibility with IPv6. The DoD—which of course was [responsible for the development of the Internet in the first place](#)—hopes to be fully transitioned to IPv6 by 2008. This will likely have a big impact on the plans of other governmental and private organizations in the United States.

Of course, the creators of IPv6 knew from the start that transition was going to be an important issue with the new protocol. IPv6 is not compatible with IPv4 because the addressing system and datagram format are different. Yet the IPv6 designers knew that since the transition would take many years, it was necessary that they provide a way for IPv4 and IPv6 hosts to interoperate. Consider that in any transition there are always "stragglers". Like the old Windows 3.11 PC in the corner that you still need to use once in a while, even when most of the Internet is IPv6 there will still likely be some devices that are still on IPv4 because they were never upgraded.

**Key Concept:** Due to the many differences between IPv4 and IPv6, and the fundamental importance of the Internet Protocol to TCP/IP, an orderly *transition* has been planned from IPv4 to IPv6 over a period of many years.

---

### **IPv4-IPv6 Transition Methods**

Due to the time that change takes, IETF has been working on specific provisions to allow a smooth transition from version 4 to version 6, and hardware and software interoperability solutions to let newer IPv6 devices access IPv4 hosts. A technique was included in IPv6 to allow administrators to [embed IPv4 addresses within IPv6 addresses](#). Special methods are defined to handle interoperability, including:

- ☉ **“Dual Stack” Devices:** Routers and some other devices may be programmed with both IPv4 and IPv6 implementations to allow them to communicate with both types of hosts.
- ☉ **IPv4/IPv6 Translation:** “Dual stack” devices may be designed to accept requests from IPv6 hosts, convert them to IPv4 datagrams, send the datagrams to the IPv4 destination and then process the return datagrams similarly.
- ☉ **IPv4 Tunneling of IPv6:** IPv6 devices that don't have a path between them consisting entirely of IPv6-capable routers may be able to communicate by encapsulating IPv6 datagrams within IPv4. In essence, they would be using IPv6 on top of IPv4; two network layers. The encapsulated IPv4 datagrams would travel across conventional IPv4 routers.

Bear in mind that these solutions generally only address backward compatibility, to allow IPv6 devices to talk to IPv4 hardware. Forward compatibility between IPv4 and IPv6 is not possible because IPv4 hosts cannot communicate with IPv6 hosts—they lack the knowledge of how IPv6 works. It is possible that certain special adaptations might be created to allow IPv4 hosts to access IPv6 hosts. But eventually, all IPv4 devices of any importance will want to migrate to IPv6.

The IETF has done such a good job in the past with introducing new technologies, and so much effort has been put into the IPv6 transition, that I am quite confident that the transition to IPv6 will come off with few, if any, problems. One good thing about the transition is that IPv4 is, at the present time, still getting the job done, so there is no big hurry to make the move to version 6. While technologies such as CIDR and NAT are “band-aids” on IPv4, they have been very successful ones in extending the useful life of the aging protocol.

---

## IPv6 Addressing

The primary motivation for creating IPv6 was to rectify the [addressing problems in IPv4](#). More addresses were required, but more than this, the IPv6 designers desired a way of interpreting, assigning and using them that was more consonant with modern internet-working. Based on this, it's no surprise that many of the changes in IPv6 are associated with IP addressing. The IPv6 addressing scheme is similar in general concept to IPv4 addressing, but has been completely overhauled to create an addressing system capable of supporting continued Internet expansion and new applications for the foreseeable future.

This section describes the concepts and methods associated with addressing under IPv6. I begin with a look at some addressing generalities in version 6, including the addressing model, address types size and address space. I discuss the unique and sometimes confusing representations and notations used for IPv6 addresses and prefixes. Then I look at how addresses are arranged and allocated into types, beginning with an overall look at address space composition and then the global unicast address format. I describe the new methods used for mapping IP addresses to underlying physical network addresses. I then describe special IPv6 addressing issues, including reserved and private addresses, IPv4 address embedding, anycast and multicast addresses, and autoconfiguration and renumbering of addresses.

Addressing under IPv6 is outlined in the main IPv6 RFC, RFC 2460 ([\*Internet Protocol Version 6 \(IPv6\) Specification\*](#)). However, most of the details of IPv6 addressing are contained in two other standards: RFC 3513 ([\*Internet Protocol Version 6 \(IPv6\) Addressing Architecture\*](#)) and RFC 3587 ([\*IPv6 Global Unicast Address Format\*](#)). These replaced the 1998 standards RFC 2373 ([\*IP Version 6 Addressing Architecture\*](#)) and RFC 2374 ([\*An IPv6 Aggregatable Global Unicast Address Format\*](#)).

**Background Information:** As with the other IPv6 sections in this Guide, our look at addressing is based somewhat on a contrast to how addressing is done in IPv4. I strongly recommend a thorough understanding of [IPv4 addressing](#), including [classless addressing using CIDR](#), before proceeding here. As with the IPv4 addressing sections, familiarity with how binary numbers work, and conversion between binary and decimal numbers is also a good idea. [The background section on data representation and the mathematics of computing](#) may be of assistance in that respect.

---

### IPv6 Addressing Overview: Addressing Model and Address Types

In the [IPv6 overview section](#) I explained that IPv6 represents a significant update to the Internet Protocol, but that its modifications and additions are made without changing the core nature of how IP works. Addressing is the place where most of the differences between IPv4 and IPv6 are seen, but the changes are mostly in how addresses are implemented and used. The overall model used for IP addressing in IPv6 is pretty much the same as it was in IPv4; some aspects have not changed at all, while others have changed only slightly.

---

## Unchanged Aspects of Addressing in IPv6

Some of the general characteristics of the IPv6 addressing model that are basically the same as in IPv4:

- ☉ **Core Functions of Addressing:** The two main functions of addressing are still [network interface identification and routing](#). Routing is facilitated through the structure of addresses on the internetwork.
- ☉ **Network Layer Addressing:** IPv6 addresses are still the ones associated with the network layer in TCP/IP networks, and are distinct from data link layer (also sometimes called *physical*) addresses.
- ☉ **Number of IP Addresses Per Device:** [Addresses are still assigned to network interfaces](#), so a regular host like a PC will usually have one (unicast) address, and routers will have more than one, for each of the physical networks to which it connects.
- ☉ **Address Interpretation and Prefix Representation:** IPv6 addresses are like classless IPv4 addresses in that they are interpreted as having a network identifier part and a host identifier part, but that the delineation is not encoded into the address itself. A prefix length number, using [CIDR-like notation](#), is used to indicate the length of the network ID (prefix length).
- ☉ **Private and Public Addresses:** Both types of addresses exist in IPv6, though they are defined and used somewhat differently.

## IPv6 Address Types

One important change in the addressing model of IPv6 is the *address types* supported. IPv4 supported three address types: unicast, multicast and broadcast. Of these, the vast majority of actual traffic was unicast. [IP multicast](#) support was not widely deployed until many years after the Internet was established, and continues to be hampered by various issues. Use of broadcast in IP had to be severely restricted for performance reasons (we don't want any device to be able to broadcast across the entire Internet!)

IPv6 also supports three address types, but with some changes:

- ☉ **Unicast Addresses:** These are standard unicast addresses as in IPv4, one per host interface.
- ☉ **Multicast Addresses:** These are addresses that represent various groups of IP devices: a message sent to a multicast address goes to all devices in the group. IPv6 includes much better multicast features and many more multicast addresses than IPv4. Since multicast under IPv4 was hampered in large part due to lack of support of the feature by many hardware devices, support for multicasting is a required, not optional, part of IPv6.
- ☉ **Anycast Addresses:** Anycast addressing is used when a message must be sent to any member of a group, but does not need to be sent to them all. Usually the member of the group that is easiest to reach will be sent the message. One common example of how anycast addressing could be used is in load sharing amongst a group of routers in an organization.

**Key Concept:** IPv6 has unicast and multicast addresses like IPv4. There is, however, no distinct concept of a broadcast address in IPv6. A new type of address, the *anycast* address, has been added to allow a message to be sent to any one member of a group of devices.

---

### ***Implications of the Changes to Address Types in IPv6***

Broadcast addressing as a distinct addressing method is gone in IPv6. Broadcast functionality is implemented using multicast addressing to groups of devices. A multicast group to which all nodes belong can be used for broadcasting in a network, for example.

An important implication of the creation of anycast addressing is removal of the strict uniqueness requirement for IP addresses. Anycast is accomplished by assigning the same IP address to more than one device. The devices must also be specifically told that they are sharing an anycast address, but the addresses themselves are structurally the same as unicast addresses.

The bulk of the remainder of this section focuses on unicast addressing, since it is by far the most important type. [Multicast and anycast addressing are given special attention separately.](#)

### **IPv6 Address Size and Address Space**

Of all the changes introduced in IPv6, easily the most “celebrated” is the increase in the size of IP addresses, and as a result, the increase in the size of the address space as well. It's not surprising that these sizes were increased compared to IPv4—everyone has known for years that the IPv4 address space was too small to support the future of the Internet. What's remarkable is just how much the increase is, and what the implications are for how Internet addresses are used.

#### ***IPv6 Address Size***

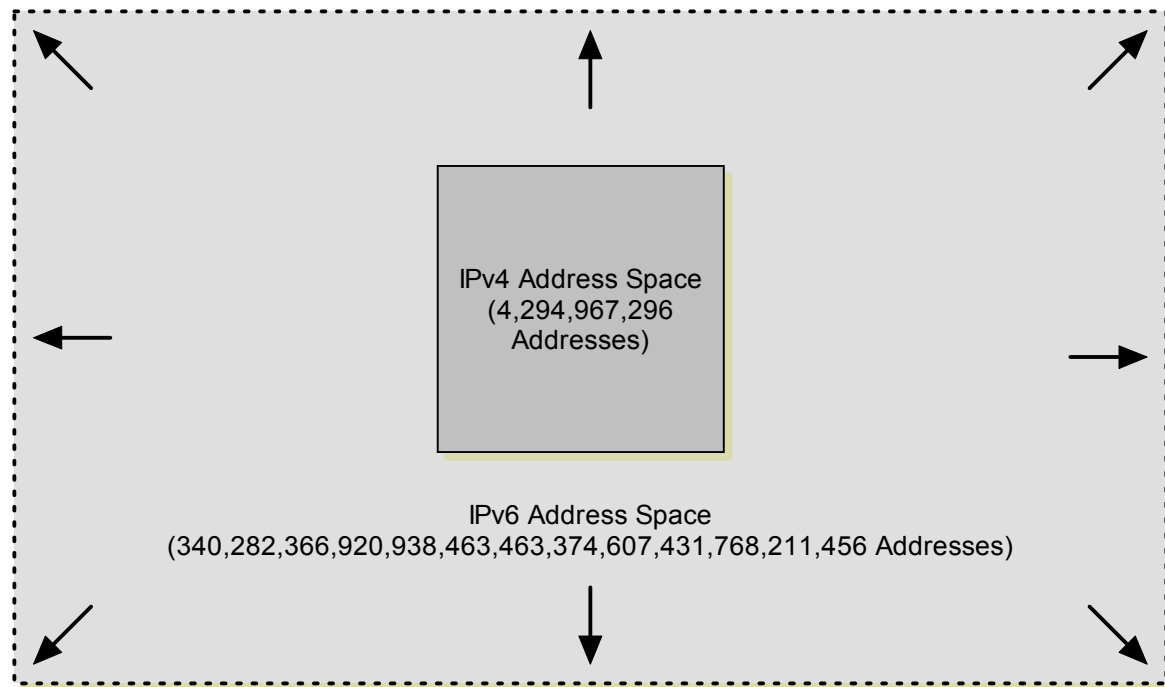

In IPv4, IP addresses are 32 bits long; these are usually grouped into four octets of eight bits each. The theoretical [IPv4 address space](#) is  $2^{32}$ , or 4,294,967,296 addresses. To increase this address space we simply increase the size of addresses; each extra bit we give to the address size doubles the address space. Based on this, some folks expected the IPv6 address size to increase from 32 to 48 bits, or perhaps 64 bits. Either of these numbers would have given a rather large number of addresses.

However, IPv6 addressing doesn't use either of these figures; instead, the IP address size jumps all the way to 128 bits, or sixteen 8-bit octets/bytes. This represents a truly remarkable increase in the address size, which surprised a lot of people.

---

## IPv6 Address Space

The 128 bits of IPv6 addresses mean the size of the IPv6 address space is, quite literally, astronomical; like the numbers that describe the number of stars in a galaxy or the distance to the furthest pulsars, the number of addresses that can be supported in IPv6 is mind-boggling. See [Figure 94](#) for an idea of what I mean by “astronomical”.

**Figure 94: A (Poor) Representation of Relative IPv4 and IPv6 Address Space Sizes**

I wanted to make a cool graphic to show the relative sizes of the IPv4 and IPv6 address spaces. You know, where I'd show the IPv6 address space as a big box and the IPv4 address space as a tiny one. The problem is that the IPv6 address space is **so** much larger than the IPv4 space that there is no way to show it to scale! To make this diagram to scale, imagine the IPv4 address space is the 1.6-inch square above. In that case, the IPv6 address space would be represented by a square **the size of the solar system**. ☺

Since IPv6 addresses are 128 bits long, the theoretical address space if all addresses were used is  $2^{128}$  addresses. This number, when expanded out, is 340,282,366,920,938,463,374,607,431,768,211,456, which is normally expressed in scientific notation as about  $3.4 \times 10^{38}$  addresses. That's about 340 trillion, *trillion*, **trillion** addresses. As I said, it's pretty hard to grasp just how large this number is. Consider:

- ☹ It's enough addresses for many trillions of addresses to be assigned to every human being on the planet.
- ☹ The earth is about 4.5 billion years old. If we had been assigning IPv6 addresses at a rate of 1 billion per second since the earth was formed, we would have by now used up less than one **trillionth** of the address space.

- 
- ☹ The earth's surface area is about 510 trillion square meters. If a typical computer has a footprint of about a tenth of a square meter, we would have to stack computers 10 billion high blanketing the entire surface of the earth to use up that same trillionth of the address space.

Okay, I think you get the idea. It's clear that one goal of the decision to go to 128-bit addresses is to make sure that we will never run out of address space again, and it seems quite likely that this will be the case.

**Key Concept:** The IPv6 address space is really, *really* big. 😊

---

### ***Why Were IPv6 Addresses Made So Large?***

However, there are drawbacks to having such a huge address space too. Consider that even with a 64-bit address, we'd have a very large address space:  $2^{64}$  is 18,446,744,073,709,551,616 or about 18 million trillion, still probably more addresses than we will ever need. However, by going instead to 128 bits we have made dealing with IP addresses unruly (as we'll see in the next topic) and we have also increased overhead, since every datagram header or other place where IP addresses are referenced must use 16 bytes for each address instead of the 4 that were needed in IPv4, or the 8 that might have been required with a 64-bit address.

So why the “overkill” of going to 128 bits? The main reason is **flexibility**. Even though we can have a couple zillion addresses if we allocate them one at a time, that makes assignment difficult. We got rid of class-oriented addressing in IPv4 due to the fact that it wasted address space, which is true. The reality, though, is that being able to “waste” address space is a useful luxury.

Having 128 bits allows us to divide the address space and assign various purposes to different bit ranges while still not having to worry about running out of space. [In the topic describing the IPv6 global unicast address format](#) we'll see one way that those 128 bits are put to good use; it allows us to create a hierarchy of networks while still saving 64 bits for host IDs, which has its own advantages.

### **IPv6 Address and Address Notation and Prefix Representation**

Increasing the size of IP addresses from 32 bits to 128 bits expands the address space to a gargantuan size, ensuring that we will never again run out of IP addresses, and allowing us flexibility in how they are assigned and used. Unfortunately, there are some drawbacks to this method, and one of them is that 128-bit numbers are very large, which makes them awkward and difficult to use.

---

## IPv6 Addresses: Too Long For Dotted Decimal Notation

Computers work in binary, and they have no problem dealing with long strings of ones and zeroes, but humans find them confusing. Even the 32-bit addresses of IPv4 are cumbersome for us to deal with, which is why we use [dotted decimal notation](#) for them unless we need to work in binary (as with subnetting). However, IPv6 addresses are so much larger than IPv4 addresses that even using dotted decimal notation becomes problematic. To use this notation, we would split the 128 bits into 16 octets and represent each with a decimal number from 0 to 255. However, we would end up not with 4 of these numbers, but **16**. A typical IPv6 address in this notation would appear as follows:

128.91.45.157.220.40.0.0.0.0.252.87.212.200.31.255

The binary and dotted decimal representations of this address are shown near the top of [Figure 95](#). In either case, the word “elegant” doesn’t exactly spring to mind.

Binary	1000000001011011001011011001110111011100001010000000000000000000 00000000000000000111110001010111101010011001000000111111111111															
Dotted Decimal	128	91	45	157	220	40	0	0	0	0	252	87	212	200	31	255
Hexadecimal	0	32			64			96			128					
Straight Hex	805B	2D9D	DC28	0000	0000	FC57	D4C8	1FFF								
Leading-Zero Suppressed	805B	2D9D	DC28	0	0	FC57	D4C8	1FFF								
Zero- Compressed	805B	2D9D	DC28	::		FC57	D4C8	1FFF								
Mixed Notation	805B	2D9D	DC28	::		FC57	212	200	31	255						

**Figure 95: Binary, Decimal and Hexadecimal Representations of IPv6 Addresses**

The top two rows show binary and dotted decimal representations of an IPv6 address; neither is commonly used (other than by computers themselves!) The top row of the lower table shows the full hexadecimal representation, while the next two rows illustrate zero suppression and compression. The last row shows mixed notation, where the final 32 bits of an IPv6 address are shown in dotted decimal notation. This is most commonly used for [embedded IPv4 addresses](#).

## IPv6 Address Hexadecimal Notation

To make addresses shorter, the decision was made in IPv6 to change the primary method of expressing addresses to use [hexadecimal](#) instead of decimal. The advantage of this is that it requires fewer characters to represent an address, and that [converting from hex to binary](#) and back again is much easier than converting from binary to decimal or vice-versa.

---

The disadvantage is that many people, even computer people, find hexadecimal difficult to comprehend and work with, especially because the notion of 16 values in each digit is a bit strange. (I'm not one of them, but then I'm a geek.)

The hexadecimal notation used for IPv6 addresses is similar to the same method used for IEEE 802 MAC addresses, for technologies like Ethernet. There, 48 bits are represented by six octets, each octet being a hexadecimal number from 0 to FF, separated by a dash or colon, like this:

0A-A7-94-07-CB-D0

Since IPv6 addresses are larger, they are instead grouped into eight 16-bit *words*, separated by colons, to create what is sometimes called *colon hexadecimal notation*, again shown in [Figure 95](#). So, the IPv6 address given in the example above would be expressed as:

805B:2D9D:DC28:0000:0000:FC57:D4C8:1FFF

To keep size down, leading zeroes can be suppressed in the notation, so we can immediately reduce this to:

805B:2D9D:DC28:0:0:FC57:D4C8:1FFF

Hmm. Well, it's definitely shorter than dotted decimal, but still not much fun to look at. When you are dealing with numbers this big, there's only so much you can do. This is part of why under IPv6, use of [DNS names for hosts](#) becomes much more important than it is in IPv4; who could remember a hex address that long?!

### **Zero Compression in IPv6 Addresses**

Fortunately, there is a short-cut that can be applied to shorten some addresses even further. This technique is sometimes called *zero compression*. The method allows a single string of contiguous zeroes in an IPv6 address to be replaced by a double-colon. So, for example, the address above could be expressed as:

805B:2D9D:DC28::FC57:D4C8:1FFF

We know how many zeroes are replaced by the "::" because we can see how many fully-expressed ("uncompressed") hex words are in the address. In this case there are six, so the "::" represents two zero words. To prevent ambiguity, the double-colon can appear only once in any IP address, because if it appeared more than once we could not tell how many zeroes were replaced in each instance. So, if our example address were 805B:2D9D:DC28:0:0:FC57:0:0, we could replace either the first pair of zeroes or the second, but not both.

Zero compression doesn't make our example much shorter, but due to how IPv6 addresses are structured, long strings of zeroes are common. For example, consider this address:

FF00:4501:0:0:0:0:0:32

---

With compression, this could be expressed as just:

FF00:4501::32

It works even better on special addresses. The full [IPv6 loopback address](#) is:

0:0:0:0:0:0:0:1

With compression, this is simply:

::1

For even more fun, consider the Even more odd, the [IPv6 “unspecified” address](#):

0:0:0:0:0:0:0:0

Apply zero compression to an address that is all zeroes, and what do you get? That’s right:

::

No numbers at all! Of course thinking of “::” as an address **does** take some getting used to.

**Key Concept:** For brevity, IPv6 addresses are represented using eight sets of four hexadecimal digits, a form called *colon hexadecimal notation*. Additional techniques, called *zero suppression* and *zero compression*, are used to reduce the size of displayed addresses further by removing unnecessary zeroes from the presentation of the address.

---

### ***IPv6 Mixed Notation***

There is also an alternative notation used in some cases, especially for expressing [IPv6 addresses that embed IPv4 addresses](#). For these, it is useful to show the IPv4 portion of the address in the older dotted decimal notation, since that’s what we use for IPv4. Since embedding uses the last 32 bits for the IPv4 address, the notation has the first 96 bits in colon hexadecimal notation, and the last 32 bits in dotted decimal. So to take our same example again from above, in *mixed notation* it would be shown as:

805B:2D9D:DC28::FC57:**212.200.31.255**

This isn’t really a great example of mixed notation, because embedding usually involves long strings of zeroes followed by the IPv4 address. Thus, zero compression comes in very handy here. Instead of seeing something like this:

0:0:0:0:0:0:212.200.31.255

---

You will typically see just:

::212.200.31.255

At first glance this appears to be an IPv4 address; you have to keep a close eye on those colons in IPv6!

**Key Concept:** A special mixed notation is defined for IPv6 addresses whose last 32 bits contain an embedded IPv4 address. In this notation, the first 96 bits are displayed in regular colon hexadecimal notation, and the last 32 bits in IPv4-style dotted decimal.

---

### ***IPv6 Address Prefix Length Representation***

Like IPv4 classless addresses, IPv6 addresses are fundamentally divided into a number of network ID bits followed by a number of host ID bits. The network identifier is called the *prefix*, and the number of bits used is the *prefix length*. This prefix is represented by following the address by a slash and then putting the prefix length after the slash. This is [the same method used for classless IPv4 addressing with CIDR](#). For example, if the first 48 bits of our example address were the network ID (prefix), then we would express this as 805B:2D9D:DC28::FC57:D4C8:1FFF/48.

**Key Concept:** In IPv6 the size of an address's prefix is indicating by the prefix length that follows the address, separated with a slash, just as this is done in IPv4 classless addressing.

---

As in IPv4, specifiers for whole networks will typically end in long strings of zeroes. These can be replaced by "::" using zero compression. For example, the 48 bit network ID for the example above is 805B:2D9D:DC28:0:0:0:0:0/48, or 805B:2D9D:DC28::/48. You **must** include the "::" if replacing the trailing zeroes.

### **IPv6 Address Space Allocation**

After dealing for so many years with the very small IPv4 address space, the enormous number of addresses in IPv6 must have made the IETF engineers feel like kids in a candy shop. They were good kids, however, and didn't run wild grabbing all the candy they could find and gobbling it up. They very carefully considered how to divide the address space for various uses. Of course, when you have this much candy, sharing becomes pretty easy.

---

## The Initial IPv6 Address Space Allocation Plan and the Format Prefix (FP)

As was the case with IPv4, the two primary concerns in deciding how to divide the IPv6 address space were address assignment and routing. The designers of IPv6 wanted to structure the address space to make allocation of addresses to ISPs, organizations and individuals as easy as possible.

At first, this perhaps ironically, this led the creators of IPv6 back full circle to the use of specific bit sequences to identify different types of addresses, just like the old “classful” addressing scheme. The address type was indicated by a set of bits at the start of the address, called the *format prefix (FP)*. The format prefix was conceptually identical to [the 1 to 4 bits used in IPv4 “classful” addressing to denote address classes](#), but was variable in length, ranging from three to ten bits. Format prefixes were described in RFC 2373.

In the years following the publication of RFC 2373, the gurus who run the Internet had a change of heart regarding how address blocks should be considered. They still wanted to divide up the IPv6 address space into variably-sized blocks for different purposes. However, they realize that many people (including myself) were starting to consider the use of format prefixes to be equivalent to the old class-oriented IPv4 system.

Their main concern was that implementors might program into IPv6 hardware logic to make routing decisions based only on the first few bits of the address. This was specifically **not** how IPv6 is supposed to work; for one thing, the allocations are subject to change. Thus, one of the modifications made in RFC 3513 was to change the language regarding IPv6 address allocations, and specifically, to remove the term “format prefix” from the standard.

### Current IPv6 Address Space Allocation Plans

The allocation of different parts of the address space still is done based on particular patterns of the first three to ten bits of the address, to allow certain categories to have more addresses than others. The elimination of the specific term denoting this is intended to convey that these bits should not be given “special attention”.

[Table 61](#) shows the allocations of the IPv6 address space, and what fraction of the total address space each represents:

**Table 61: IPv6 Address Space Allocations (Page 1 of 2)**

Leading Bits	Fraction of Total IPv6 Address Space	Allocation
0000 0000	1/256	Unassigned (Includes <a href="#">special addresses</a> such as the Unspecified and Loopback addresses)
0000 0001	1/256	Unassigned
0000 001	1/128	Reserved for NSAP Address Allocation
0000 01	1/64	Unassigned

**Table 61: IPv6 Address Space Allocations (Page 2 of 2)**

Leading Bits	Fraction of Total IPv6 Address Space	Allocation
0000 1	1/32	Unassigned
0001	1/16	Unassigned
001	1/8	Global Unicast Addresses
010	1/8	Unassigned
011	1/8	Unassigned
100	1/8	Unassigned
101	1/8	Unassigned
110	1/8	Unassigned
1110	1/16	Unassigned
1111 0	1/32	Unassigned
1111 10	1/64	Unassigned
1111 110	1/128	Unassigned
1111 1110 0	1/512	Unassigned
1111 1110 10	1/1024	Link-Local Unicast Addresses
1111 1110 11	1/1024	Site-Local Unicast Addresses
1111 1111	1/256	Multicast Addresses

This is more complicated than the IPv4 “classful” scheme because there are so many more categories and they range greatly in size, however, most of them are unassigned at the present time.

### ***Looking at the IPv6 Address Space Plan As “Eight Eighths”***

An easier way to make sense of this table is to consider the division of the IPv6 address space into ***eighths***. Of these eight groups, one (001) has been reserved for unicast addresses; a second (000) has been used to carve out smaller reserved blocks, and a third (111) has been used for sub-blocks for local and multicast addresses. Five are completely unassigned.

You can see that the IPv6 designers have taken great care to allocate only the portion of these “eighths” of the address space they felt was needed for each type of address. For example, only a small portion of the part of the address space beginning “111” was used, with most of it left aside. In total, only 71/512ths of the address space is assigned right now, or about 14%. The other 86% is unassigned and kept aside for future use. (Bear in mind that even 1/1024th of the IPv6 address space is gargantuan—it represents trillions of trillions of addresses.)

---

Subsequent topics in this section provide more information on several of these address blocks. Note that the “0000 0000” reserved block is used for several special address types, including [the loopback address](#), [the “unspecified” address](#) and [IPv4 address embedding](#). The “1111 1111” format prefix identifies [multicast addresses](#); this string is “FF” in hexadecimal, so any address beginning with “FF” is a multicast address in IPv6.

## **IPv6 Global Unicast Address Format**

It is anticipated that unicast addressing will be used for the vast majority of Internet traffic under IPv6, just as is the case for older one, IPv4. It is for this reason that the largest of the [assigned blocks of the IPv6 address space](#) is dedicated to unicast addressing. A full 1/8th slice of the enormous IPv6 address “pie” is assigned to unicast addresses, which are indicated by a “001” in the first three bits of the address. The question then is: how do we use the remaining 125 bits in our spacious IP addresses?

### ***Rationale for A Structured Unicast Address Block***

When IPv4 was first created, the Internet was rather small, and the model for allocating address blocks was based on a [central coordinator: IANA](#). Everyone who wanted address blocks would go straight the central authority. As the Internet grew, this model became impractical. Today, IPv4's classless addressing scheme allows variable-length network IDs and hierarchical assignment of address blocks. Big ISPs get large blocks from the central authority and then subdivide them and allocate them to their customers, and so on. This is managed by today's Internet providers, but there is nothing in the address space that helps manage the allocation process. In turn, each organization has the ability to further subdivide their address allocation to suit their internal requirements.

The designers of IPv6 had the benefit of this experience and realized there would be tremendous advantages to designing the unicast address structure to reflect the overall topology of the Internet. These include:

- ☉ Easier allocation of address blocks at various levels of the Internet topological hierarchy.
- ☉ IP network addresses that automatically reflect the hierarchy by which routers move information across the Internet, allowing routes to be easily aggregated for more efficient routing.
- ☉ Flexibility for organizations like ISPs to subdivide their address blocks for customers.
- ☉ Flexibility for end-user organizations to subdivide their address blocks to match internal networks, much as subnetting did in IPv4.
- ☉ Greater “meaning” to IP addresses. Instead of just being a string of 128 bits with no structure, it would become possible to look at an address and know certain things about it.

## Generic Division of the Unicast Address Space

The most generic way of dividing up the 128 bits of the unicast address space is into three sections, as shown in [Table 62](#).

**Table 62: Generic IPv6 Global Unicast Address Format**

Field Name	Size (bits)	Description
<b>Prefix</b>	"n"	<b>Global Routing Prefix:</b> The network ID or prefix of the address, used for routing.
<b>Subnet ID</b>	"m"	<b>Subnet Identifier:</b> A number that identifies a subnet within the site.
<b>Interface ID</b>	"128-n-m"	<b>Interface ID:</b> The unique identifier for a particular interface (host or other device). It is unique within the specific prefix and subnet.

The *global routing prefix* and *subnet identifier* represent the two basic levels at which addresses need to be hierarchically-constructed: global and site-specific. The routing prefix consists of a number of bits that can be further subdivided according to the needs of Internet Registries and Internet Service Providers, to reflect the topography of the Internet as a whole (we'll discuss this soon). The subnet ID gives a number of bits to site administrators for creating their own internal network structure.

## IPv6 Implementation of the Unicast Address Space

In theory, any size for "n" and "m" could be used. The implementation chosen for IPv6, however, assigns 48 bits to the routing prefix and 16 bits to the subnet identifier. This means 64 bits are available for interface identifiers, which are constructed based on the IEEE "EUI-64" format, [as described in the next topic](#). Thus, the overall IPv6 unicast address format is constructed as shown in [Table 63](#) (illustrated in [Figure 96](#).)

**Table 63: IPv6 Global Unicast Address Format**

Field Name	Size (bits)	Description
<b>Prefix</b>	48	<b>Global Routing Prefix:</b> The network ID or prefix of the address, used for routing. The first three bits are "001" to indicate a unicast address.
<b>Subnet ID</b>	16	<b>Subnet Identifier:</b> A number that identifies a subnet within the site.
<b>Interface ID</b>	64	<b>Interface ID:</b> The unique identifier for a particular interface (host or other device). It is unique within the specific prefix and subnet.

**Figure 96: IPv6 Global Unicast Address Format**

**Key Concept:** The part of the IPv6 address space set aside for unicast addresses is structured into an address format that uses the first 48 bits for the *routing prefix* (like a network ID), the next 16 bits for a *subnet ID*, and the final 64 bits for an *interface ID* (like a host ID).

---

Due to this structure, most end sites (regular companies and organizations, as opposed to Internet service providers) will be assigned IPv6 networks with a 48-bit prefix. In common parlance, these network identifiers have now come to be called *48s* or */48s*.

The 16 bits of subnet ID allow each site considerable flexibility in creating subnets that reflect the site's network structure. For example:

- ☉ A smaller organization can just set all the bits in the Subnet ID to zero and have a “flat” internal structure.
- ☉ A medium-sized organization could use all the bits in the Subnet ID to perform the equivalent of “straight” subnetting under IPv4, assigning a different Subnet ID to each subnet. There are 16 bits here, so this allows a whopping 65,536 subnets!
- ☉ A larger organization can use the bits to create a multiple-level hierarchy of subnets, exactly like IPv4's [Variable Length Subnet Masking \(VLSM\)](#). For example, the company could use two bits to create four subnets. It could then take the next three bits to create eight sub-subnets in some or all of the four subnets. There would still be 11 more bits to create sub-sub-subnets and so forth.

### ***Original Division of the Global Routing Prefix: Aggregators***

The global routing prefix is similarly divided into a hierarchy, but one that has been designed for the use of the entire Internet, a la [CIDR](#). There are 45 bits available here (48 bits less the first three that are fixed at “001”), which is a lot. When the unicast address structure was first detailed in RFC 2374, that document described a specific division of the 45 bits based on a two-level hierarchical topology of Internet registries and providers. These organizations were described as:

1. **Top-Level Aggregators (TLAs):** The largest Internet organizations, which were to be assigned large blocks of IPv6 addresses from registration authorities.
2. **Next-Level Aggregators (NLAs):** These organizations would get blocks of addresses from TLAs and divide them for end-user organizations (sites).

---

The 45 bits were split between these two uses, with a few bits reserved in the middle to allow expansion of either field if needed. Thus, the RFC 2374 structure for the 45 bits was as shown in [Table 64](#):

**Table 64: Historical IPv6 Unicast Routing Prefix Structure**

Field Name	Size (bits)	Description
<i>TLA ID</i>	13	<b>Top-Level Aggregation Identifier:</b> A globally-unique identifier for the Top-Level Aggregator. There are 13 bits so there were a maximum of 8,192 TLAs allowed.
<i>RES</i>	8	<b>Reserved:</b> These 8 bits were reserved for future use and set to zero. By leaving these 8 bits between the TLA ID and NLA ID unused, they could be later used to expand either the TLA ID or NLA ID fields as needed.
<i>NLA ID</i>	24	<b>Next-Level Aggregation Identifier:</b> Each TLA was given this 24-bit field to generate blocks of addresses for allocation to its customers. The NLA ID is unique for each TLA ID. The use of the 24 bits was left up to the TLA organization.

You'll notice my use of the past tense in the description of the TLA/NLA structure, and that table heading is a pretty big giveaway too. In August 2003, RFC 3587 was published, which in a nutshell says “uh, never mind about all that TLA/NLA stuff”. ☺ The decision was made that having this structure “hard-coded” into an Internet standard was inflexible, and it made more sense to allow the [regional Internet registries \(APNIC, ARIN, LACNIC and RIPE\)](#) decide for themselves how to use the 45 bits.

**Note:** The obsoleting of the “TLA/NLA” structure occurred after many years of people getting used to it, so for some time to come you will still routinely see mention of those terms in IPv6 descriptions. (This is why I included discussion of them here.)

---

---

## An Example Division of the Global Routing Prefix Into Levels

So, there is no longer any single structure for determining how the 48-bit routing prefix is divided in the global unicast hierarchy. As one example, it might be possible to divide it into three levels, as shown in [Table 65](#), and diagrammed in [Figure 97](#).

**Table 65: Example IPv6 Unicast Routing Prefix Structure**

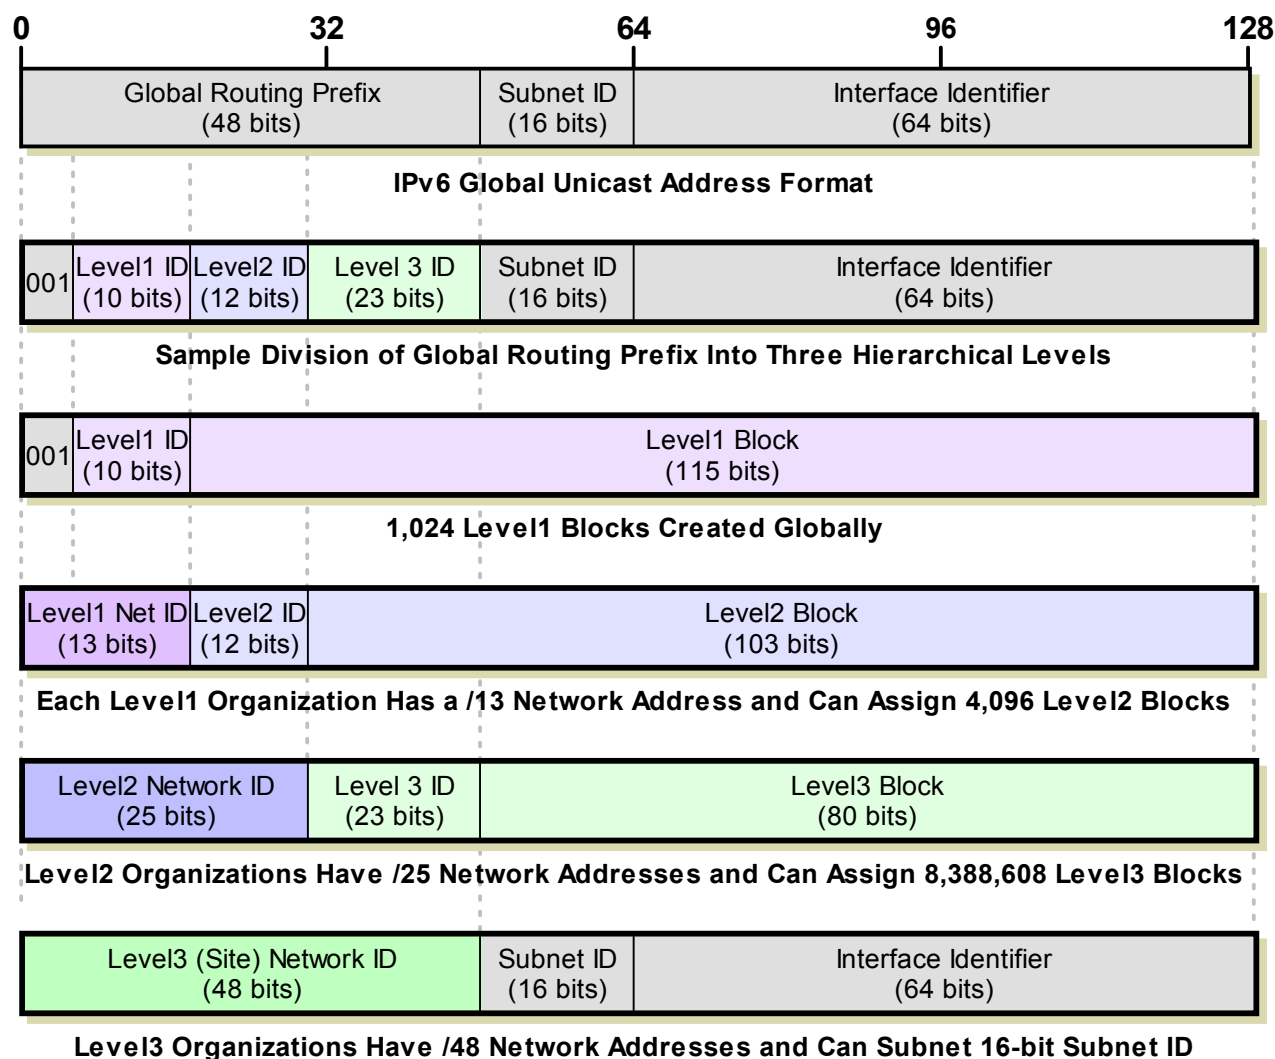

Field Name	Size (bits)	Description
<i>(Unicast Indicator)</i>	3	Each unicast address starts with “001”; there is no official name for this (it used to be called the <i>Format Prefix</i> ).
<i>Level1 ID</i>	10	<b>Level 1 Identifier:</b> The identifier of the highest level in the hierarchy. This would be used for assigning to the biggest Internet organizations the largest blocks of addresses in the global hierarchy. The number of Level 1 organizations would be $2^{10}$ or 1,024.
<i>Level2 ID</i>	12	<b>Level 2 Identifier:</b> Each block assigned to a Level 1 organization would use 12 bits to create 4,096 address blocks to divide amongst the lower-level organizations it serves.
<i>Level3 ID</i>	23	<b>Level 3 Identifier:</b> Each Level 2 organization has 23 bits to use to divide its Level 2 address block. Thus, it could create over 8 million individual “/48” address blocks to assign to end user sites. Alternately, the 23 bits could be divided further into still lower levels to reflect the structure of the Level 2 organization's customers.

This is just one possible, theoretical way that the bits in a “/48” network address could be assigned. As you can see, with so many bits there is a lot of flexibility. In the scheme above we can have over 4 million level 2 organizations, **each of which** can assign 8 million /48 addresses. And each of those is equivalent in size to an IPv4 Class B address (over 65,000 hosts)!

### Additional Notes on the Global Unicast Format

The removal of RFC 2374's “fixed structure” for the global routing prefix is consistent with the IPv6 development team's efforts to emphasize that bit fields and structures are used **only** for allocating addresses, not for routing purposes. The addresses themselves, once created, are not interpreted by hardware on an internet based on this format. To routers, the only structure is the division between the network ID and host ID is given by the prefix length that trails the IP address, and this division can occur at any bit boundary. These hardware devices just see 128 bits of an IP address and use it without any knowledge of hierarchical address divisions or “levels”.

It's also worth noting that the key to obtaining the allocation benefits of the aggregatable unicast address format is the abundance of bits available to us under IPv6. The ability to have these hierarchical levels while still allowing 64 bits for the interface ID is [one of the main reasons why IPv6 designers went all the way from 32 bits to 128 bits for address size](#). By creating this structure, we maintain flexibility while avoiding the potential chaos of trying to allocate many different network sizes within our 128 bits.

**Figure 97: Example IPv6 Unicast Routing Prefix Structure**

The top row shows the global IPv6 unicast address format. The second shows one example way to divide the Global Routing Prefix, into three levels using 10, 12 and 23 bits respectively. The third row shows how the first 10 bits are used to create  $2^{10}$  or 1,024 different Level1 blocks. The next row illustrates that for each of these 13-bit prefixes, we could have  $2^{12}$  or 4,096 Level2 blocks. Then, within each 25-bit Level2 ID, we have 23 bits or 8,388,608 Level3 blocks. At the bottom, a Level3 or "/48" would be assigned to an individual organization.

Finally, note that [anycast addresses](#) are structured in the same way as unicast addresses, so they are allocated according to this same model. In contrast, multicast addresses are not; they are allocated from their own portion of the IPv6 address space.

---

## **IPv6 Interface Identifiers and Physical Address Mapping**

In IPv4, IP addresses have no relationship to the addresses used for underlying data link layer network technologies. A host that connects to a TCP/IP network using an Ethernet network interface card (NIC) has an Ethernet MAC address and an IP address, but the two numbers are distinct and unrelated in any way. IP addresses are assigned manually by administrators without any regard for the underlying physical address.

### ***The Payoff of IPv6's Very Large Address Size***

With the overhaul of addressing in IPv6, an opportunity presented itself to create a better way of mapping IP unicast addresses and physical network addresses. Implementing this superior mapping technique was one of the reasons why IPv6 addresses were made so large. With 128 total bits, as we saw in [the previous topic](#), even with a full 45 bits reserved for network prefix and 16 bits for site subnet, we are still left with 64 bits to use for the *interface identifier*, which is analogous to the host ID under IPv4.

Having so many bits at our disposal gives us great flexibility. Instead of using arbitrary “made-up” identifiers for hosts, we can base the interface ID on the underlying data link layer hardware address, as long as that address is no greater than 64 bits in length. Since virtually all devices use layer two addresses of 64 bits or fewer, there is no problem in using those addresses for the interface identifier in IP addresses. This provides an immediate benefit: it makes networks easier to administer, since we don't have to record two arbitrary numbers for each host. The IP address can be derived from the MAC address and the network identifier. It also means we can in the future tell the IP address from the MAC address and vice-versa.

### ***The IPv6 Modified EUI-64 Format***

The actual mapping from data link layer addresses to IP interface identifiers depends on the particular technology. It is essential that all devices on the same network use the same mapping technique, of course. By far the most common type of layer 2 addresses in networking are IEEE 802 MAC addresses, used by Ethernet and other IEEE 802 Project-networking technologies. As you may already know, these addresses have 48 bits, arranged into two blocks of 24. The upper 24 bits are arranged into a block called the *organizationally unique identifier (OUI)*, with different values assigned to individual organizations; the lower 24 bits are then used for an identifier for each specific device.

The IEEE has also defined a format called the *64-bit extended unique identifier*, abbreviated *EUI-64*. It is similar to the 48-bit MAC format, except that while the OUI remains at 24 bits, the device identifier becomes 40 bits instead of 24. This provides gives each manufacturer 65,536 times as many device addresses within its OUI.

A form of this format, called *modified EUI-64*, has been adopted for IPv6 interface identifiers. To get the modified EUI-64 interface ID for a device, you simply take the EUI-64 address and change the 7th bit from the left (the “universal/local” or “U/L” bit) from a zero to a one.

---

## Converting 48-Bit MAC Addresses to IPv6 Modified EUI-64 Identifiers

Of course, most devices still use the older 48-bit MAC address format. These can be converted to EUI-64 and then to modified EUI-64 form for creating an IPv6 interface ID. The process is as follows:

1. We take the 24-bit OUI portion, the left-most 24 bits of the Ethernet address, and put them into the left-most 24 bits of the interface ID. We take the 24-bit local portion (the right-most 24 bits of the Ethernet address) and put it into the right-most 24 bits of the interface ID.
2. In the remaining 16 bits in the middle of the interface ID we put the value “11111111 11111110” (“FFFE” in hexadecimal).
3. The address is now in EUI-64 form. We change the “universal/local” bit (bit 7 from the left) from a zero to a one. This gives us the modified EUI-64 interface ID.

**Key Concept:** The last 64 bits of IPv6 unicast addresses are used for interface identifiers, which are created in a special format called *modified EUI-64*. A simple process can be used to determine the interface identifier from the 48-bit MAC address of a device like an Ethernet network interface card. This can then be combined with a network prefix (routing prefix and subnet ID) to determine a corresponding IPv6 address for the device.

---

Let's take as an example the Ethernet address of 39-A7-94-07-CB-D0 (illustrated in [Figure 98](#)):

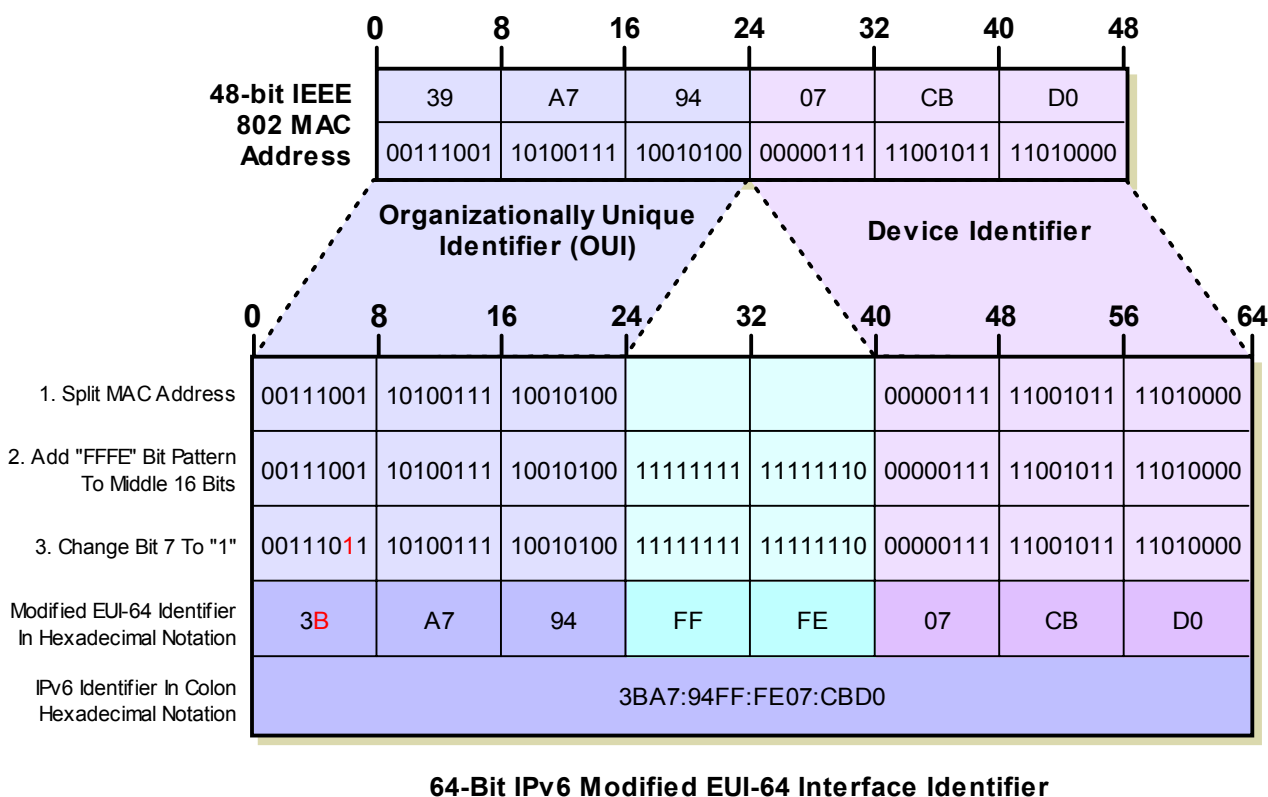

1. We take “39-A7-94”, the first 24 bits of the identifier, and put it into the first (leftmost) 24 bits of the address. The local portion of “07-CB-D0” becomes the last 24 bits of the identifier.
2. The middle 16 bits are given the value “FF-FE”.
3. We change the seventh bit from zero to one, which changes the first octet from “39” to “3B”.

The identifier thus becomes “3B-A7-94-FF-FE-07-CB-D0”, or in IPv6 colon hexadecimal notation, 3BA7:94FF:FE07:CBD0. The first 64 bits of the device's address are supplied using [the global unicast address format](#).

The only drawback of this technique is that if the physical hardware changes, so does the IPv6 address.

## IPv6 Special Addresses: Reserved, Private (Link-Local / Site-Local), Unspecified and Loopback

Just as [certain IPv4 address ranges are designated for reserved, private and other “unusual” addresses](#), a small part of the monstrous IPv6 address space has been set aside for special addresses. The purpose of these addresses and address blocks is to provide addresses for special requirements and private use in IPv6 networks. The nice thing about

**Figure 98: Converting IEEE 802 MAC Addresses To IPv6 Modified EUI-64 Identifiers**

IPv6, of course, is that even relatively small pieces of it are still enormous, so setting aside 0.1% of the address space for a particular use still generally yields more addresses than anyone will ever need.

### Special IPv6 Address Types

There are four basic types of "special" IPv6 addresses: reserved, private, loopback and unspecified.

#### Reserved Addresses

A portion of the address space is set aside as reserved for various uses by the IETF, both present and future. Unlike IPv4, which has many small reserved blocks in various locations in the address space, in IPv6 the reserved block is at the "top" of the address space: the ones starting with "0000 0000" (or 00 for the first hexadecimal octet). This represents 1/256th of the total address space. Some of the special addresses below come from this block. [IPv4 address embedding](#) is also done within this reserved address area.

**Note:** Note that reserved addresses are not the same as *unassigned* addresses. The latter term just refers to blocks whose use has not yet been determined.

---

### Private/Unregistered/Nonrouteable Addresses

A block of addresses is set aside for private addresses, just as in IPv4, except that like everything in IPv6 the private address block in IPv6 is much larger. These private addresses are local only to a particular link or site and are therefore never routed outside a particular company's network.

Private addresses are indicated by the address having "1111 1110 1" for the first nine bits. Thus, private addresses have a first octet value of "FE" in hexadecimal, with the next hex digit being from "8" to "F". These addresses are further divided into two types based on their scope, described below.

### Loopback Address

Like IPv4, provision has been made for a special [loopback address for testing](#); datagrams sent to this address "loop back" to the sending device. However, in IPv6 there is just one address for this function, not a whole block (which was never needed in the first place, really!) The loopback address is 0:0:0:0:0:0:0:1, which is normally expressed using zero compression as "::1".

### Unspecified Address

In IPv4, an IP address of all zeroes has a [special meaning](#); it refers to the host itself, and is used when a device doesn't know its own address. In IPv6 this concept has been formalized, and the all-zeroes address (0:0:0:0:0:0:0:0) is named the *unspecified address*. It is typically used in the source field of a datagram sent by a device seeking to have its IP address configured. Zero compression can be applied to this address; since it is all zeroes, the address becomes just "::". (I consider this confusing, myself. I think something like "0::0" is a lot more clear, and short enough.)

**Key Concept:** In IPv6, a special *loopback address*, 0:0:0:0:0:0:0:1 ("::1" in compressed form) is set aside for testing purposes. The *unspecified address*, 0:0:0:0:0:0:0:0 ("::" in compressed form) is used to indicate an unknown address. A block of *private* or *local* addresses is defined, which is the set of all addresses beginning with "1111 1110 1" as the first nine bits.

---

---

## IPv6 Private Addresses Types/Scopes

Now, let's take a bit more of a look at private addresses. In IPv6, these are called *local-use* addresses, the name conveying clearly what they are for. They are also sometimes called *link-layer* addresses. Recall that IPv4 private addresses were commonly used when public addresses could not be obtained for all devices, sometimes in combination with technologies like [Network Address Translation \(NAT\)](#). In IPv6, trickery like NAT isn't required. Instead, local-use addresses are intended for communication that is inherently designed only to be sent to local devices. For example, neighbor discovery functions using the [IPv6 Neighbor Discovery \(ND\)](#) protocol employ local-use addresses.

The *scope* of local addresses is obviously a local network, and not the global scope of public Internet addresses. Local addresses in IPv6 are divided further into two types, reflecting a further division of local scope.

### Site-Local Addresses

These addresses have the scope of an entire site, or organization. They allow addressing within an organization without need for using a public prefix. Routers will forward datagrams using site-local addresses within the site, but not outside it to the public Internet.

Site-local addresses are differentiated from link-local addresses by having a tenth bit of “1” following the nine starting address bits common to all private IPv6 addresses. Thus, they begin with “1111 1110 1”. In hexadecimal, site-local addresses begin with “FE” and then “C” to “F” for the third hex digit. So, these addresses start with “FEC”, “FED”, “FEE” or “FEF”.

### Link-Local Addresses

These addresses have a smaller scope than site-local addresses; they refer only to a particular physical link (physical network). Routers will not forward datagrams using link-local addresses at all, not even within the organization; they are only for local communication on a particular physical network segment. They can be used for [address configuration](#) or for the ND functions such as [address resolution](#) and [neighbor discovery](#).

Link-local addresses are differentiated from site-local addresses by having a tenth bit of “0” following the nine initial address bits common to all private IPv6 addresses: “1111 1110 1”. Thus, site-local addresses begin with “FE” and then “8” to “B” for the third hex digit. So, these addresses start with “FE8”, “FE9”, “FEA” or “FEB”.

**Key Concept:** IPv6 site-local addresses allow data to be sent only to the devices within a site or organization. They begin with “FEC”, “FED”, “FEE” or “FEF” in hexadecimal. IPv6 link-local addresses are used only on a particular local link (physical network), typically for special purposes such as address resolution or neighbor discover. They start with “FE8”, “FE9”, “FEA” or “FEB”.

---

---

Note that site-local IPv6 addresses are the equivalent of IPv4 private addresses, since they are routed throughout the organization. The concept of link-local scope is new to IPv6.

## **IPv6/IPv4 Address Embedding**

Due to the importance of the Internet Protocol and the significance of the changes made in IPv6, deployment of the newer version of the protocol will not occur all at once. A *transition* from IPv4 to IPv6 will be required, which requires careful planning. It is anticipated that the migration from IPv4 to IPv6 will take many years. [I discuss this in a special topic dedicated to IPv4/IPv6 transition issues.](#)

IPv6 is backward compatible with IPv4, provided that special techniques are used. For example, to enable communication between "islands" of IPv6 devices connected by IPv4 networks, tunneling may be employed. To support IPv4/IPv6 compatibility, a scheme was developed to allow IPv4 addresses to be *embedded* within the IPv6 address structure. This method takes regular IPv4 addresses and puts them in a special IPv6 format so they are recognized as being IPv4 addresses by certain IPv6 devices.

Since the IPv6 address space is so much bigger than that of IPv4, embedding the latter within the former is easy; it's like tucking a compact sedan into the hold of a cargo ship. The embedding address space is part of the [reserved address block](#) whose addresses begin with eight zero bits, but only a relatively small part of it. Two different embedding formats are used. Both have zeroes for the first 80 bits of the address, and put the embedded IPv4 address into the last 32 bits of the IPv6 address format. They differ on the value of the 16 remaining bits in between (bits 81 to 96, counting from the left):

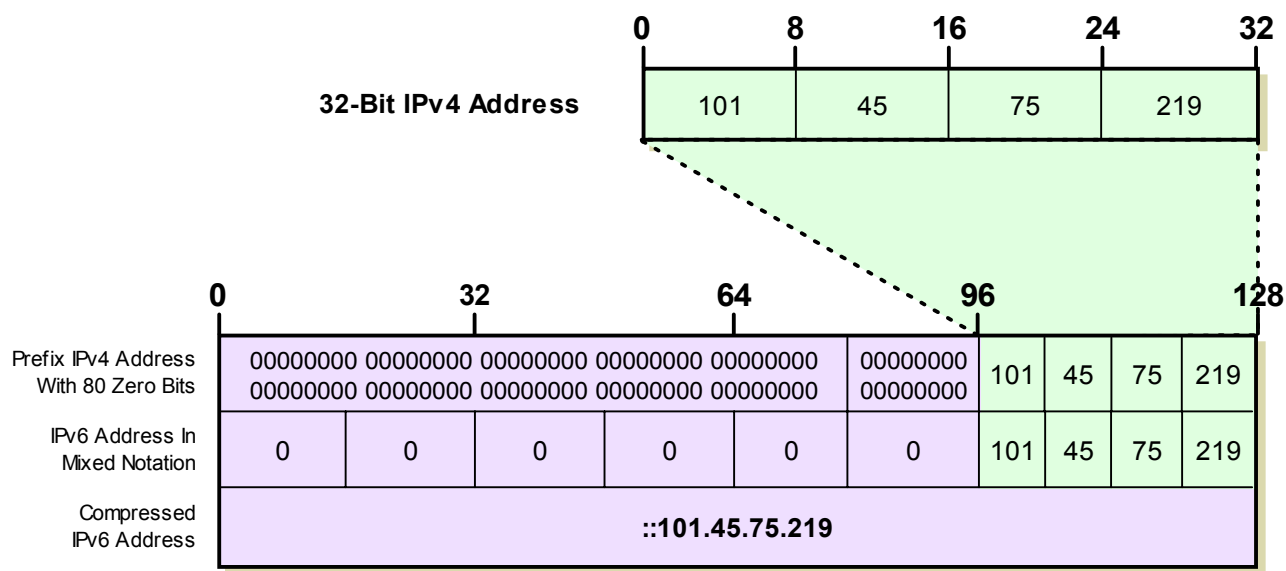

The two embedding formats are used in order to indicate the capabilities of the device using the embedded address.

### ***IPv4-Compatible IPv6 Addresses***

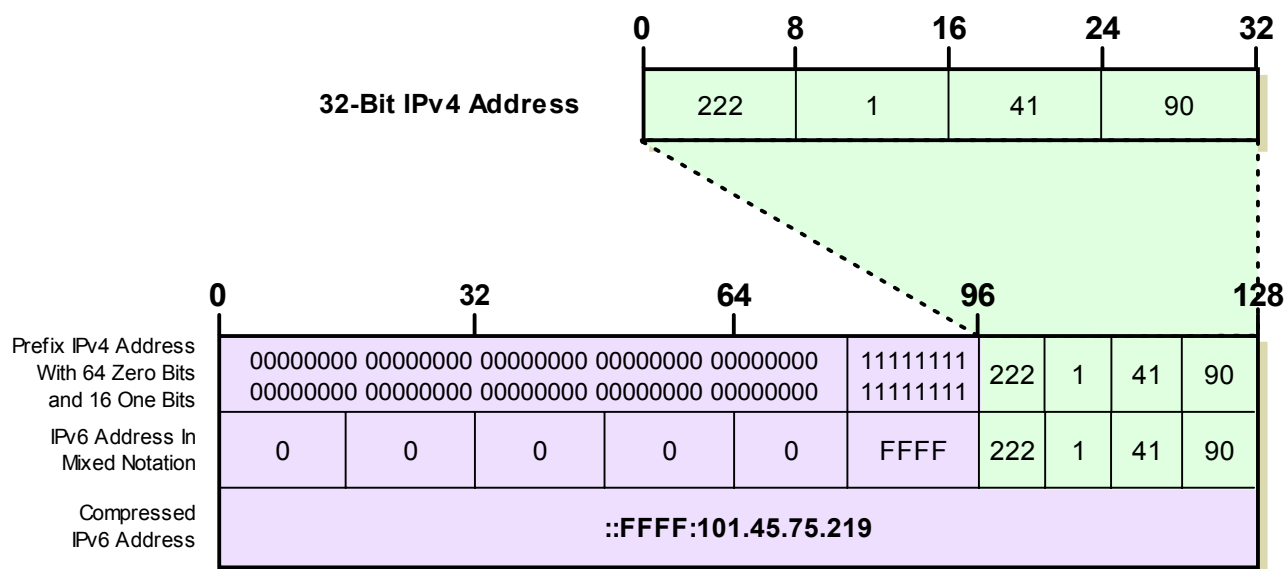

These are special addresses assigned to IPv6-capable devices, such as so-called "dual stack" devices that speak both IPv4 and IPv6. They have all zeroes for the middle 16 bits; thus, they start off with a string of 96 zeroes, followed by the IPv4 address. An example of such an address, shown in [Figure 99](#), would be 0:0:0:0:0:0:101.45.75.219 in mixed notation, or more succinctly, ::101.45.75.219.

### ***IPv4-Mapped IPv6 Addresses***

These are regular IPv4 addresses that have been mapped into the IPv6 address space, and are used for devices that are only IPv4-capable. They have a set of 16 **ones** after the initial string of 80 zeroes, and then the IPv4 address. So, if an IPv4 device has the address 222.1.41.90, such as the one in [Figure 100](#), it would be represented as 0:0:0:0:0:FFFF:222.1.41.90, or ::FFFF:222.1.41.90.

**Figure 99: IPv4-Compatible Embedded IPv6 Address Representation**

**Figure 100: IPv4-Mapped Embedded IPv6 Address Representation**

**Key Concept:** *IPv4 address embedding* is used to create a relationship between an IPv4 address and an IPv6 address to aid in the transition from IPv4 to IPv6. One type, the *IPv4-compatible IPv6 address*, is used for devices that are compatible with both IPv4 and IPv6; it begins with 96 zero bits. The other, the *IPv4-mapped address*, is used for mapping IPv4 devices that are not compatible with IPv6 into the IPv6 address space; it begins with 80 zeroes followed by 16 ones.

---

## ***Comparing IPv4-Compatible and IPv4-Mapped Embedded IPv6 Addresses***

The difference between these two kinds of addresses is subtle, but important. The first 80 bits are always zero, so when this is seen you know it is an embedded IPv4 address of some sort. IPv4-compatible IPv6 addresses are only used for devices that are actually IPv6-aware; the IPv4-compatible address is in addition to its conventional IPv6 address. In contrast, if the "FFFF" is seen for the 16 bits after the initial 80, this designates a conventional IPv4 device whose IPv4 address has been mapped into the IPv6 format. It is not an IPv6-capable device.

## **IPv6 Multicast and Anycast Addressing**

One of the most significant modifications in the general addressing model in IPv6 was a change to the basic types of addresses and how they were used. Unicast addresses are still the choice for the vast majority of communications as in IPv4, but the “bulk” addressing methods are different in IPv6. Broadcast as a specific addressing type has been eliminated. Instead, support for multicast addressing has been expanded and made a required part of the protocol, and a new type of addressing called *anycast* has been implemented.

### ***IPv6 Multicast Addresses***

Let's start by looking at multicast under IPv6. Multicasting is used to allow a single device to send a datagram to a group of recipients. IPv4 supported [multicast addressing](#) using the Class D address block in the “classful” addressing scheme. Under IPv6, multicast addresses are allocated from the multicast block. This is 1/256th of the address space, consisting of all addresses that begin with “1111 1111”. Thus, any address starting with “FF” in colon hexadecimal notation is an IPv6 multicast address.

The remaining 120 bits of address space are enough to allow the definition of, well, a gazillion or three multicast addresses. (Okay, it's officially about 1.3 trillion trillion trillion addresses.) Much the way the allocation of unicast addresses was organized by using a [special format](#) to divide up these many bits, the same thing was done for multicast addresses.

---

## IPv6 Multicast Address Format

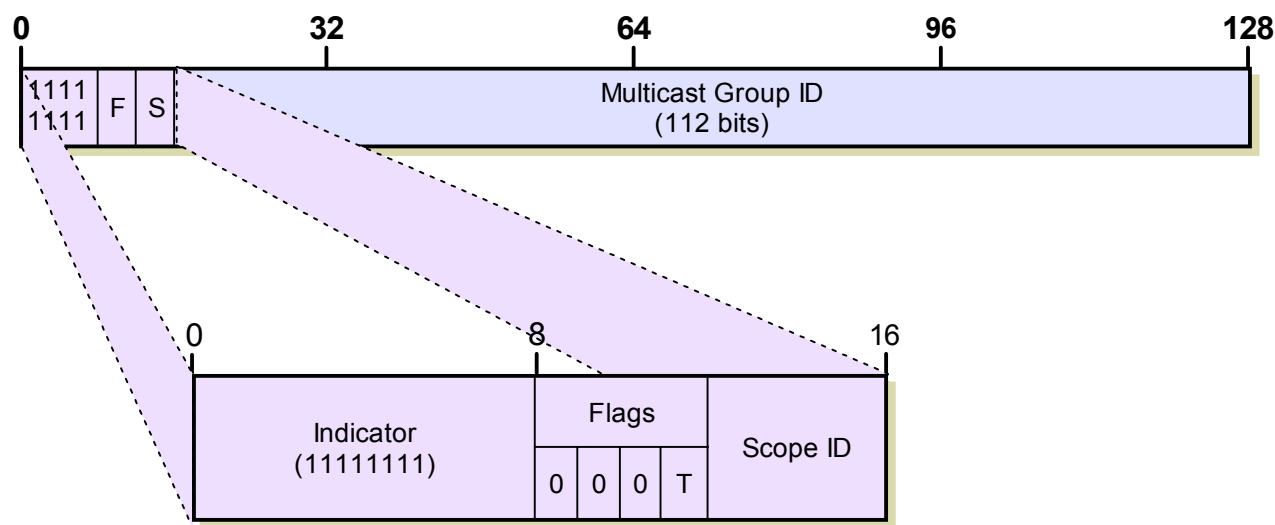

The format for multicast addresses is explained in [Table 66](#) and illustrated in [Figure 101](#).

**Table 66: IPv6 Multicast Address Format**

Field Name	Size (bits)	Description																
(Indicator)	8	The first eight bits are always “1111 1111” to indicate a multicast address. This used to be called the “Format Prefix” before the term was dropped as explained in <a href="#">the topic on IPv6 address space allocation</a> ; the field now has no name.																
Flags	4	<b>Flags:</b> Four bits are reserved for flags that can be used to indicate the nature of certain multicast addresses. At the present time the first three of these are unused and set to zero. The fourth is the “T” ( <i>Transient</i> ) flag. If left as zero, this marks the multicast address as a permanently-assigned, “well-known” multicast address, as we will see below. If set to one, this means this is a <i>transient</i> multicast address, meaning that it is not permanently assigned.																
Scope ID	4	<b>Scope ID:</b> These four bits are used to define the scope of the multicast address; 16 different values from 0 to 15 are possible. This field allows multicast addresses to be created that are global to the entire Internet, or restricted to smaller spheres of influence such as a specific organization, site or link (see below). The currently defined values (in decimal) are: <table><tr><th>Scope ID Value</th><th>Multicast Address Scope</th></tr><tr><td>0</td><td>Reserved</td></tr><tr><td>1</td><td>Node-Local Scope</td></tr><tr><td>2</td><td>Link-Local Scope</td></tr><tr><td>5</td><td>Site-Local Scope</td></tr><tr><td>8</td><td>Organization-Local Scope</td></tr><tr><td>14</td><td>Global Scope</td></tr><tr><td>15</td><td>Reserved</td></tr></table>	Scope ID Value	Multicast Address Scope	0	Reserved	1	Node-Local Scope	2	Link-Local Scope	5	Site-Local Scope	8	Organization-Local Scope	14	Global Scope	15	Reserved
Scope ID Value	Multicast Address Scope																	
0	Reserved																	
1	Node-Local Scope																	
2	Link-Local Scope																	
5	Site-Local Scope																	
8	Organization-Local Scope																	
14	Global Scope																	
15	Reserved																	
Group ID	112	<b>Group ID:</b> Defines a particular group within each scope level.																

### Multicast Scopes

The notion of explicitly scoping multicast addresses is important. Globally-scoped multicast addresses must be unique across the entire Internet, but locally-scoped addresses are unique only within the organization. This provides tremendous flexibility, as every type of multicast address actually comes in several “versions”: one that multicasts only within a node, one on the local link (local network), one on the local site and so on. The scope also allows routers to immediately determine how broadly they should propagate multicast datagrams, to improve efficiency and eliminate problems with traffic being sent outside the area for which it is intended. [Figure 102](#) illustrates the notion of scope graphically (and it’s quite pretty, wouldn’t you say? ☺)

**Figure 101: IPv6 Multicast Address Format**

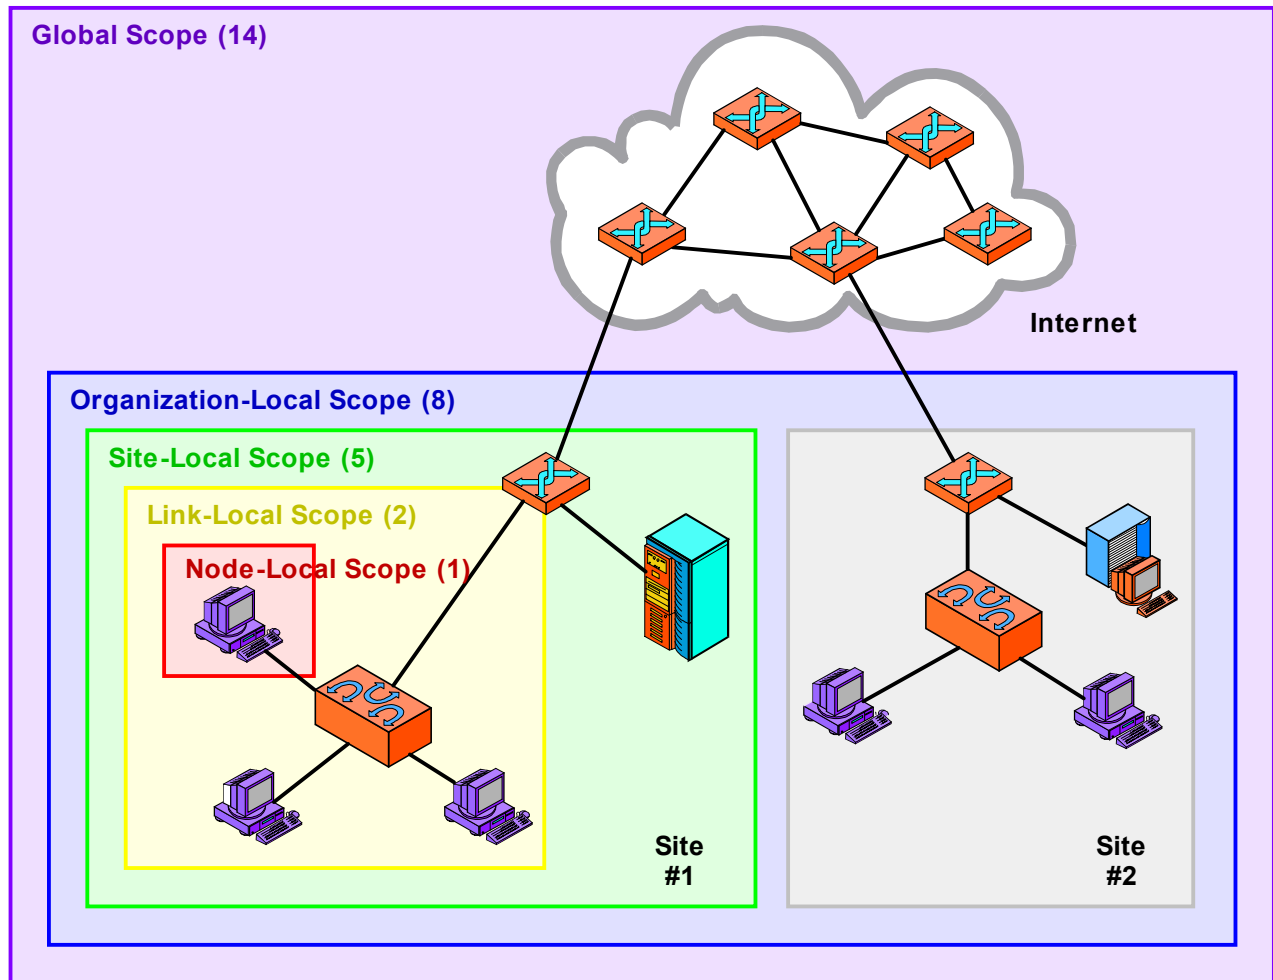

**Key Concept:** Multicast addresses are used to send data to a number of devices on an internetwork simultaneously. In IPv6 each multicast address can be specified for a variety of different *scopes*, allowing a transmission to be targeted to either a wide or narrow audience of recipient devices.

### Well-Known Multicast Addresses

The *Transient* flag allows for explicit determination of which multicast addresses are available for normal use compared to which are set aside as “well-known”. Several predefined well-known multicast addresses are defined, by setting aside certain Group IDs that are used for a number of different scope ID values. [Table 67](#) shows these values; the “x” in the multicast address pattern is the hexadecimal digit corresponding to the 4-bit scope ID field.

The “All Nodes” and “All Routers” multicast addresses enable the equivalent function of what broadcast used to perform in IPv4. Again, the concept of scope is important in a multicast of this type because we don’t want to try to send a message to “all nodes” on the

**Figure 102: IPv6 Multicast Scope**

This diagram shows how the notion of scope allows IPv6 multicasts to be limited to specific spheres of influence. The “tightest” scope is node-local scope, with a *Scope ID* value of 1. As the *Scope ID* value increases, the scope expands to cover the local network, site, organization, and finally, the entire Internet.

global Internet, for example. So, when the “all routers” address is used with a scope value of 2, it means “all routers on the local link”. If it is used with a value of 5, it means “all routers in this site”.

**Table 67: Important IPv6 “Well-Known” Multicast Addresses (Page 1 of 2)**

Multicast Address Pattern	Valid Scope Values (decimal)	Designation	Description
FF0x:0:0:0:0:0	0 to 15	Reserved	All multicast addresses where the 112-bit Group ID is zero are reserved.

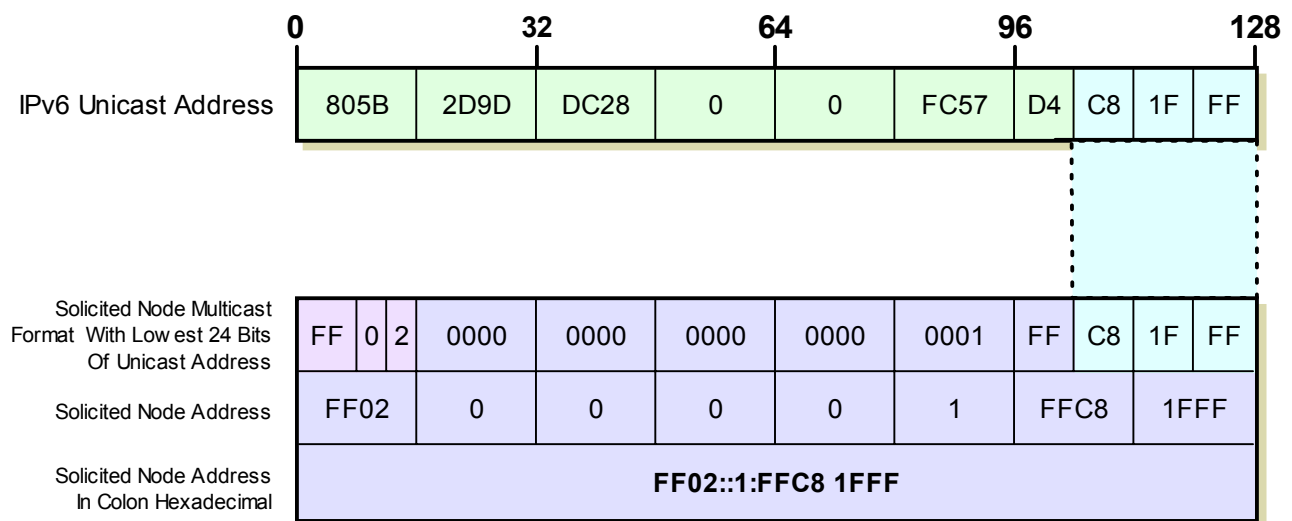

**Table 67: Important IPv6 “Well-Known” Multicast Addresses (Page 2 of 2)**

Multicast Address Pattern	Valid Scope Values (decimal)	Designation	Description
FF0x:0:0:0:0:1	1, 2	All Nodes	When the Group ID is equal to exactly 1, this is a multicast to all nodes. Both node-local (FF01:0:0:0:0:1) and link-local (FF02:0:0:0:0:1) “all nodes” multicast addresses are possible.
FF0x:0:0:0:0:2	1, 2, 5	All Routers	When the group ID is equal to exactly 2, this designates all routers within a specific scope as the recipients. Valid scope values are node-local, link-local and site-local.

### Solicited-Node Multicast Addresses

In addition to the regular multicast addresses, each unicast address has a special multicast address called its *solicited-node address*. This address is created through a special mapping from the device’s unicast address. Solicited-node addresses are used by the [IPv6 Neighbor Discovery \(ND\) protocol](#) to provide [more efficient address resolution](#) than the ARP technique used in IPv4.

All solicited-node addresses have their *T* flag set to zero and a scope ID of 2, so they start with “FF02”. The 112-bit group ID is broken down as follows (see [Figure 103](#)):

**Figure 103: IPv6 Solicited Node Address Calculation**

The solicited node multicast address is calculated from a unicast address by taking the last 24 bits of the address and prepending them with the IPv6 partial address “FF02:0:0:0:1:FF”. This shows the example address from [Figure 95](#) converted to its solicited node address, FF02::1:FFC8:1FFF.

- 
- ☉ 80 bits consisting of 79 zeroes followed by a single one; this means that in colon hexadecimal notation, the next five hexadecimal values are “0000:0000:0000:0000:0001”, or more succinctly, “0:0:0:0:1”.
  - ☉ 8 ones: “FF”.
  - ☉ 24 bits taken from the bottom 24 bits of its unicast address.

So, these addresses start with “FF02:0:0:0:0:1:FF” followed by the bottom 24 bits of the unicast address. So, the node with IP address 805B:2D9D:DC28:0:0:FC57:D4C8:1FFF would have a solicited-node address of FF02:0:0:0:0:1:FFC8:1FFF (or FF02::1:FFC8:1FFF).

**Key Concept:** Each unicast address has an equivalent *solicited-node multicast address*, which is created from the unicast address and used when other devices need to reach it on the local network.

---

### **IPv6 Anycast Addresses**

Anycast addresses are a new, unique type of address that is new to IP in IPv6; the IPv6 implementation is based on the material in RFC 1546, *Host Anycasting Service*. Anycast addresses can be considered a conceptual cross between unicast and multicast addressing. Where unicast says “send to this one address” and multicast says “send to every member of this group”, anycast says “send to any one member of this group”. Naturally, in choosing which member to send to, we would for efficiency reasons normally send to the closest one—closest in routing terms. So we can normally also consider anycast to mean “send to the closest member of this group”.

The idea behind anycast is to enable functionality that was previously difficult to implement in TCP/IP. Anycast was specifically intended to provide flexibility in situations where we need a service that is provided by a number of different servers or routers but don't really care which one provides it. In routing, anycast allows datagrams to be sent to whichever router in a group of equivalent routers is closest, to allow load sharing amongst routers and dynamic flexibility if certain routers go out of service. Datagrams sent to the anycast address will automatically be delivered to the device that is easiest to reach.

Perhaps surprisingly, there is no special anycast addressing scheme: anycast addresses are the same as unicast addresses. An anycast address is created “automatically” when a unicast address is assigned to more than one interface.

Like multicast, anycast creates more work for routers; it is more complicated than unicast addressing. In particular, the further apart the devices that share the anycast address are, the more complexity is created. Anycasting across the global Internet would be potentially difficult to implement, and IPv6 anycasting was designed for devices that are proximate to each other, generally in the same network. Also, due to the relative inexperience of the Internet community in using anycast, for the present time anycast addresses are used only by routers and not individual hosts.

**Key Concept:** Anycast addresses are new in IPv6 and can be used to set up a group of devices any one of which can respond to a request sent to a single IP address.

---

## **IPv6 Autoconfiguration and Renumbering**

One of the most interesting and potentially valuable addressing features implemented in IPv6 is a facility to allow devices on an IPv6 to actually configure themselves independently. In IPv4 hosts were originally configured manually. Later, [host configuration protocols like DHCP](#) enabled servers to allocate IP addresses to hosts that joined the network. IPv6 takes this a step further, by defining a method for some devices to automatically configure their IP address and other parameters without the need for a server. It also defines a method whereby the IP addresses on a network can be renumbered (changed en masse). These are the sorts of features that make TCP/IP network administrators drool.

The IPv6 autoconfiguration and renumbering feature is defined in RFC 2462, *IPv6 Stateless Address Autoconfiguration*. The word “stateless” contrasts this method to the server-based method using something like [DHCPv6](#), which is called “stateful”. (Another word like “classful” that makes me cringe.) This method is called “stateless” because it begins from a “dead start” with no information (or “state”) at all for the host to work with, and has no need for a DHCP server.

### ***IPv6 Stateless Autoconfiguration***

Stateless autoconfiguration exploits several other new features in IPv6, including [link-local addresses](#), [multicasting](#), [the Neighbor Discovery \(ND\) protocol](#), and [the ability to generate the interface identifier of an address from the underlying data link layer address](#). The general idea is to have a device generate a temporary address until it can determine the characteristics of the network it is on, and then create a permanent address it can use based on that information. In the case of multi-homed devices, autoconfiguration is performed for each interface separately, as you would expect.

The following is a summary of the steps a device takes when using stateless autoconfiguration:

1. **Link-Local Address Generation:** The device generates a link-local address. Recall that this is one of the two types of [local-use IPv6 addresses](#). Link-local addresses have “1111 1110 10” for the first ten bits. The generated address uses those ten bits followed by 54 zeroes and then the 64 bit interface identifier. Typically this will be derived from the data link layer (MAC) address as explained in [the topic on interface identifiers](#), or it may be a “token” generated in some other manner.
2. **Link-Local Address Uniqueness Test:** The node tests to ensure that the address it generated isn't for some reason already in use on the local network. (This is very unlikely to be an issue if the link-local address came from a MAC address but more likely if it was based on a generated token.) It sends a *Neighbor Solicitation* message

---

using the [Neighbor Discovery \(ND\) protocol](#). It then listens for a *Neighbor Advertisement* in response that indicates that another device is already using its link-local address; if so, either a new address must be generated, or autoconfiguration fails and another method must be employed.

3. **Link-Local Address Assignment:** Assuming the uniqueness test passes, the device assigns the link-local address to its IP interface. This address can be used for communication on the local network, but not on the wider Internet (since link-local addresses are not routed).
4. **Router Contact:** The node next attempts to contact a local router for more information on continuing the configuration. This is done either by listening for *Router Advertisement* messages sent periodically by routers, or by sending a specific *Router Solicitation* to ask a router for information on what to do next. [This process is described in the section on the IPv6 Neighbor Discovery protocol](#).
5. **Router Direction:** The router provides direction to the node on how to proceed with the autoconfiguration. It may tell the node that on this network “stateful” autoconfiguration is in use, and tell it the address of a DHCP server to use. Alternately, it will tell the host how to determine its global Internet address.
6. **Global Address Configuration:** Assuming that stateless autoconfiguration is in use on the network, the host will configure itself with its globally-unique Internet address. This address is generally formed from a network prefix provided to the host by the router, combined with the device's identifier as generated in the first step.

Clearly, this method has numerous advantages over both manual and server-based configuration. It is particularly helpful in supporting mobility of IP devices, as they can move to new networks and get a valid address without any knowledge of local servers or network prefixes. At the same time, it still allows management of IP addresses using the (IPv6-compatible) version of DHCP if that is desired. Routers on the local network will typically tell hosts which type of autoconfiguration is supported using special flags in [ICMPv6 Router Advertisement messages](#).

**Key Concept:** IPv6 includes an interesting feature called stateless address autoconfiguration, which allows a host to actually determine its own IPv6 address from its layer two address by following a special procedure.

---

## ***IPv6 Device Renumbering***

Renumbering of devices is a method related to autoconfiguration. Like host configuration, it can be implemented using protocols like DHCP, through the use of IP address “leases” that expire after a period of time. Under IPv6, networks can be renumbered by having routers specify an expiration interval for network prefixes when autoconfiguration is done. Later, they can send a new prefix to tell devices to regenerate their IP addresses. Devices can actually maintain the old “deprecated” address for a while and then move over to the new address.

---

A similar technique was also defined for renumbering router addresses, in RFC 2894. [It uses special ICMPv6 messages and is described in a topic in that section.](#)

---

## **IPv6 Datagram Encapsulation and Formatting**

Delivery of data over IPv6 internetworks is accomplished by encapsulating higher-layer data into *IPv6 datagrams*. These serve the same general purpose for IPv6 as [IPv4 datagrams](#) do in the older version of the protocol. However, they have been redesigned as part of the overall changes represented by IPv6. IPv6 datagrams have a flexible structure and their format better matches the needs of current IP networks.

In this section I take a look at the format used for IPv6 datagrams. I begin with an overview of the general structure of IPv6 datagrams, describing the major changes and showing how main and extension headers are arranged in the datagram. I then describe the format of the main header, and define and describe the various extension header types. I conclude with a brief explanation of IPv6 options and how they are implemented.

**Background Information:** This section assumes basic understanding of [IPv6 addressing concepts](#), and also general familiarity with [the IPv4 datagram format](#).

---

### **IPv6 Datagram Overview and General Structure**

The method by which IPv6 encapsulates data received from higher-layer protocols for transmission across the internetwork is basically the same as [that used by IPv4](#). The data received from the transport or higher layers is made the payload of an IPv6 datagram, which has one or more headers that control the delivery of the message. These headers provide information to routers to enable them to move the datagram across the network, and also to hosts so they can tell which datagrams they are intended to receive.

#### ***Overview of Major Changes to Datagram Structure and Fields in IPv6***

While the basic use of datagrams hasn't changed since IPv4, many modifications were made to their structure and format when IPv6 was created. This was done partly out of necessity: IPv6 addresses are different than IPv4 addresses and IP addresses go in the datagram header. The increase in the size of IP addresses from 32 bits to 128 bits adds a whopping extra 192 bits, or 24 bytes of information to the header. This in turn led to an effort to remove fields that weren't strictly necessary, to compensate for the necessary increase in size. However, changes were also made to IPv6 datagrams to add features to them and to make them better suit the needs of modern internetworking.

The following is a list of the most significant overall changes to datagrams in IPv6:

- 🕒 **Multiple Header Structure:** Rather than a single header that contains all fields for the datagram (possibly including options), the IPv6 datagram supports a “main” header and then *extension headers* for additional information when needed.

- 🔊 **Streamlined Header Format:** Several fields have been removed from the main header to reduce its size and increase efficiency. Only the fields that are truly required for pretty much *all* datagrams remain in the main header; others are put into extension headers and used as needed. Some were removed because they were no longer needed, such as the *Internet Header Length* field; the IPv6 header is of fixed length. This is discussed more thoroughly in [the topic on the main IPv6 header](#).
- 🔊 **Renamed Fields:** Some fields have been renamed to better reflect their actual use in modern networks.
- 🔊 **Greater Flexibility:** The [extension headers](#) allow a great deal of extra information to accompany datagrams when needed. [Options](#) are also supported in IPv6.
- 🔊 **Elimination of Checksum Calculation:** In IPv6, a checksum is no longer computed on the header. This saves both the calculation time spent by every device that packages IP datagrams (hosts and routers) and the space the checksum field took up in the IPv4 header.
- 🔊 **Improved Quality of Service Support:** A new field, the *Flow Label*, is defined to help support the prioritization of traffic.

**Key Concept:** IPv6 datagrams use a general structure that begins with a mandatory main header 40 bytes in length, followed by optional *extension headers* and then a variable-length *Data* area. This structure was created to allow the main header to be streamlined while allowing devices to add extra information to datagrams when needed.

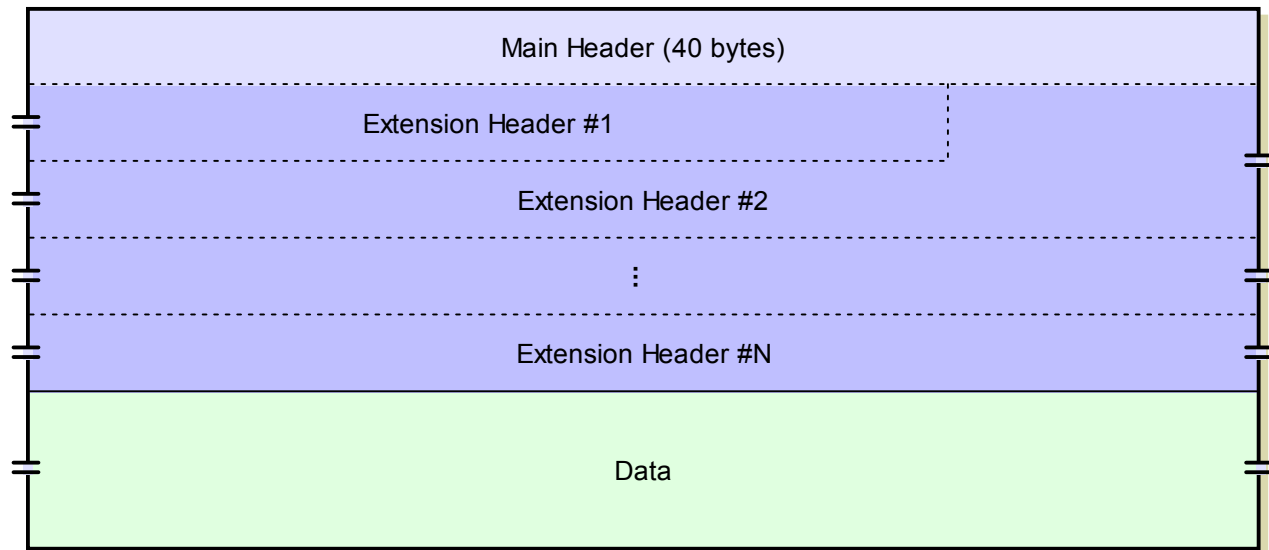

## IPv6 General Datagram Structure

As I mentioned above, IPv6 datagrams now includes a main header format (which has no official name in the standards, it's just “the header”) and zero or more extension headers. The overall structure therefore is as shown in [Table 68](#) and [Figure 104](#).

**Table 68: IPv6 General Datagram Structure**

Component	Number of Components Per Datagram	Size (bytes)	Description
<i>Main Header</i>	1	40	Contains the source and destination addresses, and important information required for every datagram.
<i>Extension Headers</i>	0 or more	Variable	Each contains one type of extra information to support various features, including fragmentation, source routing, security and options.
<i>Data</i>	1	Variable	The payload from the upper layer to be transmitted in the datagram.

Note that as with IPv4, large payloads may be fragmented prior to encapsulation, to ensure that the total size of the datagram doesn't exceed the maximum size permitted on an underlying network. However, [the details of fragmentation in IPv6 are different than in IPv4](#).

**Figure 104: IPv6 General Datagram Structure**

### IPv6 Datagram Main Header Format

As we saw in [the previous topic](#), IPv6 datagrams use a structure that includes a regular header and optionally, one or more extension headers. This regular header is like [the header of IPv4 datagrams](#), though it has a different format, as we will see shortly. The standards don't give this header a name; it is just "*the IPv6 header*". To differentiate it from IPv6 extension headers, I call it the *main header*.

#### **Main Header Format**

The IPv6 main header is required for every datagram. It contains addressing and control information that are used to manage the processing and routing of the datagram. The main header format of IPv6 datagrams is described in [Table 69](#) and illustrated in [Figure 105](#).

**Table 69: IPv6 Main Header Format (Page 1 of 2)**

Field Name	Size (bytes)	Description
<b>Version</b>	1/2 (4 bits)	<b>Version:</b> Identifies the version of IP used to generate the datagram. This field is used the same way as in IPv4, except of course that it carries the value 6 (0110 binary).
<b>Traffic Class</b>	1	<b>Traffic Class:</b> This field replaces the <i>Type Of Service (TOS)</i> field in the IPv4 header. It is used not in the original way that the TOS field was defined (with Precedence, D, T and R bits) but using the new <i>Differentiated Services (DS)</i> method defined in RFC 2474. That RFC actually specifies quality of service (QOS) techniques for both IPv4 and IPv6; <a href="#">see the IPv4 format description for a bit more information</a> .

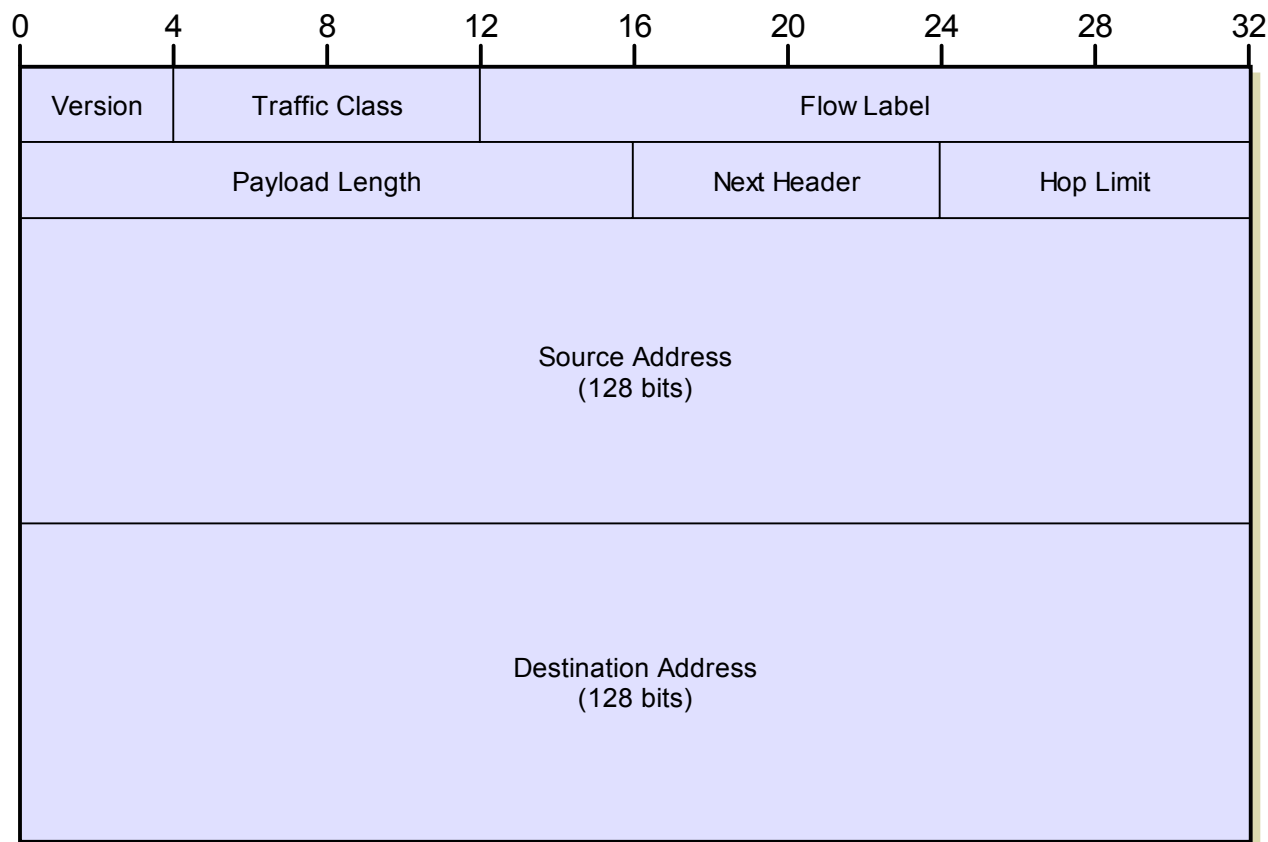

**Table 69: IPv6 Main Header Format (Page 2 of 2)**

Field Name	Size (bytes)	Description
<b>Flow Label</b>	2 1/2 (20 bits)	<p><b>Flow Label:</b> This large field was created to provide additional support for real-time datagram delivery and quality of service features. The concept of a <i>flow</i> is defined in RFC 2460 as a sequence of datagrams sent from a source device to one or more destination devices. A unique flow label is used to identify all the datagrams in a particular flow, so that routers between the source and destination all handle them the same way, to help ensure uniformity in how the datagrams in the flow are delivered. For example, if a video stream is being sent across an IP internetwork, the datagrams containing the stream could be identified with a flow label to ensure that they are delivered with minimal latency.</p> <p>Not all devices and routers may support flow label handling, and use of the field by a source device is entirely optional. Also, the field is still somewhat experimental and may be refined over time.</p>
<b>Payload Length</b>	2	<p><b>Payload Length:</b> This field replaces the <i>Total Length</i> field from the IPv4 header, but it is used differently. Rather than measuring the length of the whole datagram, it only contains the number of bytes of the payload. However, if extension headers are included, their length is counted here as well.</p> <p>In simpler terms, this field measures the length of the datagram less the 40 bytes of the main header itself.</p>
<b>Next Header</b>	1	<p><b>Next Header:</b> This field replaces the <i>Protocol</i> field and has two uses. When a datagram has extension headers, this field specifies the identity of the first extension header, which is the next header in the datagram. When a datagram has just this “main” header and no extension headers, it serves the same purpose as the old IPv4 <i>Protocol</i> field and has the same values, though new numbers are used for IPv6 versions of common protocols. In this case the “next header” is the header of the upper layer message the IPv6 datagram is carrying. See below for more details.</p>
<b>Hop Limit</b>	1	<p><b>Hop Limit:</b> This replaces the <i>Time To Live (TTL)</i> field in the IPv4 header; its name better reflects the way that <i>TTL</i> is used in modern networks (since <i>TTL</i> is really used to count hops, not time.)</p>
<b>Source Address</b>	16	<p><b>Source Address:</b> The 128-bit IP address of the originator of the datagram. As with IPv4, this is always the device that originally sent the datagram.</p>
<b>Destination Address</b>	16	<p><b>Destination Address:</b> The 128-bit IP address of the intended recipient of the datagram; unicast, anycast or multicast. Again, even though devices such as routers may be the intermediate targets of the datagram, this field is always for the ultimate destination.</p>

### IPv6 Next Header Field

The *Next Header* field is one of the most important additions to the IPv6 datagram format. When an IPv6 datagram uses extension headers, this field contains an identifier for the first extension header, which in turn uses its own *Next Header* to point to the next header, and so on. The last extension header then references the encapsulated higher-layer protocol—

**Figure 105: IPv6 Main Header Format**

since the higher-layer protocol's header appears at the start of the IPv6 *Data* field, it is like the “next header” to the device receiving the datagram. For some folks this is a bit tough to see conceptually; much more detail on how the field works (including a useful illustration) can be found in [the next topic, describing extension headers](#). Some of the most common values for *Next Header* in IPv6 are shown in [Table 70](#).

**Table 70: Common IPv6 Next Header Values (Page 1 of 2)**

Value (Hexadecimal)	Value (Decimal)	Protocol / Extension Header
00	0	Hop-By-Hop Options Extension Header (note that this value was “Reserved” in IPv4)
01	1	ICMPv4
02	2	IGMPv4
04	4	IP in IP Encapsulation
06	6	TCP
08	8	EGP
11	17	UDP
29	41	IPv6

---

**Table 70: Common IPv6 Next Header Values (Page 2 of 2)**

Value (Hexadecimal)	Value (Decimal)	Protocol / Extension Header
2B	43	Routing Extension Header
2C	44	Fragmentation Extension Header
2E	46	Resource Reservation Protocol (RSVP)
32	50	Encrypted Security Payload (ESP) Extension Header
33	51	Authentication Header (AH) Extension Header
3A	58	ICMPv6
3B	59	No Next Header
3C	60	Destination Options Extension Header

The total length of the main IPv6 header format is 40 bytes. This is double the size of the IPv4 header without options, largely because of the extra 24 bytes needed for the monstrous IPv6 addresses. There are only 8 bytes of non-address header fields in the IPv6 main header, compared to 12 in the IPv4 header.

### **Key Changes to Main Header Between IPv4 and IPv6**

To summarize, the IPv6 main header compares to the IPv4 header as follows:

- 🕒 **Unchanged Fields:** Three fields are used the same way and retain the same name (though they have different content and/or size): *Version*, *Source Address* and *Destination Address*.
- 🕒 **Renamed Fields:** Two fields are used the same way but renamed: *Traffic Class* and *Hop Limit*.
- 🕒 **Modified Fields:** Two fields are used in a way similar way to their IPv4 predecessors but are slightly different in meaning and also renamed: *Payload Length* and *Next Header*.
- 🕒 **Added Fields:** There is one new field: *Flow Label*.
- 🕒 **Removed Fields:** To cut down on header length and unnecessary work, five IPv4 header fields are removed from the IPv6 header:
  - 🕒 **Internet Header Length:** No longer needed, as the main IPv6 header is fixed in length at 40 bytes.
  - 🕒 **Identification, Flags, Fragment Offset:** These are used for fragmentation, which is done less in IPv6 than IPv4, so these fields are now found only when needed in the [Fragmentation extension header](#).
  - 🕒 **Header Checksum:** The decision was made to eliminate header checksum calculations in IPv6. It was viewed as redundant with higher-layer error-checking and data link layer CRC calculations. This saves processing time for routers and 2 bytes in the datagram header.

In addition, while options were formerly considered part of the main header in IPv4, [they are separate in IPv6](#).

---

## IPv6 Datagram Extension Headers

After the mandatory “main” header in an IPv6 datagram, one or more *extension headers* may appear before the encapsulated payload. These headers were created in an attempt to provide both flexibility and efficiency in the creation of IPv6 datagrams. All fields that are needed only for special purposes are put into extension headers and placed in the datagram when needed. This allows the size of the main datagram header to be made small and streamlined, containing only those fields that really must be present all the time.

There is often confusion regarding the role of extension headers, especially compared to datagram options. The IPv4 datagram had only one header, but it included a provision for options, and IPv6 also has options, so why bother with extension headers? Good question.

It would have been possible to do everything using options. However, it was deemed a better design to employ extension headers for certain sets of information that are needed for common functions such as fragmenting. Options are indeed still supported in IPv6; they are used to provide even more flexibility by providing variable-length fields that can be used for any purpose. They are themselves defined using extension headers as we will see below (and in [their own topic, which follows](#).)

When extension headers are included in an IPv6 datagram, they appear one after the other following the main header. Each extension header type has its own internal structure of fields.

### ***IPv6 Header Chaining Using the Next Header Field***

The only field common to all extension header types is the *Next Header* field (which actually appears at the end of one header type, the [ESP header](#)). The 8-bit *Next Header* field is used to logically link all the headers in an IPv6 datagram as follows:

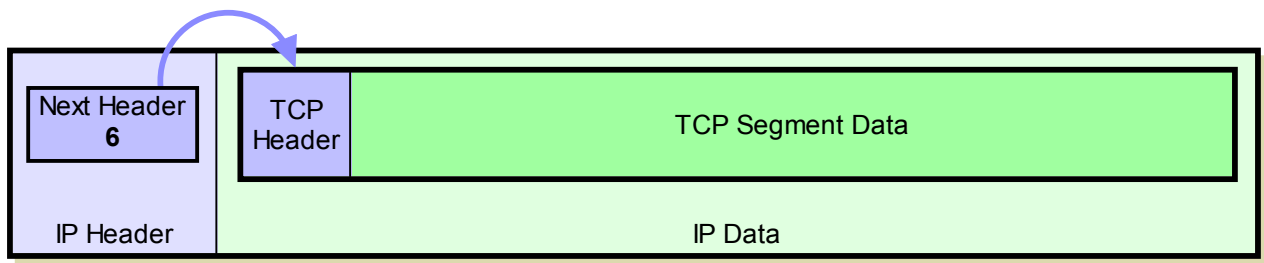

- ☉ The *Next Header* field in the main header contains a reference number for the first extension header type.
- ☉ The *Next Header* field in the first extension header contains the number of the second extension header type, if there is a second one. If there's a third, the second header's *Next Header* points to it, and so on.
- ☉ The *Next Header* field of the last extension header contains the protocol number of the encapsulated higher-layer protocol. In essence, this field points to the “next header” within the payload itself.

For example, suppose a datagram that encapsulates TCP has a *Hop-By-Hop Options* extension header and a *Fragment* extension header. Then, the *Next Header* fields of these headers would contain the following values:

- ☉ The main header would have a *Next Header* value of 0, indicating the *Hop-By-Hop Options* header.
- ☉ The *Hop-By-Hop Options* header would have a *Next Header* value of 44 (decimal), the value for the *Fragment* extension header.
- ☉ The *Fragment* header would have a *Next Header* value of 6.

---

This is illustrated in [Figure 106](#).

**IPv6 Datagram With No Extension Headers Carrying TCP Segment**

**IPv6 Datagram With Two Extension Headers Carrying TCP Segment**

**Figure 106: IPv6 Extension Header Linking Using the *Next Header* Field**

The *Next Header* field allows a device to more easily process the headers in a received IPv6 datagram. When a datagram has no extension headers, the “next header” is actually the header at the start of the IP *Data* field, in this case a TCP header with a value of 6. This is the same way the *Protocol* field is used in IPv4. When extension headers do appear, the *Next Header* value of each header contains a number indicating the type of the following header in the datagram, so they logically “chain together” the headers, as shown above.

**Key Concept:** The IPv6 *Next Header* field is used to “chain together” the headers in an IPv6 datagram. The *Next Header* field in the main header contains the number of the first extension header; its *Next Header* contains the number of the second, and so forth. The last header in the datagram contains the number of the encapsulated protocol that begins the *Data* field.

---

---

## Summary of IPv6 Extension Headers

Table 71 lists the different extension headers, showing its *Next Header* value, length and defining RFC, and providing a brief description of how each is used.

**Table 71: IPv6 Extension Headers**

Next Header Value (decimal)	Extension Header Name	Length (bytes)	Description	Defining RFC
0	<b><i>Hop-By-Hop Options</i></b>	Variable	Defines an arbitrary set of options that are intended to be examined by all devices on the path from the source to destination device(s).  This is one of two extension headers used to define <a href="#">variable-format options</a> .	2460
43	<b><i>Routing</i></b>	Variable	Defines a method for allowing a source device to specify the route for a datagram. This header type actually allows the definition of multiple routing types. The IPv6 standard defines the Type 0 <i>Routing</i> extension header, which is equivalent to the “loose” source routing option in IPv4 and used in a similar way.  See below for the format of this extension header.	2460
44	<b><i>Fragment</i></b>	8	When a datagram contains only a fragment of the original message, this extension header is included. It contains the <i>Fragment Offset</i> , <i>Identification</i> and <i>More Fragment</i> fields that were removed from the main header.  See below for the format of this extension header, and <a href="#">the topic on fragmentation and reassembly</a> for details on how the fields are used.	2460
50	<b><i>Encapsulating Security Payload (ESP)</i></b>	Variable	Carries encrypted data for secure communications. <a href="#">This header is described in detail in the section on IPSec.</a>	2406
51	<b><i>Authentication Header (AH)</i></b>	Variable	Contains information used to verify the authenticity of encrypted data. <a href="#">This header is described in detail in the section on IPSec.</a>	2402
60	<b><i>Destination Options</i></b>	Variable	Defines an arbitrary set of options that are intended to be examined only by the destination(s) of the datagram.  This is one of two extension headers used to define <a href="#">variable-format options</a> .	2460

---

Note that the *Next Header* value of the IPv6 main header is 41; that of an IPv4 header is 4 (its protocol number). Note that there is also a “dummy” extension header called *No Next Header* that has a value of 59. This is a placeholder that when found in the *Next Header* field indicates that there is nothing after that extension header.

As I mentioned in the table, the formats for several of the headers are provided in other topics. Two of them I will describe here, however.

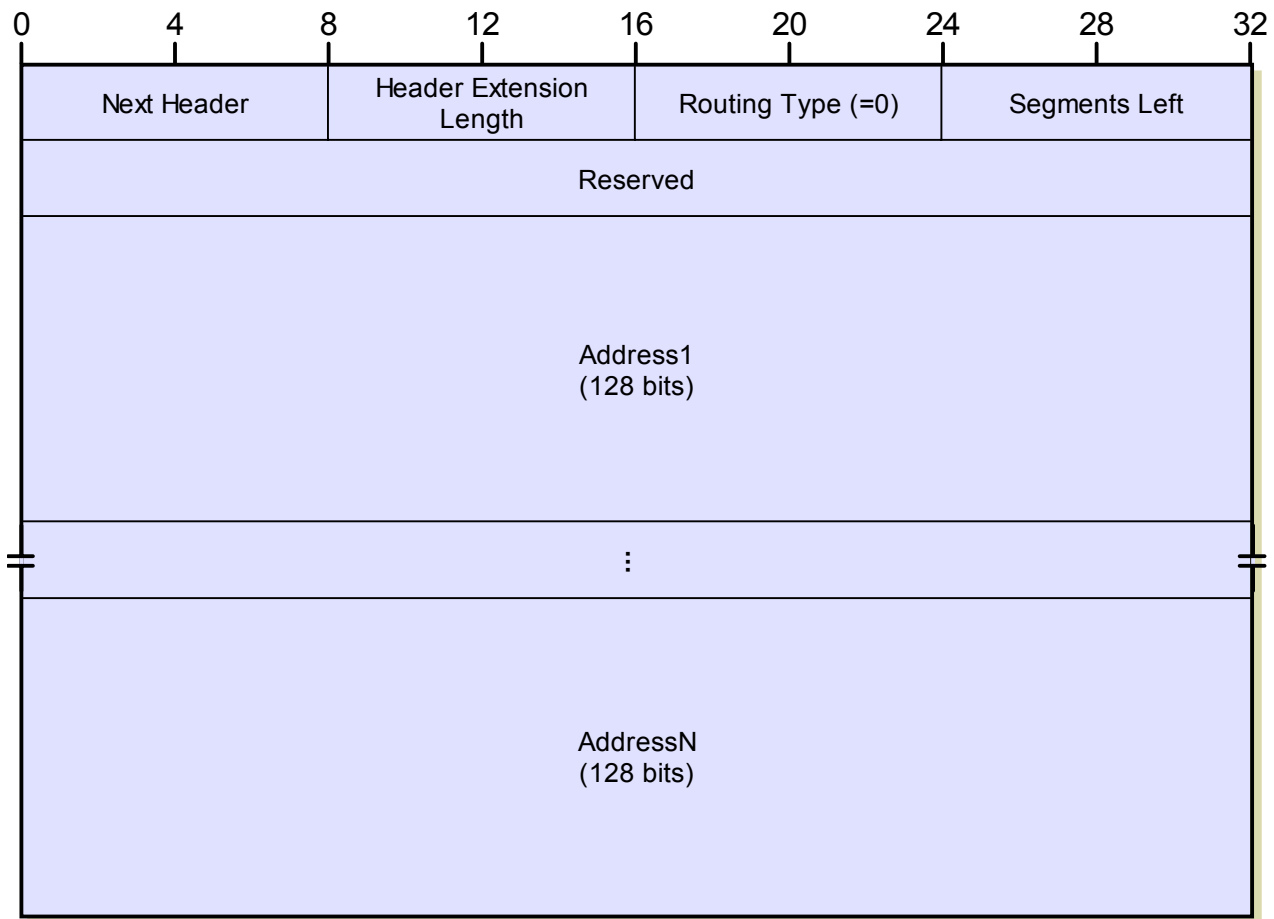

### **IPv6 Routing Extension Header**

The *Routing* extension header is used to perform source routing in IPv6. It is described in [Table 72](#), and illustrated in [Figure 107](#).

**Table 72: IPv6 Routing Extension Header Format**

Field Name	Size (bytes)	Description
<b><i>Next Header</i></b>	1	<b><i>Next Header</i></b> : Contains the protocol number of the next header after the Routing header. Used to link headers together as described above.
<b><i>Hdr Ext Len</i></b>	1	<b><i>Header Extension Length</i></b> : The length of the Routing header in 8-byte units, not including the first 8 bytes of the header. For a Routing Type of 0, this value is thus two times the number addresses embedded in the header.
<b><i>Routing Type</i></b>	1	<b><i>Routing Type</i></b> : This field allows multiple routing types to be defined; at present, the only value used is 0.
<b><i>Segments Left</i></b>	1	<b><i>Segments Left</i></b> : Specifies the number of explicitly-named nodes remaining in the route until the destination.
<b><i>Reserved</i></b>	4	<b><i>Reserved</i></b> : Not used; set to zeroes.
<b><i>Address1 ... AddressN</i></b>	Variable (multiple of 16)	<b><i>Addresses</i></b> : A set of IPv6 addresses that specify the route to be used.

**Figure 107: IPv6 *Routing* Extension Header Format**

### ***IPv6 Fragment Extension Header***

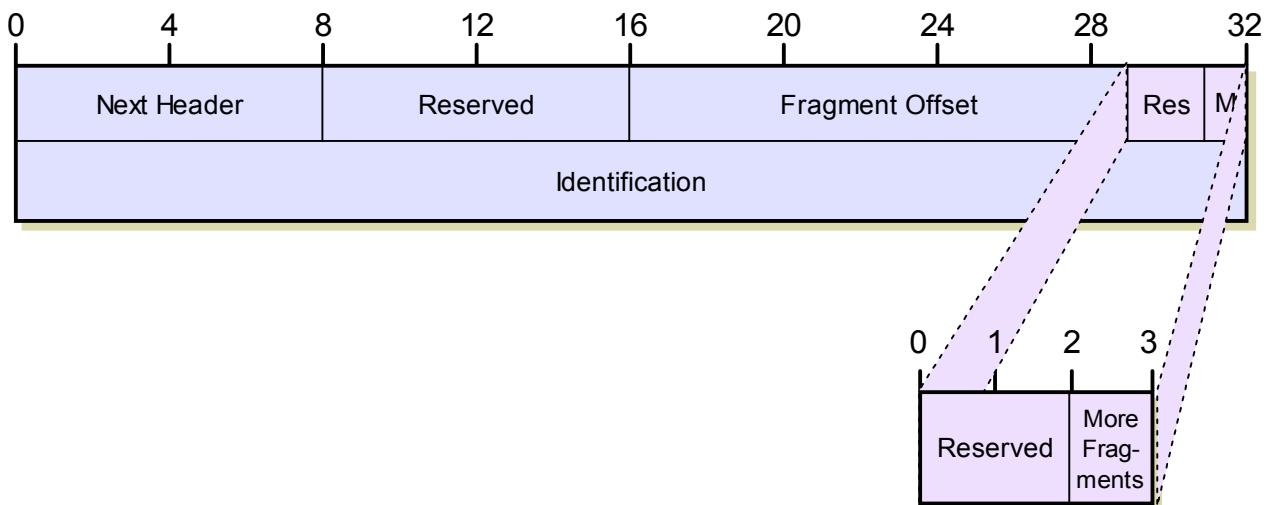

The *Fragment* extension header is included in fragmented datagrams to provide the information necessary to allow the fragments to be reassembled. Its format can be found in [Table 73](#) and [Figure 108](#).

**Table 73: IPv6 *Fragment* Extension Header Format (*Page 1 of 2*)**

Field Name	Size (bytes)	Description
<b><i>Next Header</i></b>	1	<b><i>Next Header:</i></b> Contains the protocol number of the next header after the Fragment header. Used to link headers together as described above.
<b><i>Reserved</i></b>	1	<b><i>Reserved:</i></b> Not used; set to zeroes.
<b><i>Fragment Offset</i></b>	13/8 (13 bits)	<b><i>Fragment Offset:</i></b> Specifies the offset, or position, in the overall message where the data in this fragment goes. It is specified in units of 8 bytes (64 bits) and used in a manner very similar to the field of the same name in the IPv4 header.

**Table 73: IPv6 *Fragment* Extension Header Format (Page 2 of 2)**

Field Name	Size (bytes)	Description
<b>Res</b>	1/4 (2 bits)	<b>Reserved:</b> Not used; set to zeroes.
<b>M Flag</b>	1/8 (1 bit)	<b>More Fragments Flag:</b> Same as the flag of the same name in the IPv4 header—when set to 0, indicates the last fragment in a message; when set to 1, indicates that more fragments are yet to come in the fragmented message.
<b>Identification</b>	4	<b>Identification:</b> Same as the field of the same name in the IPv4 header, but expanded to 32 bits. It contains a specific value that is common to each of the fragments belonging to a particular message, to ensure that pieces from different fragmented messages are not mixed together.

**Figure 108: IPv6 *Fragment* Extension Header Format**

### **IPv6 Extension Header Order**

Each extension header appears only once in any datagram (with one exception; see below). Also, extension headers are only examined by the final recipients of the datagram, not intermediate devices (again with one exception, which we will get to momentarily). RFC 2460 specifies that when multiple headers appear, they should be in the following order after the main header and before the higher-layer encapsulated header in the IPv6 datagram payload:

1. *Hop-By-Hop Options*
2. *Destination Options* (for options to be processed by the destination as well as devices specified in a Routing header)
3. *Routing*
4. *Fragmentation*

- 
5. *Authentication Header*
  6. *Encapsulating Security Payload*
  7. *Destination Options* (for options processed only by the final destination)

Now let's look at those exceptions. The only header that can appear twice is *Destination Options*. Normally, it appears as the last header. However, a *Destination Options* header may exist that contain options that must be examined by a list of devices specified in a source route, in addition to the destination. In this case, the *Destination Options* header for these options is placed before the *Routing* header. A second such header containing options only for the final destination may also appear.

**Key Concept:** Each extension header may appear only once in an IPv6 datagram, and they must appear in a fixed order. The exception is the *Destination Options* header, which may appear twice; near the start of the datagram for options to be processed by devices en route to the destination, and at the end of the extension headers for options intended only for the final destination.

---

The only header normally examined by all intermediate devices is the *Hop-By-Hop Options* extension header. It is used specifically to convey management information to all routers in a route. The *Hop-By-Hop Options* extension header must appear as the first extension header if present. Since it is the only one that must be read by every router (which represents a performance drain on routers) it is given “top billing” to make it easier and faster to find and process.

Finally, note that all extension headers must be a multiple of 8 bytes in length for alignment purposes. Also, remember that the *Next Header* value for a particular extension header appears in the *Next Header* field of the *preceding* header, not the header itself.

## **IPv6 Datagram Options**

In IPv4, all “extra” information required for various purposes is placed into the datagram in the form of [options that appear in the IPv4 header](#). In IPv6, the new concept of [extension headers](#) is introduced; these headers take the place of many of the predefined IPv4 options. However, the concept of options is still maintained in IPv6, for a slightly different purpose. Options allow the IPv6 datagram to be supplemented with arbitrary sets of information that aren't defined in the regular extension headers. They provide maximum flexibility, allowing the basic IPv6 protocol to be extended in ways the designers never anticipated, with the goal of reducing the chances of the protocol becoming obsolete.

### ***IPv6 Option Extension Header Types***

I said that IPv6 options supplement extension headers; in fact, they are actually implemented as extension headers. There are two different ones used to encode options. These two headers only differ in terms of how the options they contain are to be processed by devices; otherwise, they are formatted the same and used in the same way.

The two extension header types are:

- ☉ **Destination Options:** Contains options that are intended only for the ultimate destination of the datagram (and perhaps a set of routers specified in a Routing header, if present).
- ☉ **Hop-By-Hop Options:** Contains options that carry information for every device (router) between the source and destination

### IPv6 Option Format

Each of these header types has a one-byte *Next Header* field, and a one-byte *Header Extension Length* field that indicates the header's overall length. The rest of the header has one or more option fields. [Figure 109](#) illustrates the overall format of these two headers. The format of each option is similar to that of IPv4 options, and is shown in [Table 74](#).

**Table 74: IPv6 Option Format (Page 1 of 2)**

Subfield Name	Size (bytes)	Description																						
Option Type	1	<b>Option Type:</b> This field indicates the type of option. The bits are interpreted according to the following “sub-subfield” structure:																						
		<table><tr><th>Sub-Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr><tr><td rowspan="5">Unrecognized Option Action</td><td rowspan="5">2/8 (2 bits)</td><td>The first two bits specify what action should be taken if the device processing the option doesn't recognize the Option Type. The four values are:<table><tr><th>Value</th><th>Action on Unrecognized Option</th></tr><tr><td>00</td><td>Skip option; process rest of header.</td></tr><tr><td>01</td><td>Discard datagram; do nothing else.</td></tr><tr><td>10</td><td>Discard datagram and send an <a href="#">ICMP Parameter Problem message</a> with code 2 back to the datagram source.</td></tr><tr><td>11</td><td>Discard datagram and send the above ICMP message, only if destination was not a multicast address.</td></tr></table></td></tr><tr><td>Option Change Allowed Flag</td><td>1/8 (1 bit)</td><td>Set to 1 if the Option Data can change while the datagram is en route, or left at 0 if it cannot.</td></tr><tr><td>Remainder of Option Type</td><td>5/8 (5 bits)</td><td>Five remaining bits that allow the specification of 32 different combinations for each combination of the three bits above.</td></tr></table>	Sub-Subfield Name	Size (bytes)	Description	Unrecognized Option Action	2/8 (2 bits)	The first two bits specify what action should be taken if the device processing the option doesn't recognize the Option Type. The four values are: <table><tr><th>Value</th><th>Action on Unrecognized Option</th></tr><tr><td>00</td><td>Skip option; process rest of header.</td></tr><tr><td>01</td><td>Discard datagram; do nothing else.</td></tr><tr><td>10</td><td>Discard datagram and send an <a href="#">ICMP Parameter Problem message</a> with code 2 back to the datagram source.</td></tr><tr><td>11</td><td>Discard datagram and send the above ICMP message, only if destination was not a multicast address.</td></tr></table>	Value	Action on Unrecognized Option	00	Skip option; process rest of header.	01	Discard datagram; do nothing else.	10	Discard datagram and send an <a href="#">ICMP Parameter Problem message</a> with code 2 back to the datagram source.	11	Discard datagram and send the above ICMP message, only if destination was not a multicast address.	Option Change Allowed Flag	1/8 (1 bit)	Set to 1 if the Option Data can change while the datagram is en route, or left at 0 if it cannot.	Remainder of Option Type	5/8 (5 bits)	Five remaining bits that allow the specification of 32 different combinations for each combination of the three bits above.
		Sub-Subfield Name	Size (bytes)	Description																				
		Unrecognized Option Action	2/8 (2 bits)	The first two bits specify what action should be taken if the device processing the option doesn't recognize the Option Type. The four values are: <table><tr><th>Value</th><th>Action on Unrecognized Option</th></tr><tr><td>00</td><td>Skip option; process rest of header.</td></tr><tr><td>01</td><td>Discard datagram; do nothing else.</td></tr><tr><td>10</td><td>Discard datagram and send an <a href="#">ICMP Parameter Problem message</a> with code 2 back to the datagram source.</td></tr><tr><td>11</td><td>Discard datagram and send the above ICMP message, only if destination was not a multicast address.</td></tr></table>	Value			Action on Unrecognized Option	00	Skip option; process rest of header.	01	Discard datagram; do nothing else.	10	Discard datagram and send an <a href="#">ICMP Parameter Problem message</a> with code 2 back to the datagram source.	11	Discard datagram and send the above ICMP message, only if destination was not a multicast address.								
				Value	Action on Unrecognized Option																			
00	Skip option; process rest of header.																							
01	Discard datagram; do nothing else.																							
10	Discard datagram and send an <a href="#">ICMP Parameter Problem message</a> with code 2 back to the datagram source.																							
11	Discard datagram and send the above ICMP message, only if destination was not a multicast address.																							
Option Change Allowed Flag	1/8 (1 bit)	Set to 1 if the Option Data can change while the datagram is en route, or left at 0 if it cannot.																						
Remainder of Option Type	5/8 (5 bits)	Five remaining bits that allow the specification of 32 different combinations for each combination of the three bits above.																						

Table 74: IPv6 Option Format (*Page 2 of 2*)

Subfield Name	Size (bytes)	Description
<b>Opt Data Len</b>	1	<b>Option Data Length:</b> Specifies the length of the <i>Option Data</i> subfield below. Note that this is a change in semantics from IPv4, where the length field indicated the size of the entire option; in IPv6 the length of the <i>Option Type</i> and <i>Option Data Length</i> fields are not included.
<b>Option Data</b>	Variable	<b>Option Data:</b> The data to be sent as part of the option, which is specific to the option type. Also sometimes referred to as the <i>Option Value</i> .

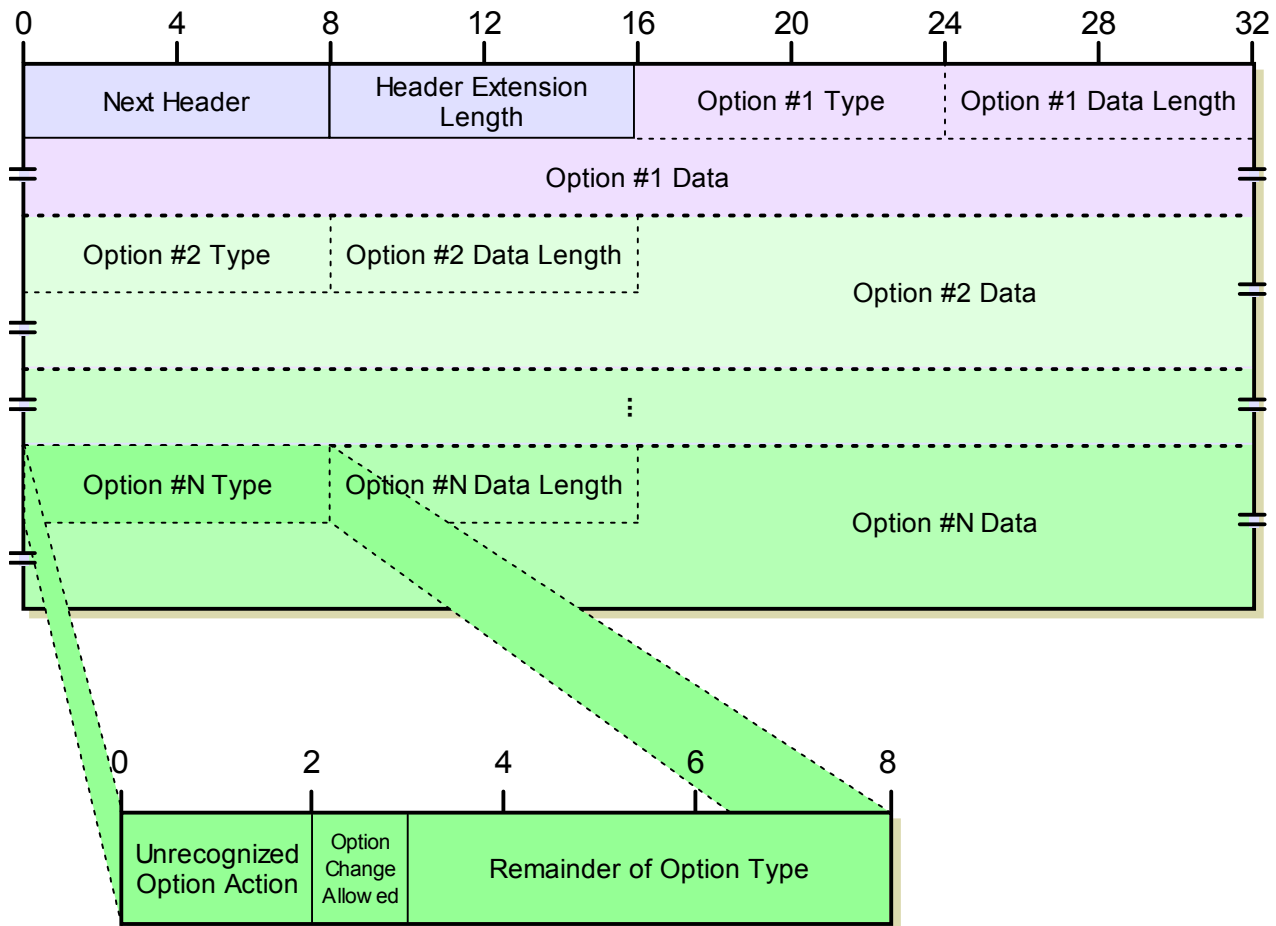

Figure 109: IPv6 *Hop-By-Hop Options* and *Destination Options* Header Formats

Each of these extension headers begins with two fixed fields, *Next Header* and *Header Extension Length*. The rest of the header consists of a sequence of variable-length options. Each option has the structure shown in [Table 74](#), consisting of a type / length / value triplet.

**Note:** The *Option Type* subfield is a bit strange in terms of how it is interpreted. Even though it has a substructure with three sub-subfields as shown in [Table 74](#), that structure is “informal”. What I mean by this is that the 8 bits of this field are taken as a single entity. Despite the special meaning of the three highest-order bits, the **entire field** is called the *Option Type*, not just the last five bits, and the whole is used as a single value from 0 to 255. In fact, the “sub-subfield” names aren't even specified in the standard; I made them up to help explain these fields.

---

Since each option has a subfield for type, length and value (data), they are sometimes said to be *TLV-encoded*. If there are multiple options, they are placed one after each other in the header. At the end of all the options in a *Hop-By-Hop Options* or *Destination Options* extension header, padding may be placed to ensure that the header is a multiple of 8 bytes in length.

**Key Concept:** Two IPv6 extension header types, *Hop-By-Hop Options* and *Destination Options*, are used to carry arbitrary optional information in IPv6 datagrams. Each consists of a set of variable-length options that are defined using three subfields indicating the option's type, length and value.

---

---

## **IPv6 Datagram Size, Maximum Transmission Unit (MTU), Fragmentation and Reassembly**

The job of the Internet Protocol is to convey messages across an internet of connected networks. When datagrams are sent between hosts on distant networks they are carried along their journey by routers, one hop at a time, over many physical network links. On each step of this journey the datagram is encoded in a data link layer frame for transmission.

### ***Overview of IPv6 Datagram Sizing and Fragmentation***

In order for a datagram to be successfully carried along a route, its size must be small enough to fit within the lower-layer frame at each step on the way. The term *maximum transmission unit (MTU)* describes the size limit for any given physical network. If a datagram is too large for the MTU of a network, it must be broken into pieces, a process called *fragmentation*, and then the pieces *reassembled* at the destination device. This has been a requirement since IPv4, and [I explain the concepts and issues related to datagram size, MTUs, fragmentation and reassembly in detail in a section devoted to these matters in IPv4](#).

All of these issues apply to sending datagrams in IPv6 as much as they did in IPv4. However, as in other areas of the protocol, some important details of how fragmentation and reassembly are done have changed. These changes were made to improve the efficiency of the routing process, and also to reflect the realities of current networking technologies: most can handle average IP datagrams without needing fragmentation.

The most important differences between IPv4 and IPv6 with respect to datagram size, MTU, fragmentation and reassembly are:

- ④ **Increased Default MTU:** In IPv4, the minimum MTU that routers and physical links were required to handle was 576 bytes. In IPv6, all links must handle a datagram size of at least 1280 bytes. This more-than-doubling in size improves efficiency by increasing the ratio of maximum payload to header length, and reduces the frequency with which fragmentation is required.
- ④ **Elimination of En Route Fragmentation:** In IPv4, datagrams may be fragmented by either the source device, or by routers during delivery. In IPv6, only the source node can fragment; routers do not. The source must therefore fragment to the size of the smallest MTU on the route before transmission. This has both advantages and disadvantages, as we will see. Reassembly is of course still done only by the destination, as in IPv4.
- ④ **MTU Size Error Feedback:** Since routers cannot fragment datagrams, they must drop them if they are forced to try to send a too-large datagram over a physical link. A feedback process has been defined using ICMPv6 that lets routers tell source devices that they are using datagrams that are too large for the route.
- ④ **Path MTU Discovery:** Since source devices must decide on the correct size of fragments, it is helpful if they have a mechanism for determining what this should be. This capability is provided through a special technique called *Path MTU Discovery*, which was originally defined for IPv4 but has been refined for IPv6.

- 
- ☉ **Movement of Fragmentation Header Fields:** To reflect the decreased importance of fragmentation in IPv4, the permanent fields related to the process that were in the IPv4 header have been farmed out to a *Fragment* extension header, included only when needed.

### ***Implications of IPv6's "Source Only" Fragmentation Rule***

I find the changes in the fragmentation and reassembly process interesting. While many other changes in IPv6 represent a shift in “responsibility” for functions from host devices to routers, this one is the opposite. In IPv4, a source node can really send a datagram of any size its local link can handle, and let the routers take care of fragmenting it as needed. This seems like a sensible model; nodes communicate on a large “virtual” network and the details of splitting messages as needed for physical links are handled invisibly.

The problem with this is that it represents a performance drag on routing. It is much faster for a router to forward a datagram intact than to spend time fragmenting it. In some cases, fragmentation would have to occur multiple times during transmission of a datagram, and remember that this must happen for **every** datagram on a route. It is a lot more efficient for the source to just send datagrams that are the right size in the first place.

### ***Determining the Appropriate Datagram Size***

Of course, there's a problem here: how does the source know what size to use? It has no idea of the physical networks used by the route datagrams will take to a destination; in fact, it doesn't even know what the routes **are**! It has two choices:

1. **Use Default MTU:** The first option is simply to use the default MTU of 1280, which all physical networks must be able to handle. This is a good choice especially for short communications or for sending small amounts of data.
2. **Use Path MTU Discovery:** The alternative is to make use of the *Path MTU Discovery* feature, described below. This method, defined in RFC 1981, defines a method whereby a node sends messages over a route to determine what the overall minimum MTU for the path is, in a technique very similar to [how it is done in IPv4](#).

Since routers can't fragment in IPv6, if a datagram is sent by a source that is too large for a router, it must drop the datagram. It will then send back to the source feedback about this occurrence, in the form of an [ICMPv6 Packet Too Big](#) message. This tells the source that its datagram was dropped and that it must fragment (or reduce the size of its fragments.)

This feedback mechanism is also used in discovering path MTUs. The source node sends a datagram that has the MTU of its local physical link, since that represents an upper bound on the MTU of the path. If this goes through without any errors, it knows it can use that value for future datagrams to that destination. If it gets back any *Packet Too Big* messages, it tries again using a smaller datagram size. The advantage of this over the default of 1280 is that it may allow a large communication to proceed with a higher MTU, to improve performance.

---

One drawback of the decision to only fragment at the source is that it introduces the potential for problems if there is more than one route between devices or if routes change. In IPv4, fragmentation is dynamic and automatic; it happens on its own and adjusts as routes change. Path MTU Discovery is a good feature, but it is static. It requires that hosts keep track of MTUs for different routes, and update them regularly. This is done by redoing path MTU discovery if a node receives a *Packet Too Big* message on a route for which it has previously performed path MTU discovery, but this takes time.

**Key Concept:** In IPv6 fragmentation is only performed by the device sending a datagram, not by routers. If a router encounters a datagram too large to send over a physical network with a small MTU, the router sends an ICMPv6 *Packet Too Big* message back to the source of the datagram. This can be used as part of a process called *Path MTU Discovery* to determine the minimum MTU of an entire route.

---

### **IPv6 Fragmentation Process**

The actual mechanics of fragmentation in IPv6 are similar to those in IPv4, with the added complication that extension headers must be handled carefully. For purposes of fragmentation, IPv6 datagrams are broken into two pieces:

- 🕒 **Unfragmentable Part:** This includes the main header of the original datagram, as well as any extension headers that need to be present in each fragment. This means the main header, and any of the following headers if present: *Hop-By-Hop Options*, *Destination Options* (for those options to be processed by devices along a route) and *Routing*.
- 🕒 **Fragmentable Part:** This includes the data portion of the datagram, along with the other extension headers if present—*Authentication Header*, *Encapsulating Security Payload* and/or *Destination Options* (for options to be processed only by the final destination).

The *Unfragmentable Part* must be present in each fragment, while the fragmentable part is split up amongst the fragments. So to fragment a datagram, a device creates a set of fragment datagrams, each of which contains the following, in order:

1. **Unfragmentable Part:** The full *Unfragmentable Part* of the original datagram, with its *Payload Length* changed to the length of the fragment datagram.
2. **Fragment Header:** A *Fragment* header with the *Fragment Offset*, *Identification* and *M* flags set in the same way they are used in IPv4.
3. **Fragment:** A fragment of the *Fragmentable Part* of the original datagram.

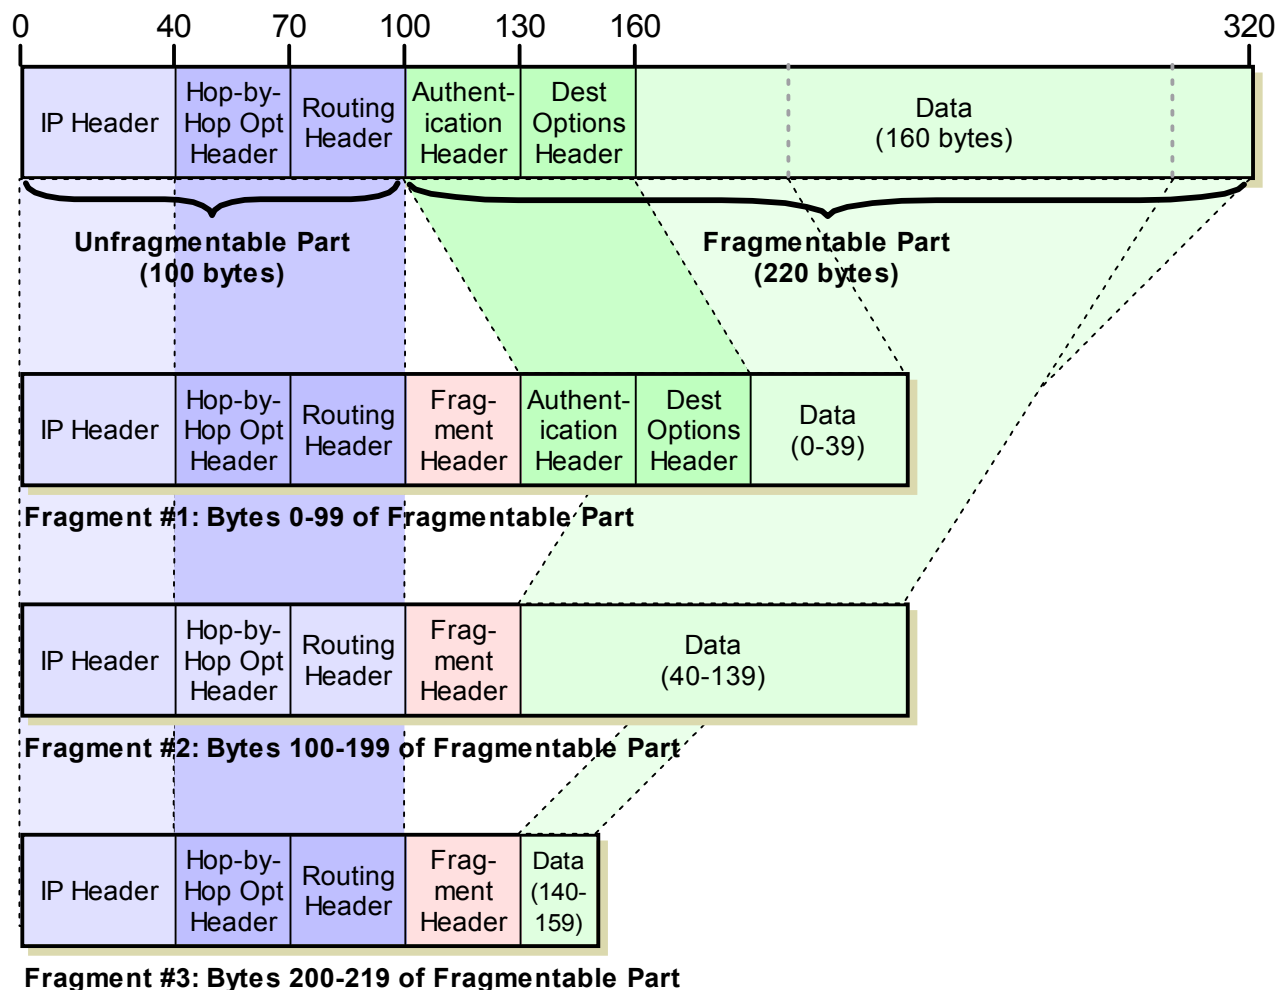

**Key Concept:** Fragmentation is done in IPv6 in a manner similar to that of IPv4, except that extension headers must be handled specially. Certain extension headers are considered *unfragmentable* and appear in each fragment; others are fragmented along with the data.

---

## IPv6 Fragmentation Example

Let's take an example to illustrate how IPv6 fragmentation works (see [Figure 110](#)). Suppose we have an IPv6 datagram exactly 320 bytes wide, consisting of a 40-byte IP header, four 30-byte extension headers, and 160 bytes of data. Two of the extension headers are unfragmentable, while two are fragmentable. (In practice we would never need to fragment such a small datagram but I am trying to keep the numbers simple.) Suppose we need to send this over a link with an MTU of only 230 bytes. We would actually require three fragments, not the two you might expect, because of the need to put the two 30-byte unfragmentable extension headers in each fragment. Here is how the fragments would be structured:

**Figure 110: IPv6 Datagram Fragmentation**

In this illustration, a 320-byte IPv6 datagram, containing four 30-byte extension headers, is broken into three fragments. The sizes of the fields are shown to scale. The *Unfragmentable Part*, shown in blue, begins each fragment, followed by the *Fragment* header. Then, portions of the *Fragmentable Part* are placed into each fragment in sequence. The *Authentication* and *Destination Options* extension headers are part of the *Fragmentable Part* so they appear as part of the first fragment.

- 
1. **First Fragment:** The first fragment would consist of the 100-byte *Unfragmentable Part*, followed by a 30-byte *Fragment* header and the first 100 bytes of the *Fragmentable Part* of the original datagram. This would contain the two fragmentable extension headers and the first 40 bytes of data. This leaves 120 bytes of data to send.
  2. **Second Fragment:** This would also contain the 100-byte *Unfragmentable Part*, followed by a *Fragment* header and 100 bytes of data (bytes 40 to 139). This would leave 20 bytes of data remaining.
  3. **Third Fragment:** The last fragment would contain the 100-byte *Unfragmentable Part*, a *Fragment* header and the final 20 bytes of data.

The “M” (*More Fragments*) flag would be set to one in the first two fragments and zero in the third, and the *Fragment Offset* values would be set appropriately. [See the topic on IPv4 fragmentation for more on how these fields are used.](#)

The receiving device reassembles by taking the *Unfragmentable Part* from the first fragment and then assembling the *Fragment* data from each fragment in sequence.

---

## IPv6 Datagram Delivery and Routing

IP functions such as addressing, datagram encapsulation and if necessary, fragmentation and reassembly, all lead up to the ultimate objective of the protocol: the actual *delivery* of datagrams from a source device to one or more destination devices.

### ***Unchanged Aspects of Datagram Delivery and Routing in IPv6***

Most of the concepts related to how datagram delivery is accomplished in IPv6 are [the same as in IPv4](#):

- ☉ Datagrams are delivered directly when the source and destination nodes are on the same network. When they are on different networks, delivery is indirect using routing to the destination's network, and then direct to the destination.
- ☉ [Routing](#) is performed by looking at IP addresses and determining which portion is the network ID and which the host ID. IPv6 does this in the same basic way as in classless IPv4, despite the fact that IPv6 unicast addresses are assigned using a special hierarchical format.
- ☉ [Routing is still done on a next-hop basis](#), with sources generally not knowing how datagrams get from Point A to Point B.
- ☉ Routing is performed by devices called *routers* that maintain [tables of routes](#) that tell them where to forward datagrams to reach different destination networks.
- ☉ [Routing protocols](#) are used to allow routers to exchange information about routes and networks.

### ***Changes in Datagram Delivery and Routing in IPv6***

Most of the changes in routing in IPv6 are directly related to changes that we have seen in other areas of the protocol. Some of the main issues of note related to routing and routers in IPv6 include the following:

- ☉ **Hierarchical Routing and Aggregation:** One of the goals of the structure used for organizing unicast addresses was to improve routing. The [unicast addressing format](#) is designed to provide a better match between addresses and Internet topology, and to facilitate route aggregation. Classless addressing using CIDR in IPv4 was an improvement, but lacked any formal mechanism for creating a scalable hierarchy.
- ☉ **Scoped Local Addresses:** [Local-use addresses](#) including site-local and link-local are defined in IPv6, and routers must be able to recognize them. They must route them or *not* route them when appropriate. Multicast addresses also have various levels of scope.
- ☉ **Multicast and Anycast Routing:** [Multicast](#) is standard in IPv6, not optional as in IPv4, so routers must support it. [Anycast addressing](#) is a new type of addressing in IPv6.
- ☉ **More Support Functions:** Capabilities must be added to routers to support new features in IPv6. For example, routers play a key role in implementing [serverless autoconfiguration](#) and [path MTU discovery](#) in the new IPv6 fragmentation scheme.
- ☉ **New Routing Protocols:** Routing protocols such as [RIP](#) must be updated to support IPv6.

- 
- ☛ **Transition Issues:** Last but certainly not least, routers play a major role in supporting [the transition from IPv4 to IPv6](#). They will be responsible for connecting together IPv6 “islands” and performing translation to allow IPv4 and IPv6 devices to communicate with each other during the multi-year migration to the new protocol.

---

## **IP Network Address Translation (NAT) Protocol**

To help extend the life of the [IPv4 addressing scheme](#) while the newer [IPv6 protocol](#) is developed and deployed, other technologies have been developed. One of the most important of these is *IP Network Address Translation*. This technology allows a small number of public IP addresses to be shared by a large number of hosts using private addresses. This essential little “trick” allows the global Internet to actually have far more hosts on it than its address space would normally support. At the same time, it provides some security benefits by making hosts more difficult to address directly by foreign machines on the public Internet.

In this section I provide a description of the concepts behind IP NAT and an explanation of operation of IP NAT types. I begin with an overview of the protocol and discussion of its advantages and disadvantages. I describe the address terminology that you need to know to understand how NAT functions and the differences between various translation techniques. I explain the way that address mappings are performed and the difference between static and dynamic address mapping.

I then explain the operation of the four main types of NAT:

1. *Unidirectional NAT* (also called outbound or traditional NAT)
2. *Bidirectional* (inbound or “two-way”) *NAT*
3. *Port-Based* or “*Overloaded*” *NAT* (also called *NAPT* or *PAT*)
4. “*Overlapping*” *NAT* (also called “*Twice NAT*”).

I conclude with a bit more information on compatibility issues associated with NAT.

Incidentally, most people just call this technology “Network Address Translation” without the “IP”. However, this sounds to me rather generic, and since the version being discussed here is specific to IP, I prefer to make it clear that this is an IP feature. That said, for simplicity I often just say “NAT” too, since that’s shorter. I should also point out that there are quite a few people who don’t consider NAT to be a “protocol” in the strictest sense of the word.

**Note:** NAT was developed in large part to deal with the address shortage problem in IPv4, so it is associated and used with IPv4. It is possible to implement an IPv6-compatible version of NAT, but address translation isn’t nearly as important in IPv6, which was designed to give every TCP/IP device its own unique address. For this reason I focus in this section on the use of NAT with IPv4.

---

## **IP NAT Overview, Motivation, Advantages and Disadvantages**

The decision to make IP addresses only 32 bits long as part of the original design of the Internet Protocol led to a serious problem when the Internet exploded in popularity beyond anyone’s expectations: [exhaustion of the address space](#). [Classless addressing](#) helped

---

make better use of the address space, and IPv6 was created to ensure that we will never run out of addresses again. However, classless addressing has only slowed the consumption of the IPv4 address space, and IPv6 has taken years to develop and will require years more to deploy.

The shortage of IP addresses promised to grow critical by the end of the 1990s unless some sort of solution was implemented until the transition to IPv6 was completed. Creative engineers on the [Internet Engineering Task Force \(IETF\)](#) were up to the challenge. They created a technique that would not only forestall the depletion of the address space but could also be used to address two other growing issues in the mid-to-late 1990s:

- ① **Increasing Cost of IP Addresses:** As any resource grows scarce, it becomes more expensive. Even when IP addresses were available, it cost more to get a larger number from a service provider than a smaller number. It was desirable to conserve them not only for the sake of the Internet as a whole, but to save money.
- ② **Growing Concerns Over Security:** As Internet use increased in the 1990s, more “bad guys” started using the network also. The more machines a company had directly connected to the Internet, the greater their potential exposure to security risks.

### ***Indirect Internet Connectivity***

One solution to the problems of IP address space and security was to set up a system where a company's network was not connected directly to the Internet, but rather ***indirectly***. Setting up a network this way is possible due to several important characteristics of how most organizations use the Internet:

- ① **Most Hosts Are Client Devices:** The Internet is client/server based, and the majority of hosts are clients. Client devices generally don't need to be made publicly accessible. For example, when using your local PC to access the World Wide Web, you issue requests to servers and they respond back, but servers don't have any reason to try to initiate contact with you. Most correspondence is begun by clients and not servers, by definition.
- ② **Few Hosts Access The Internet Simultaneously:** When you have a large number of hosts on the same network connected to the Internet, at any given time usually only a small number of them are trying to access the 'net. It isn't necessary to assume they will all need to access servers at once. Even while you actively browse the Web, you pause for a number of seconds to read information from time to time; you are only accessing the Web server for the time it takes to perform a transaction.
- ③ **Internet Communications Are Routed:** Communications between an organization's network and the Internet go through a router, which acts as a “control point” for traffic flows.

The best way to explain why these attributes matter is to draw an analogy to how telephones are used in an organization, because many of the same attributes apply there. Most of the telephones in a typical organization are used to let employees make phone calls out. Usually there is no need to have any way to call employees directly; instead one system or person can handle all incoming calls. Only a few employees are ever making a call to the “outside world” at any given time. And all calls are routed through a central point that manages the telephone system.

---

For these reasons, to save money, organizations don't run separate public telephone lines to every employee's desk. Instead, it sets up a telephone system where each employee gets an *extension*, which is basically a local telephone number valid only within the organization. A small number of outside lines is made available in a pool for employees to share, and the telephone system matches the inside extensions to the outside lines as needed. A voice mail system and/or human receptionist handle routing of calls in to the organization.

(Yes, some companies have a direct mapping between extension numbers and real telephone numbers. Don't make trouble. ☺)

### **Overview of IP Network Address Translation (NAT)**

A very similar technique can be used for connecting an organization's computers to the Internet. In TCP/IP networks, this technology was first formalized in RFC 1631, *The IP Network Address Translator (NAT)*, adopted in May 1994. The word “translator” refers to the device (router) that implements NAT. More commonly, the technology as a whole is called *IP Network Address Translation (IP NAT or NAT)*.

**Note:** The document status of RFC 1631 is “informational”. This means that technically, IP NAT is not an official Internet standard.

---

A basic implementation of NAT involves setting up an organization's internal network using one of the [private addressing ranges set aside for local IP networks](#). One or more public (Internet) addresses are also assigned to the organization as well, and one or more NAT-capable routers are installed between the local network and the public Internet. The public IP addresses are like “outside lines” in the telephone system, and the private addresses are like “internal extensions”.

The NAT router plays the role of telephone system computer and receptionist. It maps internal extensions to outside lines as needed, and also handles “incoming calls” when required. It does this by not just routing IP datagrams but **modifying** them as needed, translating addresses in datagrams from the private network into public addresses for transmission on the Internet, and back again.

Over time, newer versions of NAT have also been created that solve other problems or provide additional capabilities. *Port-Based NAT* allows sharing of even more hosts on a limited number of IP addresses, by letting two or more devices share one IP address at a time. So-called “*Twice NAT*” helps with the implementation of virtual private networks (VPN) by translating both source and destination addresses in both incoming and outgoing datagrams.

**Key Concept:** *IP Network Address Translation (IP NAT or NAT)* is a technique that allows an organization to set up a network using private addresses, while still being able to communicate on the public Internet. A NAT-capable router translates private to public addresses and vice-versa as needed. This allows a small number of public IP addresses to be shared amongst a large number of devices, and provides other benefits as well (but also has some drawback).

---

### ***Advantages of NAT***

NAT is one of those technologies that has a long list of both advantages **and** disadvantages. This means it can be extremely useful in a variety of scenarios, but also problematic in others. The main advantages are:

- ☉ **Public IP Address Sharing:** A large number of hosts can share a small number of public IP addresses. This saves money and also conserves IP address space.
- ☉ **Easier Expansion:** Since local network devices are privately addressed and a public IP address isn't needed for each one, it is easy to add new clients to the local network.
- ☉ **Greater Local Control:** Administrators get all the benefits of control that come with a private network, but can still connect to the Internet.
- ☉ **Greater Flexibility In ISP Service:** Changing the organization's Internet Service Provider (ISP) is easier because only the public addresses change. It isn't necessary to renumber all the client machines on the network.
- ☉ **Increased Security:** The NAT translation represents a level of indirection. Thus, it automatically creates a type of firewall between the organization's network and the public Internet. It is more difficult for any client devices to be accessed directly by someone malicious because the clients don't have publicly-known IP addresses.
- ☉ **(Mostly) Transparent:** NAT implementation is mostly transparent, because the changes take place in one or perhaps a few routers. The dozens or hundreds of hosts themselves don't need to be changed.

### ***Disadvantages of NAT***

The above are all good reasons to use NAT, but there are drawbacks to the technique as well. Some of these take away part of the benefit in certain items in the list above:

- ☉ **Complexity:** NAT represents one more complexity in setting up and managing the network. It also makes troubleshooting more confusing due to address substitutions.
- ☉ **Problems Due to Lack of Public Addresses:** Certain functions won't work properly due to lack of a "real" IP address in the client host machines.
- ☉ **Compatibility Problems With Certain Applications:** I said above that NAT was only **mostly** transparent. There are in fact compatibility issues with certain applications that arise because NAT "tinkers" with the IP header fields in datagrams but not in the application data. This means tools like [FTP](#), which pass IP addresses and port numbers in commands, must be specially handled, and some applications may not work.

- 
- ☉ **Problems With Security Protocols:** Protocols like [IPSec](#) are designed to detect modifications to headers and commonly balk at the changes that NAT makes, since they cannot differentiate those changes from malicious datagram “hacking”. It is still possible to combine NAT and IPSec, but this becomes more complicated.
  - ☉ **Poor Support for Client Access:** The lack of a public IP address for each client is a double-edged sword; it protects against hackers trying to access a host but also makes it difficult for legitimate access to clients on the local network. “Peer-to-peer” applications are harder to set up, and something like an organizational web site (accessed from the Internet as a whole) usually needs to be set up without NAT.
  - ☉ **Performance Reduction:** Each time a datagram transitions between the private network and the Internet, an address translation is required. In addition, other work must be done as well, such as recalculating header checksums. Each individual translation takes little effort but when you add it up, you are giving up some performance.

Many organizations feel that the advantages outweigh the disadvantages, especially if they do use the Internet in primarily a [client/server](#) fashion, as most do. For this reason NAT has become quite popular. One should always bear in mind, however, that the main problem that led to NAT is lack of address space. IPv6 fixes this problem, while NAT merely finds a clever “workaround” for it. For this reason, many people consider NAT a “kludge”. Once IPv6 is deployed, it will no longer be needed, and some folks don't like it even for IPv4. On the other hand, some feel its other benefits make it worthy of consideration even in IPv6.

---

**Note:** A “kludge” (or “kluge”) is something that is used to address a problem in an inelegant way, like hammering a nail using the side of an adjustable wrench. (I would never do such a thing, of course not...)

---

## **IP NAT Address Terminology**

As its name clearly indicates, IP Network Address Translation is all about the *translation* of IP addresses. When datagrams pass between the private network of an organization and the public Internet, one or more of the addresses in these datagrams are changed by the NAT router. This translation means that every transaction in a NAT environment involves not just a source address and a destination address, but potentially multiple addresses for each of the source and destination.

In order to make more clear the explanation of how NAT operates, several special designations have been developed to refer to the different types of addresses that can be found in an IP datagram when NAT is used. Unfortunately, the terminology used for addressing in NAT can be confusing, because it's hard to visualize what the differences are between the (often similar-sounding) names. However, without knowing what these addresses mean a proper understanding of NAT operation is impossible, so we need to start by explaining them.

---

## NAT Address Terms Based on Device Location (Inside/Outside)

The first way that addresses are differentiated is based on where in the network the device is that the address refers to:

- ☉ **Inside Address:** Any device on the organization's private network that is using NAT is said to be on the *inside network*. Thus, any address that refers to a device on the local network in any form is called an *inside* address.
- ☉ **Outside Address:** The public internet—that is, everything outside the local network—is considered the *outside network*. Any address that refers to a public Internet device is an *outside* address.

**Key Concept:** In NAT, the terms *inside* and *outside* are used to identify the **location** of devices. *Inside* addresses refer to devices on the organization's private network; *outside* addresses refer to devices on the public Internet.

---

## NAT Address Terms Based on Datagram Location (Local/Global)

An inside device always has an inside address; an outside device always has an outside address. However, there are two different ways of addressing either an inside or an outside device, depending on in which part of the network the address appears in a datagram:

- ☉ **Local Address:** This term describes an address that appears in a datagram on the inside network, **whether it refers to an inside or outside address**.
- ☉ **Global Address:** This term describes an address that appears in a datagram on the outside network, again **whether it refers to an inside or outside address**.

**Key Concept:** In NAT, the terms *local* and *global* are used to indicate in what network a particular **address** appears. *Local* addresses are used on the organization's private network (whether to refer to an inside device or an outside device); *global* addresses are used on the public Internet (again, whether referring to an inside or outside device).

---

## Combining Inside/Outside and Local/Global Address Designations

This is a bit confusing, so I will try to explain further. The NAT translating router has the job of interfacing the inside network to the outside network (the Internet). Inside devices need to be able to talk to outside devices and vice-versa, but inside devices can only use addressing consistent with the local network addressing scheme. Similarly, outside devices cannot use local addressing. Thus, both inside and outside devices can be referred to with local or global address versions. This yields four different specific address types:

- 
1. **Inside Local Address:** An address of a device on the local network, expressed using its normal local device representation. So for example, if we had a client on a network using the 10.0.0.0 private address block, and assigned it address 10.0.0.207, this would be its *inside local* address.
  2. **Inside Global Address:** This is a global, publicly-routable IP address used to represent an inside device to the outside world. In a NAT configuration, *inside global* addresses are those “real” IP addresses assigned to an organization for use by the NAT router.

Let's say that device 10.0.0.207 wants to send an HTTP request to an Internet server located at address 204.51.16.12. It forms the datagram using 10.0.0.207 as the source address. However, if this datagram is sent out to the Internet as is, the server cannot reply back because 10.0.0.207 is not a publicly-routable IP address. So the NAT router will translate 10.0.0.207 in the datagram into one of the organization's registered IP addresses, say it's 194.54.21.10. This is the *inside global* address that corresponds to 10.0.0.207. It will be used as the destination when the server sends its HTTP response. Note that in some situations the inside local address and outside local address may be the same.

3. **Outside Global Address:** An address of an external (public Internet) device as it is referred to on the global Internet. This is basically a regular, publicly-registered address of a device on the Internet. In the example above, 204.51.16.12 is an *outside global* address of a public server.
4. **Outside Local Address:** An address of an external device as it is referred to by devices on the local network. In some situations, this may be identical to the *outside global* address of that outside device.

### **Local/Global Address Designations from the Perspective of Device Location**

Phew, it's still confusing, isn't it? Let's try another way of looking at this. Of these four addresses, two types are the addresses as they are known “natively” by either an inside or outside device, while two are translated addresses:

- ☞ **Inside Device Designations:** For an inside device, the *inside local* address is its “normal” or “native” address. The *inside global* address is a translated address used to represent the inside device on the outside network, when necessary.
- ☞ **Outside Device Designations:** For an outside device, the *outside global* address is its “normal/native” address. The *outside local* address is a translated address used to represent the outside device on the inside network, when necessary.

So, what NAT does then is translate the identity of either inside or outside devices from local representations to global representations and vice-versa. Which addresses are changed, and how, depends on the specific type of NAT employed. For example, in traditional NAT, inside devices refer to outside devices using their proper (global) representation, so the outside global and outside local addresses of these outside devices are the same.

**Key Concept:** A NAT router translates *local* addresses to *global* ones, and vice-versa. Thus, an *inside local* address is translated to an *inside global* address (and vice-versa) and an *outside local* address is translated to an *outside global* address (and vice-versa).

---

### **Graphical Illustration of NAT Terminology**

And after all that... it's still confusing. ☺ One of the big problems is that the words “inside” and “local” are somewhat synonymous, as are “outside” and “global”, yet they mean different things in NAT. And the typical paradox in trying to explain networking concepts rears its ugly head here again: I wanted to define these addresses to make describing NAT operation easier, but find myself wanting to use an example of NAT operation to clarify how the addresses are used.

Even after writing this section I find these terms confusing, so I created [Figure 111](#), which shows this same terminology in graphical form and may be of some help. That diagram is also used as a template for the illustrations of each of the different types of NAT in subsequent topics, which use the same color coding for each of the four address types for consistency. As you read the topics that discuss NAT operation, remember to look back here if you want to double-check the meaning of address types. Don't get discouraged if it takes a couple of times to get the addresses straight.

### **IP NAT Static and Dynamic Address Mappings**

NAT allows us to connect a private (inside) network to a public (outside) network such as the Internet, by using an address translation algorithm implemented in a router that connects the two. Each time a NAT router encounters an IP datagram that crosses the boundary between the two networks it must translate addresses as appropriate. But how does it know what to translate, and what to use for the translated address?

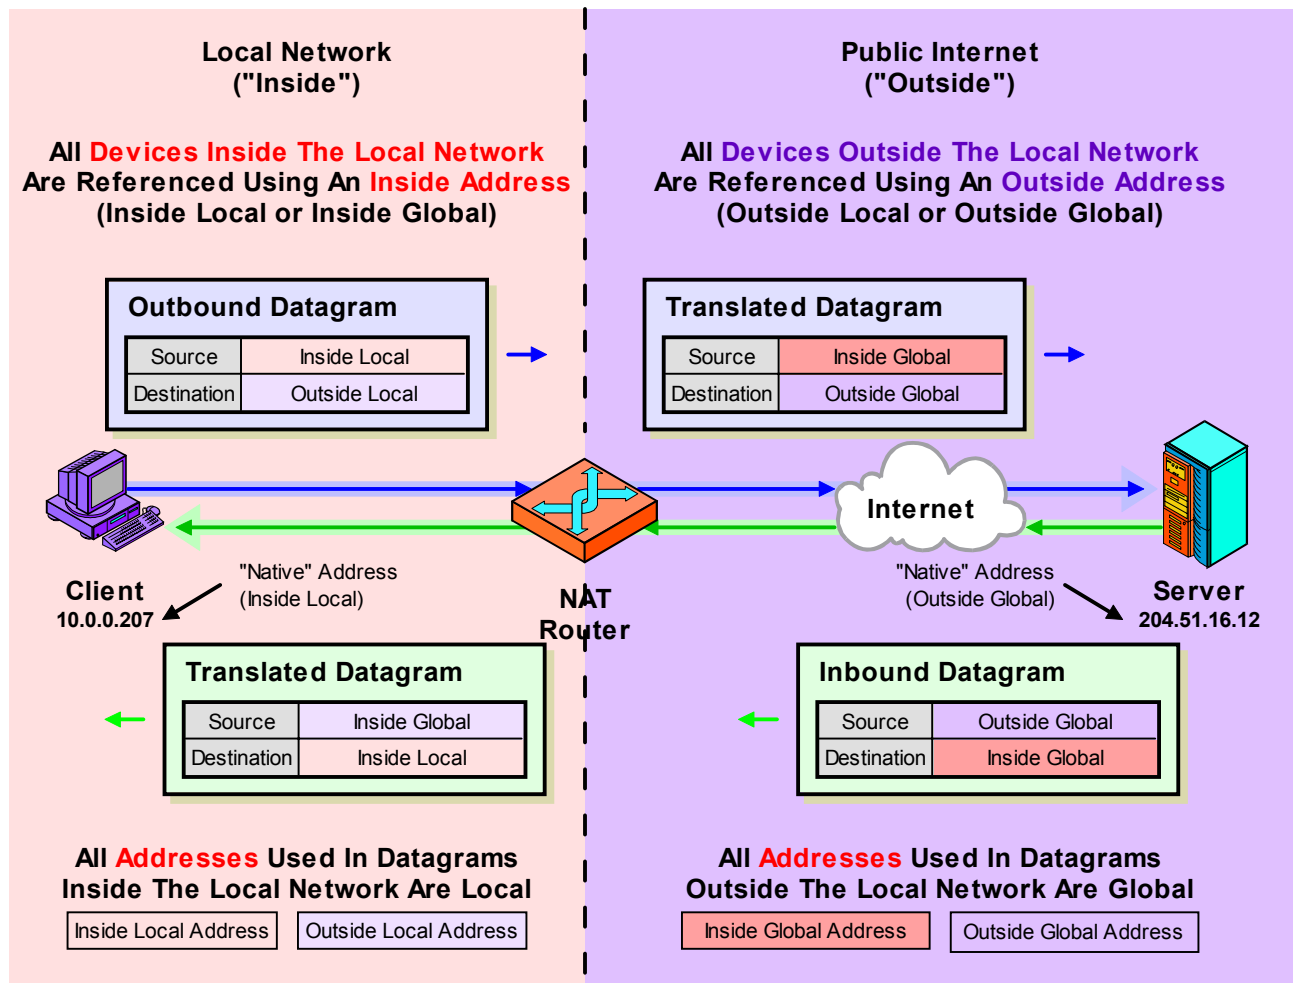

The NAT software in the router must maintain a *translation table* to tell it how to operate. The translation table contains information that maps the *inside local* addresses of internal devices (their regular addresses) to *inside global* address representations (the special public addresses used for external communication). It may also contain mappings between *outside global* addresses and *outside local* addresses for inbound transactions, if appropriate.

There are two basic ways that entries can be added to the NAT translation table.

#### **Static Mappings**

When static mappings are used, a permanent, fixed relationship is defined between a *global* and a *local* representation of the address of either an *inside* or an *outside* device. For example, we can use a static translation if we want the internal device with an *inside local*

**Figure 111: IP Network Address Translation (NAT) Terminology**

Hopefully this diagram will help you better understand the whole "inside/outside/local/global" thing. ☺

address of 10.0.0.207 to **always** use the *inside global* address of 194.54.21.10. Whenever 10.0.0.207 initiates a transaction with the Internet, the NAT router will replace that address with 194.54.21.10.

### Dynamic Mappings

With dynamic mappings, *global* and *local* address representations are generated automatically by the NAT router, used as needed, and then discarded. The most common way that this is employed is in allowing a *pool* of *inside global* addresses to be shared by a large number of *inside* devices.

For example, say we were using dynamic mapping with a pool of *inside global* addresses available from 194.54.21.1 through 194.54.21.20. When 10.0.0.207 sent a request to the Internet it would not automatically have its source address replaced by 194.54.21.10. One of the 20 addresses in the pool would be chosen by the NAT router. The router would then

---

watch for replies back using that address and translate them back to 10.0.0.207. When the session was completed, it would discard the entry to return the *inside global* address to the pool.

### ***Comparing Static and Dynamic Mappings***

The trade-offs between static and dynamic NAT mappings are pretty much the same as they always are when the choice is between “static” and “dynamic”; for example, the same issues arises in [ARP caching](#). Static mappings are permanent and therefore ideal for devices that need to be always represented with the same public address on the outside network. They may also be used to allow inbound traffic to a particular device; that is, for transactions initiated on the public network that send to a special server on the inside network. However, they require manual setup and maintenance, and they don't allow IP sharing on the internal network.

Dynamic mapping is normally used for regular clients in order to facilitate public IP address sharing, a prime goal of most NAT implementations. It is more complicated than static mapping, but once set up is automatic.

It is possible to mix dynamic and static mapping on the same system, of course. We can designate certain devices that are statically mapped and let the rest use dynamic mapping. We just have to make sure that the static mappings don't overlap with the pool used for dynamic assignment.

Incidentally, another way that dynamic mapping of global and local addressing is performed is through domain name resolution using [DNS](#). This is particularly common when external devices access internal hosts using bidirectional NAT (inbound transactions). Since hosts on the public Internet know nothing about the organization's private network, they issue a request for the DNS name of the device they want to access. This causes a NAT translation entry to be generated that maps the inside local public address of the host to an inside global address for use by those outside the network. [See the description of bidirectional NAT for more details on how this works.](#)

### **IP NAT Unidirectional (Traditional/Outbound) Operation**

Now that we understand [the motivation behind NAT and its pros and cons](#), and have also [covered NAT address terminology](#) and [translation table creation](#), it's time to get down to the nitty gritty of how it works. There are many different flavors of NAT, and four common ones are covered in this Guide. It makes sense to start by looking at the original variety of NAT described in RFC 1631. This is the simplest NAT method and therefore the easiest one to explain.

NAT was of course designed to allow hosts on a private network to share public IP addresses in accessing an Internet. Since most hosts are clients that initiate transactions, NAT was designed under the assumption that a client/server request/response communication would begin with a datagram sent from the *inside* network to the *outside*. For this

---

reason, this first type of NAT is sometimes called *Unidirectional* or *Outbound* NAT. Since it is the oldest flavor it is also now called *Traditional* NAT, to differentiate it from newer varieties.

### ***Unidirectional NAT Example***

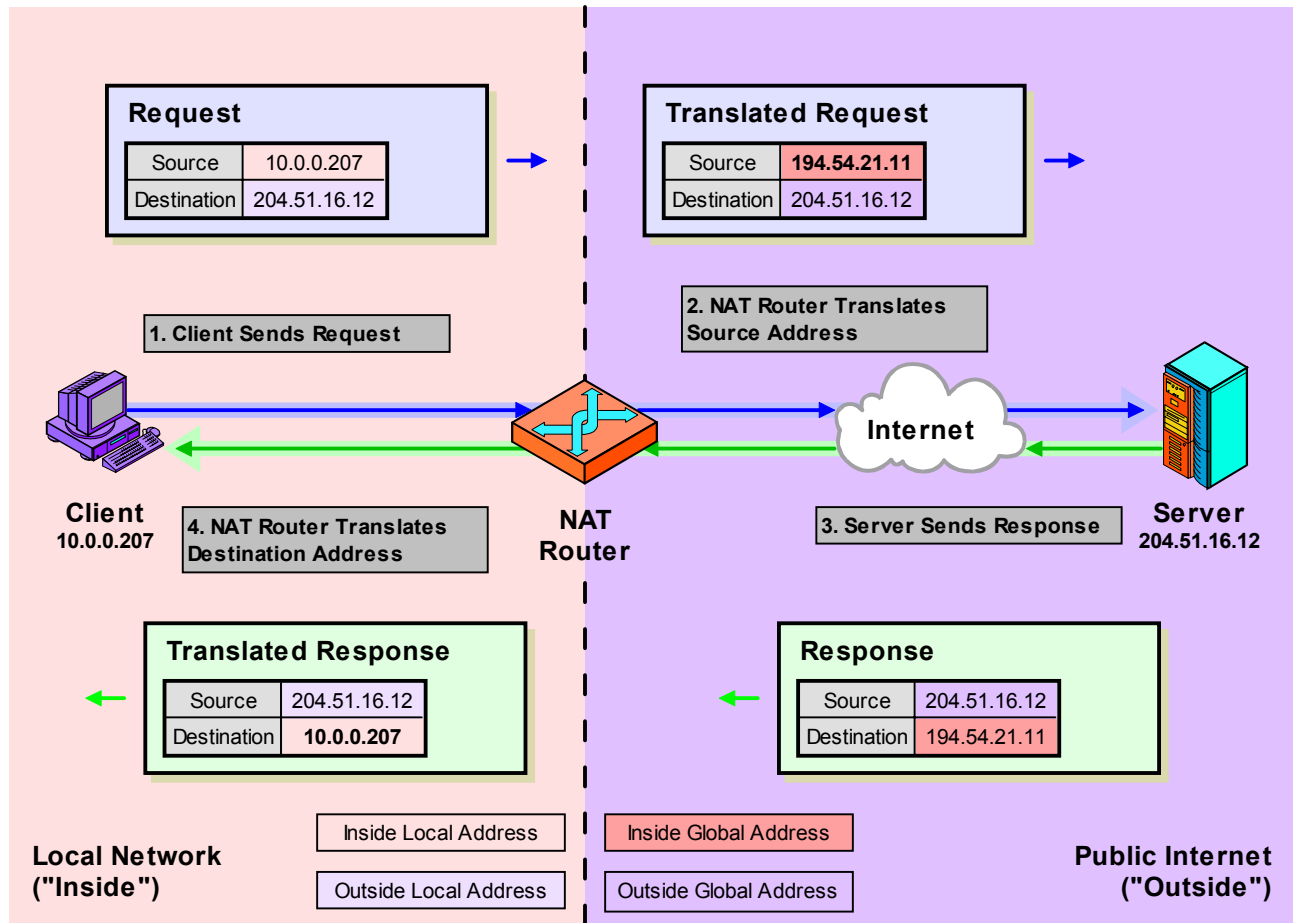

To show how unidirectional NAT works, we will of course use an example. Explaining things is always easier with examples, especially when it is a confusing thing like NAT. Let's use the same numbers from the previous two topics. We'll assume the inside network has 250 hosts that use private (inside local) addresses from the 10.0.0.0/8 address range (which I selected because it has small numbers!) These hosts use dynamic NAT sharing a pool of 20 inside global addresses from 194.54.21.1 through 194.54.21.20.

In our example, device 10.0.0.207 wants to access the World Wide Web server at public address 204.51.16.12. [Table 75](#) shows the four basic steps that are involved in this (simplified) transaction. I did this in table form instead of bullet points so I could show you explicitly what happens to the addresses in both the request datagram (in steps #1 and #2) and the response datagram (steps #3 and #4). I have also highlighted the translated address values for clarity, and provided [Figure 112](#), which shows the process graphically.

**Table 75: Operation Of Unidirectional (Traditional/Outbound) NAT**

Step #	Description	Data-gram Type	Datagram Source Address	Datagram Destination Address
1	<b>Inside Client Generates Request And Sends To NAT Router:</b> Device 10.0.0.207 generates an HTTP request that is eventually passed down to IP and encapsulated in an IP datagram. The source address is itself, 10.0.0.207, and the destination is 204.51.16.12. The datagram is sent to the NAT-capable router that connects the organization's internal network to the Internet.	<b>Request</b> (from inside client to outside server)	10.0.0.207 ( <i>Inside Local</i> )	204.51.16.12 ( <i>Outside Local</i> )
2	<b>NAT Router Translates Source Address and Sends To Outside Server:</b> The NAT router realizes that 10.0.0.207 is an <i>inside local</i> address and knows it must substitute an <i>inside global</i> address in order to let the public Internet destination respond. It consults its pool of addresses and sees the next available one is 194.54.21.11. It changes the source address in the datagram from 10.0.0.207 to 194.54.21.11. The destination address is not translated in traditional NAT. In other words, the <i>outside local</i> address and <i>outside global</i> address are the same.  The NAT router puts the mapping from 10.0.0.207 to 194.54.21.11 into its translation table. It sends out the modified datagram, which is eventually routed to the server at 204.51.16.12.		194.54.21.11 ( <i>Inside Global</i> )	204.51.16.12 ( <i>Outside Global</i> )
3	<b>Outside Server Generates Response And Sends Back To NAT Router:</b> The server at 204.51.16.12 generates an HTTP response. It of course has no idea that NAT was involved; it sees 194.54.21.11 in the request sent to it, so that's where it sends back the response. It is then routed back to the original client's NAT router.	<b>Response</b> (from outside server to inside client)	204.51.16.12 ( <i>Outside Global</i> )	194.54.21.11 ( <i>Inside Global</i> )
4	<b>NAT Router Translates Destination Address And Delivers Datagram To Inside Client:</b> The NAT router sees 194.54.21.11 in the response that arrived from the Internet. It consults its translation table and knows this datagram is intended for 10.0.0.207. This time the destination address is changed but not the source. It then delivers the datagram back to the originating client.		204.51.16.12 ( <i>Outside Local</i> )	10.0.0.207 ( <i>Inside Local</i> )

As you can see, this really isn't rocket science, and it's fairly easy to understand what is going on as soon as you get used to the terminology and concepts. In unidirectional NAT the source address is translated on outgoing datagrams and the destination address on

**Figure 112: Operation Of Unidirectional (Traditional/Outbound) NAT**

The four steps in this process can be seen by following the steps in clockwise order. Translated addresses are shown in bold. Please refer to [Table 75](#) for an explanation of the steps in this diagram, or to [Figure 111](#) for an explanation of the four address types.

incoming ones. Traditional NAT only supports this sort of *outbound* transaction, which is started by a device on the inside network. It cannot handle a device on the public Internet sending a request to a private address.

### Other Functions of the Router in NAT

Also note that even though I am focusing on the changes that the NAT router makes to addresses, it also has to make other changes to the datagram. Changing any field in the IP header means that the *IP Header Checksum* field will need to be recalculated. UDP and TCP checksums need to be recalculated, and depending on the nature of the data in the datagram, other changes may also be required. [I discuss these issues in the topic on NAT compatibility issues.](#)

This simplified example assumes the existence of just one router between the private and public networks. It is possible to have more than one router between these networks. If this configuration is used, however, it is essential that they both use the same translation table. Otherwise, if the request is processed by router R1 but the response received by router R2,

---

R2 won't know how to translate back the destination address on the incoming datagram. Of course, this makes dynamic mapping extremely difficult: routers would have to coordinate their address mappings.

**Key Concept:** In *unidirectional (traditional)* NAT, the NAT router translates the source address of an outgoing request from *inside local* to *inside global* form. It then transforms the destination address of the response from *inside global* to *inside local*. The *outside local* and *outside global* addresses are the same in both request and reply.

---

## IP NAT Bidirectional (Two-Way/Inbound) Operation

**Traditional NAT** is designed to handle only *outbound* transactions; clients on the local network initiate requests and devices on the Internet send back responses. However, in some circumstances, we may want to go in the opposite direction. That is, we may want to have a device on the outside network initiate a transaction with one on the inside. To permit this, we need a more capable type of NAT than the traditional version. This enhancement goes by various names, most commonly *Bidirectional NAT*, *Two-Way NAT* and *Inbound NAT*. All of these convey the concept that this kind of NAT allows both the type of transaction we saw in the previous topic and also transactions initiated from the outside network.

### ***The Problem With Inbound NAT: Hidden Addresses***

Performing NAT on inbound transactions is more difficult than conventional outbound NAT. To understand why, remember that the network configuration when using NAT is inherently **asymmetric**: the inside network generally knows the IP addresses of outside devices, since they are public, but the outside network doesn't know the private addresses of the inside network. Even if they did know them, they could never be specified as the target of an IP datagram initiated from outside since they are **not routable**—there would be no way to get them to the private network's local router.

Why does this matter? Well, consider the case of outbound NAT from device A on the inside network to device B on the outside. The local client, A, always starts the transaction, so device A's NAT router is able to create a mapping between device A's inside local and inside global address during the request. Device B is the recipient of the already-translated datagram, so the fact that device A is using NAT is hidden. Device B responds back and the NAT router does the reverse translation without device B ever even knowing NAT was used for device A.

Now, let's look at the inbound case. Here, device B is trying to send to device A, which is using NAT. Device B can't send to device A's private (inside local) address. It needs device A's inside global address in order to start the ball rolling. However, device A's NAT router isn't proximate to device B. In fact, device B probably doesn't even know the identity of device A's NAT router!

---

## Facilitating Inbound NAT Using DNS

There are only two methods to resolve the hidden address problem. One is to use static mapping for devices like servers on the inside network that need to be accessed from the outside. When static mapping is employed, the global address of the device that is using the static mapping will be publicly known, which solves the “where do I send my request to” problem.

The other solution is to make use of the TCP/IP *Domain Name System (DNS)*. [As explained in detail in the section on DNS](#), this protocol allows requests to be sent as names instead of IP addresses; the DNS server translates these names to their corresponding addresses. It is possible to integrate DNS and NAT so they work together. This process is described in RFC 2694, *DNS extensions to Network Address Translators (DNS\_ALG)*.

In this technique, an outside device can in fact make use of dynamic mapping. The basic process (highly simplified) is as follows:

1. The outside device sends a DNS request using the name of the device on the inside network it wishes to reach. For example, it might be “www.ilikenat.com”.
2. The DNS server for the internal network [resolves](#) the “www.ilikenat.com” name into an *inside local* address for the device that corresponds to this DNS entry.
3. The *inside local* address is passed to NAT and used to create a dynamic mapping between the *inside local* address of the server being accessed from the outside, and an *inside global* address. This mapping is put into the NAT router's translation table.
4. When the DNS server sends back the name resolution, it tells the outside device not the *inside local* (private) address of the server being sought, but the *inside global* (public) address mapped in the previous step.

## Bidirectional NAT Example

Once the inside global address of the device on the inside network is known by the outside device, the transaction can begin. Let's use the same example as in the previous topic, only we reverse it, so that outside device 204.51.16.12 is initiating a request (and is thus now the **client**) to inside device 10.0.0.207 (which is the **server**). Let's say that either static mapping

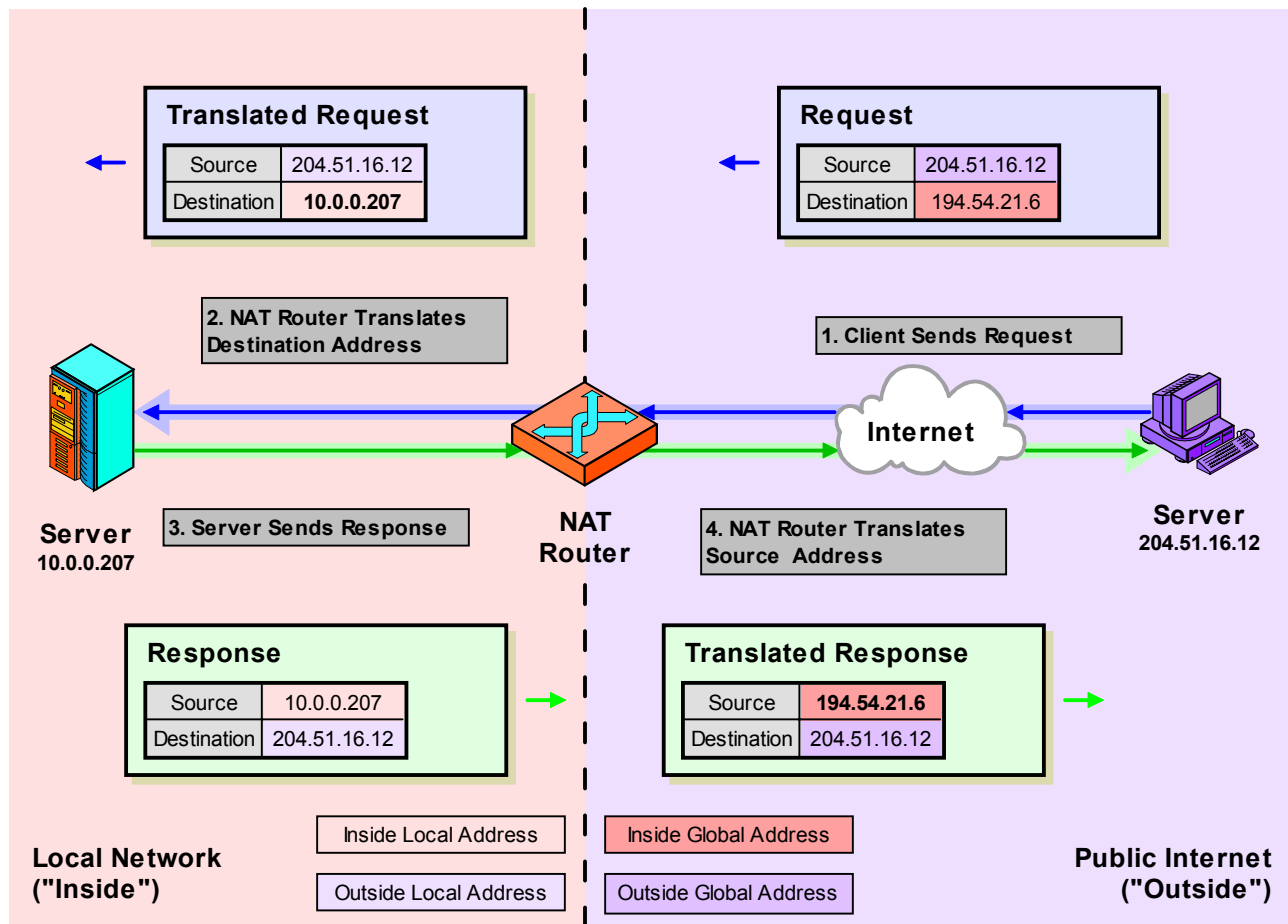

or DNS has been used so that the outside device knows the inside global address of 10.0.0.207 is actually 194.54.21.6. [Table 76](#) describes the transaction in detail; it is illustrated in [Figure 113](#) as well.

**Table 76: Operation Of Bidirectional (Two-Way/Inbound) NAT**

Step #	Description	Data-gram Type	Datagram Source Address	Datagram Destination Address
1	<b>Outside Client Generates Request And Sends To NAT Router:</b> Device 194.54.21.6 generates a request to the inside server. It uses the <i>inside global</i> address 194.54.21.6 as the destination. The datagram will be routed to the local router for that address, which is the NAT router that services the inside network where the server is located.	<b>Request</b> (from outside client to inside server)	204.51.16.12 ( <i>Outside Global</i> )	194.54.21.6 ( <i>Inside Global</i> )
2	<b>NAT Router Translates Destination Address and Sends To Inside Server:</b> The NAT router already has a mapping from the <i>inside global</i> address to the <i>inside local</i> address of the server. It replaces the 194.54.21.6 destination address with 10.0.0.207, and performs checksum recalculations and other work as necessary. The source address is not translated. The router then delivers the modified datagram to the inside server at 10.0.0.207.		204.51.16.12 ( <i>Outside Local</i> )	10.0.0.207 ( <i>Inside Local</i> )
3	<b>Inside Server Generates Response And Sends Back To NAT Router:</b> The server at 10.0.0.207 generates a response, which it addresses to 204.51.16.12 since that was the source of the request to it. This is then routed to the server's NAT router.	<b>Response</b> (from inside server to outside client)	10.0.0.207 ( <i>Inside Local</i> )	204.51.16.12 ( <i>Outside Local</i> )
4	<b>NAT Router Translates Source Address And Routes Datagram To Outside Client:</b> The NAT router sees the private address 10.0.0.207 in the response and replaces it with 194.54.21.6. It then routes this back to the original client on the outside network.		194.54.21.6 ( <i>Inside Global</i> )	204.51.16.12 ( <i>Outside Global</i> )

As you can see, once the outside device knows the inside device's *inside global* address, inbound NAT is very similar to outbound NAT. It just does the exact opposite translation. Instead of modifying the source address on the outbound request and the destination on the inbound response, the router changes the destination on the inbound request and the source on the outbound reply.

**Figure 113: Operation Of Bidirectional (Two-Way/Inbound) NAT**

This figure is very similar to [Figure 112](#), except that the transaction is in reverse, so please start at the upper right and go counter-clockwise. Translated addresses are shown in bold. [Table 76](#) contains a complete explanation of the four steps. Refer to [Figure 111](#) for an explanation of address types.

**Key Concept:** In traditional NAT, a transaction must begin with a request from a client on the local network, but in *bidirectional (two-way/inbound)* NAT, it is possible for a device on the public Internet to access a local network server. This requires the use of either static mapping or DNS to provide to the outside client the address of the server on the inside network. Then the NAT transaction is pretty much the same as in the unidirectional case, except in reverse: the incoming request has its destination address changed from *inside global* to *inside local*; the response has its source changed from *inside local* to *inside global*.

---

## **IP NAT Port-Based ("Overloaded") Operation: Network Address Port Translation (NAPT) / Port Address Translation (PAT)**

Both [traditional NAT](#) and [bidirectional NAT](#) work by swapping inside network and outside network addresses as needed to allow a private network to access a public one. For each transaction, there is a one-to-one mapping between the *inside local* address of a device on the private network, and the *inside global* address that represents it on the public network. We can use [dynamic address assignment](#) to allow a large number of private hosts to share a small number of registered public addresses.

However, there is a potential snag here. Consider our earlier NAT example, where 250 hosts share 20 inside global (public) addresses. If 20 hosts already have transactions in progress, what happens when the 21st tries to access the Internet? There aren't any *inside global* addresses available for it to use, so it won't be able to.

### ***Using Ports to Multiplex Private Addresses***

Fortunately, there is a mechanism already built into TCP/IP that can help us alleviate this situation. [The two TCP/IP transport layer protocols, TCP and UDP](#), both make use of additional addressing components called *ports*. The port number in a TCP or UDP message helps identify individual connections between two addresses. It is used to allow many different applications on a TCP/IP client and server to talk to each simultaneously, without interference. For example, you use this capability when you open multiple browser windows to access more than one Web page on the same site at the same time. This [sharing of IP addresses amongst many connections](#) is called *multiplexing*. [The section on TCP and UDP ports describes all of this in much more detail.](#)

Now, let's come back to NAT. We are already translating IP addresses as we send datagrams between the public and private portions of the internetwork. What if we could also translate port numbers? Well, we can! The combination of an address and port uniquely identifies a connection. As a datagram passes from the private network to the public one, we can change not just the IP address but also the port number in the TCP or UDP header. The datagram will be sent out with a different source address and port. The response will come back to this same address and port combination (called a *socket*) and can be translated back again.

This method goes by various names. Since it is a technique whereby we can have multiple inside local addresses share a single inside global address, it is called *overloading* of an *inside global* address, or alternately, just *overloaded NAT*. More elegant names that better indicate how the technique works include *Port-Based NAT*, *Network Address Port Translation (NAPT)* and *Port Address Translation (PAT)*.

Whatever its name, the use of ports in translation has tremendous advantages. It can allow all 250 hosts on our private network to use only 20 IP addresses—and potentially even fewer than that. In theory you could even have all 250 share a single public IP address at once! You don't want to share so many local hosts that you run out of port numbers, but there are thousands of port numbers to choose from.

---

Port-based NAT of course requires a router that is programmed to make the appropriate address and port mappings for datagrams as it transfers them between networks. The disadvantages of the method include this greater complexity, and also more potential compatibility issues (such as with applications like FTP) since we must now watch for port numbers at higher layers and not just IP addresses.

**Key Concept:** *Port-based* or “*overloaded*” NAT is an enhancement of regular NAT that allows a large number of devices on a private network to simultaneously “share” a single inside global address by changing the port numbers used in TCP and UDP messages.

---

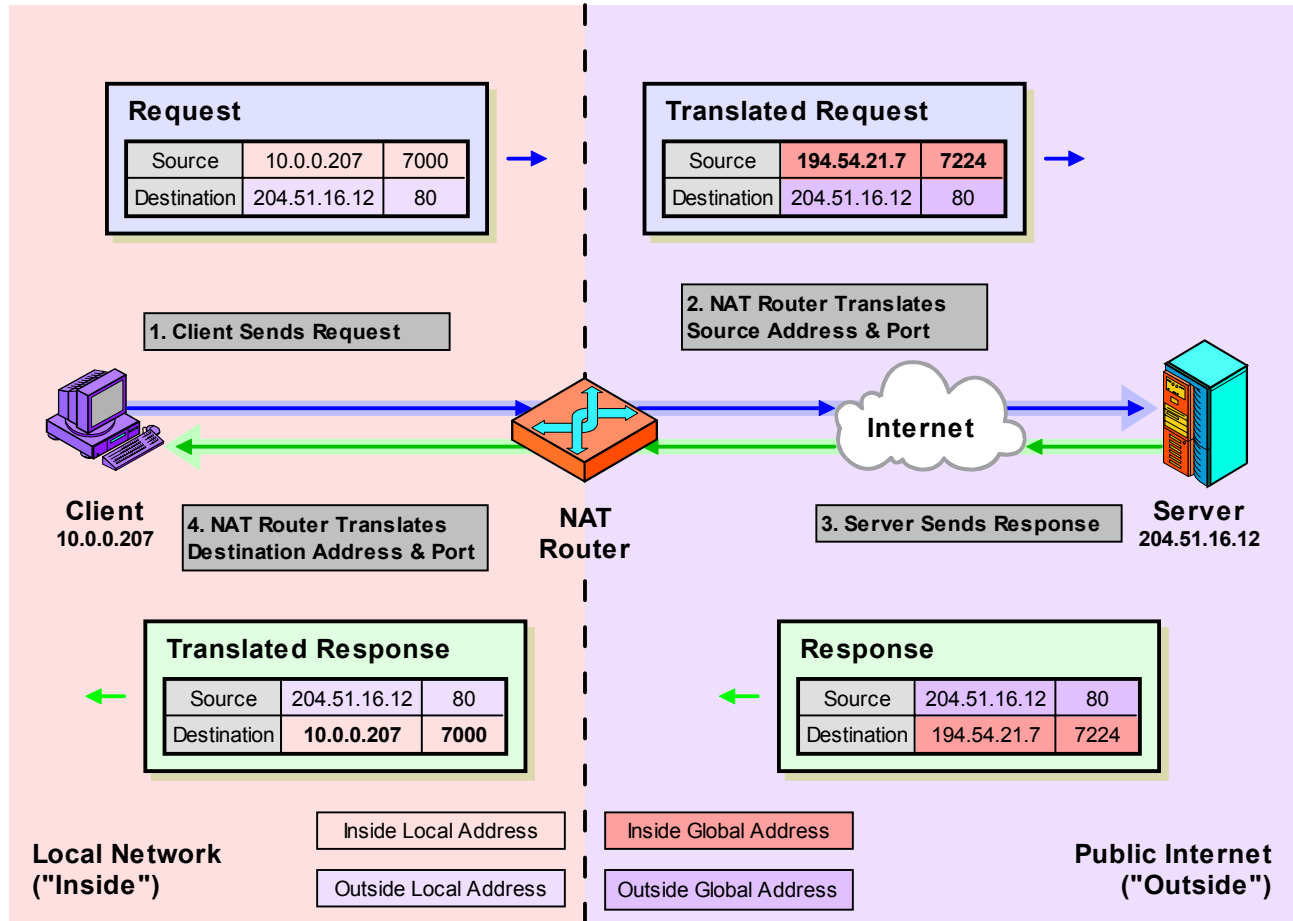

### ***Port-Based NAT Example***

The operation of NAT/PAT is very similar to the way regular NAT works, except that port numbers are also translated. For a traditional outbound transaction, the source port number is changed on the request at the same time that the source address is modified; the destination port number is modified on the response with the destination address.

Let's consider again [the example we looked at in the topic on Traditional NAT](#), but this time in a PAT environment. Device 10.0.0.207 was one of 250 hosts on a private network accessing the WWW server at 204.51.16.12. Let's say that because PAT is being used, to save money all 250 are sharing a single *inside global* address, 194.54.21.7, instead of a pool of 20. The transaction would proceed as described in [Table 77](#) and diagrammed in [Figure 114](#).

**Table 77: Operation Of Port-Based (“Overloaded”) NAT**

Step #	Description	Data-gram Type	Datagram Source Address:Port	Datagram Destination Address:Port
1	<b>Inside Client Generates Request And Sends To NAT Router:</b> Device 10.0.0.207 generates an HTTP request to the server at 204.51.16.12. The standard server port for WWW is 80, so the destination port of the request is 80; let's say the source port on the client is 7000. The datagram is sent to the NAT-capable router that connects the organization's internal network to the Internet.	<b>Request</b> (from inside client to outside server)	10.0.0.207:7000 ( <i>Inside Local</i> )	204.51.16.12:80 ( <i>Outside Local</i> )
2	<b>NAT Router Translates Source Address And Port And Sends To Outside Server:</b> The NAT router realizes that 10.0.0.207 is an <i>inside local</i> address and knows it must substitute an <i>inside global</i> address. Here though, there are multiple hosts sharing the single <i>inside global</i> address 194.54.21.7. Lets say that port 7000 is already in use for that address by another private host connection. The router substitutes the <i>inside global</i> address and also chooses a new source port number, say 7224, for this request. The destination address and port are not changed.  The NAT router puts the address and port mapping into its translation table. It sends the modified datagram out, which arrives at the server at 204.51.16.12.		194.54.21.7:7224 ( <i>Inside Global</i> )	204.51.16.12 ( <i>Outside Global</i> )
3	<b>Outside Server Generates Response And Sends Back To NAT Router:</b> The server at 204.51.16.12 generates an HTTP response. It of course has no idea that NAT was involved; it sees an address of 194.54.21.7 and port of 7224 in the request sent to it, so it sends back to that address and port.	<b>Response</b> (from outside server to inside client)	204.51.16.12:80 ( <i>Outside Global</i> )	194.54.21.7:7224 ( <i>Inside Global</i> )
4	<b>NAT Router Translates Destination Address And Port And Delivers Datagram To Inside Client:</b> The NAT router sees the address 94.54.21.7 and port 7224 in the response that arrived from the Internet. It consults its translation table and knows this datagram is intended for 10.0.0.207, port 7000. This time the destination address and port are changed but not the source. The router then delivers the datagram back to the originating client.		204.51.16.12:80 ( <i>Outside Local</i> )	10.0.0.207:7000 ( <i>Inside Local</i> )

**Figure 114: Operation Of Port-Based ("Overloaded") NAT**

This figure is very similar to [Figure 112](#), except that the source and destination port numbers have been shown, since they are used in this type of NAT. Translated addresses/ports are in bold. [Table 77](#) contains a complete explanation of the four steps in port-based NAT. Refer to [Figure 111](#) for an explanation of address types.

**Key Concept:** In port-based NAT, the NAT router translates the source address and port of an outgoing request from *inside local* to *inside global* form. It then transforms the destination address and port of the response from *inside global* to *inside local*. The *outside local* and *outside global* addresses are the same in both request and reply.

One other issue related to NAT/PAT is worth mentioning: it assumes that all traffic uses either UDP or TCP at the transport layer. While generally the case, this may not always be true. If there is no port number, port translation cannot be done and the method will not work.

---

## **IP NAT "Overlapping" / "Twice NAT" Operation**

All three of the versions of NAT discussed so far—[traditional](#), [bidirectional](#) and [port-based](#)—are normally used to connect a network using private, non-routable addresses to the public Internet, which uses unique, registered, routable addresses. With these kinds of NAT, there will normally be no overlap between the address spaces of the inside and outside network, since the former are private and the latter public. This enables the NAT router to be able to immediately distinguish inside addresses from outside addresses just by looking at them.

In the examples we've seen so far, the inside addresses were all from the [RFC 1918 block](#) 10.0.0.0. These can't be public Internet addresses so the NAT router knew any address referenced by a request from the inside network within this range was a local reference within the inside network. Similarly, any addresses outside this range are easy to identify as belonging to the "outside world".

### ***Cases With Overlapping Private and Public Address Blocks***

There are circumstances however where there may indeed be an overlap between the addresses used for the inside network, and the addresses used for part of the outside network. Consider the following cases:

- ☉ **Private Network To Private Network Connections:** Our example network using 10.0.0.0 block addresses might want to connect to another network using the same method. This situation might occur if two corporations merge and happened to be using the same addressing scheme (and there aren't that many private IP blocks, so this isn't that uncommon).
- ☉ **Invalid Assignment of Public Address Space To Private Network:** Some networks might have been set up not using a designated private address block but rather a block containing valid Internet addresses. For example, suppose an administrator decided that the network he was setting up "would never be connected to the Internet" (ha!) and numbered the whole thing using 18.0.0.0 addresses, which belong to the Massachusetts Institute of Technology (MIT). Then later, this administrator's short-sightedness would backfire when the network did indeed need to be connected to the 'net.
- ☉ **"Stale" Public Address Assignment:** Company A might have been using a particular address block for years that was reassigned or reallocated for whatever reason to company B. Company A might not want to go through the hassle of renumbering their network, and would then keep their addresses even while Company B started using them on the Internet.

What these situations all have in common is that the inside addresses used in the private network **overlap** with addresses on the public network. When a datagram is sent from within the local network, the NAT router can't tell if the intended destination is within the inside network or the outside network. For example, if we want to connect host 10.0.0.207 in our private network to host 10.0.0.199 in a different network, and we put 10.0.0.199 in the destination of the datagram and send it, how does the router know if we mean 10.0.0.199 on our own local network or the remote one? For that matter, we might need to send a

---

request to 10.0.0.207 in the other private network, our own address! Take the network that was numbered with MIT's address block. How does the router know when a datagram is actually being sent to MIT as opposed to another device on the private network?

### ***Dealing With Overlapping Blocks By Using NAT Twice***

The solution to this dilemma is to use a more sophisticated form of NAT. The other versions we have seen so far always translate either the source address **or** the destination address as a datagram passes from the inside network to the outside network or vice versa. To cope with overlapping addresses, we must translate both the source address **and** the destination address on each transition from the inside to the outside or the other direction. This technique is called *Overlapping NAT* in reference to the problem it solves, or "*Twice NAT*" due to how it solves it. (Incidentally, despite the latter name, regular NAT is *not* called "Once NAT".)

Twice NAT functions by creating a set of mappings not only for the private network the NAT router serves, but also for the overlapping network (or networks) that conflict with the inside network's address space. In order for this to function, Twice NAT relies on the use of the [TCP/IP Domain Name System \(DNS\)](#), just like bidirectional NAT. This lets the inside network send requests to the overlapping network in a way that can be uniquely identified. Otherwise, the router can't tell what overlapping network our inside network is trying to contact.

### ***"Overlapping" / "Twice" NAT Example***

Let's try a new example. Suppose our network has been improperly numbered so that it is not in the 10.0.0.0 private block but in the 18.0.0.0 block used by MIT. A client on our private network, 18.0.0.18, wants to send a request to the server "www.twicenat.mit.edu", which has the address 18.1.2.3 at MIT. Our client can't just make a datagram with 18.1.2.3 as the destination and send out, as the router will think it's on the local network and not route it. Instead, 18.0.0.18 uses a combination of DNS and NAT to get the outside device address as follows:

1. The client on our local network (18.0.0.18) sends a DNS request to get the address of "www.twicenat.mit.edu".
2. The (Twice-NAT compatible) NAT router serving our local network intercepts this DNS request. It then consults its tables to find a special mapping for this outside device. Let's say, it is programmed to translate "www.twicenat.mit.edu" into the address 172.16.44.55. This is a private non-routable RFC 1918 address.
3. The NAT router returns this value, 172.16.44.55 to the source client, which uses it for the destination.

Once our client has the translated address, it initiates a transaction just as before. NAT now will perform both translation of the inside devices and the outside devices as well. The outside device address must be translated because the inside device is using 172.16.44.55, which isn't a valid address for the server it is trying to reach. The inside

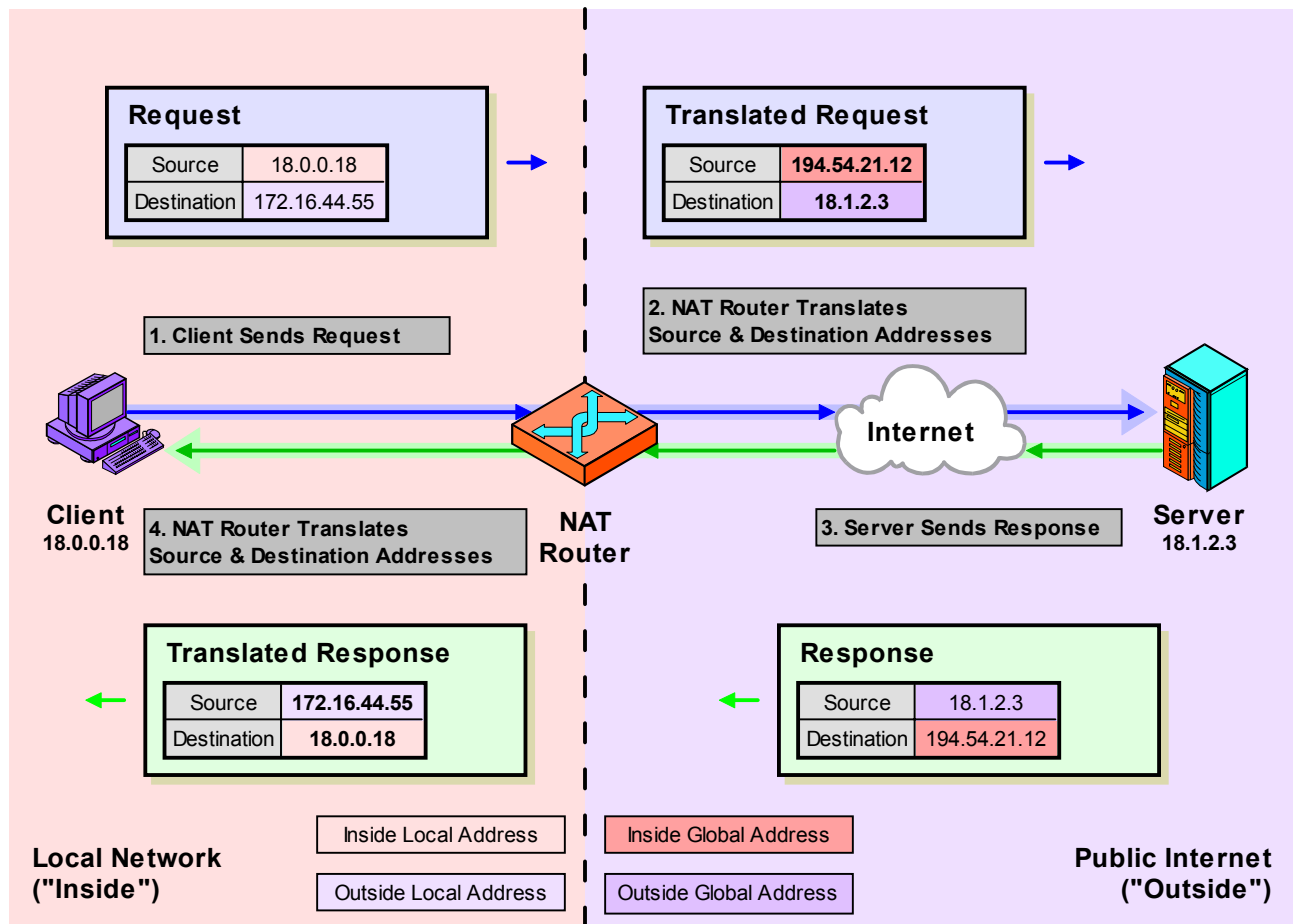

device address must still be translated as in regular NAT because 18.0.0.18 is not a valid public address for us. It may refer to a real machine in MIT and we aren't supposed to be using it on the Internet!

Let's say that we are still using the pool of 20 inside global addresses from 194.54.21.1 through 194.54.21.20 for inside addresses, and let's further suppose the NAT router chooses 194.54.21.12 for this particular exchange. The transaction sequence would be roughly as described in [Table 78](#), and illustrated in [Figure 115](#).

**Table 78: Operation Of “Overlapping” NAT / “Twice NAT”**

Step #	Description	Data-gram Type	Datagram Source Address	Datagram Destination Address
1	<b>Inside Client Generates Request And Sends To NAT Router:</b> Device 18.0.0.18 generates a request using the destination 172.16.44.55 that it got from the (NAT-intercepted) DNS query for “www.twicenat.mit.edu”. The datagram is sent to the NAT router for the local network.	<b>Request</b> (from inside client to outside server)	18.0.0.18 ( <i>Inside Local</i> )	172.16.44.55 ( <i>Outside Local</i> )
2	<b>NAT Router Translates Source Address And Destination Address And Sends To Outside Server:</b> The NAT router makes two translations. First, it substitutes the 18.0.0.18 address with a publicly registered address, which is 194.54.21.12 for this example. It then translates the bogus 172.16.44.55 back to the real MIT address for “www.twicenat.mit.edu”. It routes the datagram to the outside server.		194.54.21.12 ( <i>Inside Global</i> )	18.1.2.3 ( <i>Outside Global</i> )
3	<b>Outside Server Generates Response And Sends Back To NAT Router:</b> The MIT server at 18.1.2.3 generates a response and sends it back to 194.54.21.12, which causes it to arrive back at the NAT router.	<b>Response</b> (from outside server to inside client)	18.1.2.3 ( <i>Outside Global</i> )	194.54.21.12 ( <i>Inside Global</i> )
4	<b>NAT Router Translates Source Address And Destination Address And Delivers Datagram To Inside Client:</b> The NAT router translates back the destination address to the actual address being used for our inside client, as in regular NAT. It also substitutes back in the 172.16.44.55 value it is using as a substitute for the real address of “www.twicenat.mit.edu”.		172.16.44.55 ( <i>Outside Local</i> )	18.0.0.18 ( <i>Inside Local</i> )

As you can see, in this example the *outside local* and *outside global* addresses are different, unlike in the preceding NAT examples. Twice NAT can also handle an inbound transaction, by watching for datagrams coming in from the Internet that overlap with the addresses used on the local network and doing double substitutions as required.

**Figure 115: Operation Of “Overlapping” NAT / “Twice NAT”**

This figure is very similar to [Figure 112](#), except that the as you can see, both source and destination addresses are translated by the NAT router each time (shown in bold). [Table 78](#) contains a complete explanation of the four steps in “overlapping” NAT. Refer to [Figure 111](#) for an explanation of address types.

**Key Concept:** “*Overlapping*” NAT is used in situations where both the source and destination addresses in a datagram are private addresses or otherwise cannot be used regularly on the public Internet. In this case, unlike the other types of NAT, the NAT router translates both the source and destination addresses of incoming and outgoing datagrams. On outgoing messages, *inside local* addresses are changed to *inside global* and *outside local* to *outside global*; on incoming messages, *inside global* addresses are changed to *inside local* and *outside global* to *outside local*.

## IP NAT Compatibility Issues and Special Handling Requirements

In a perfect world, Network Address Translation could be made transparent to the devices using it. We'd like to be able to have a NAT router change IP addresses in request datagrams as they leave the network and change them back in responses that come back and have none of the hosts be any the wiser. Unfortunately, this ain't a perfect world.

---

It is not possible for NAT to be completely transparent to the devices that use it. There are potential compatibility problems that arise if NAT doesn't perform certain functions that go beyond simply swapping IP addresses and possibly port numbers in the IP header. The main problem is that even though IP addresses are supposedly the domain of the Internet Protocol, they are really used by other protocols as well, both at the network layer and in higher layers. When NAT changes the IP address in an IP datagram, it must often also change addresses in other places to make sure that the addresses in various headers and payloads still match.

These compatibility issues require that even though NAT should theoretically work only at the level of IP at the network layer, in practical terms NAT routers must be “aware” of many more protocols and perform special operations as required. Some are required for all datagrams that are translated, while others only apply to certain datagrams and not others. And even when these techniques are added to NAT routers, some things still may not work properly in a NAT environment.

Most NAT implementations do take these concerns into account. Certainly common applications like FTP are widely supported by NAT routers, or nobody would want to use NAT. That said, there may be some applications that will not work over NAT. The fact that NAT really isn't transparent and must do these extra sorts of “hacks” to other protocol headers and even payloads is a big part of the reason why many people refer to NAT as a “kludge”; elegant solutions don't have so many special cases that need special handling.

Let's take a look at some of the specific issues and requirements.

### ***TCP and UDP Checksum Recalculations***

Changing the IP addresses in the IP header means the [IP header checksum](#) must be calculated. Since both UDP or TCP also have checksums, and these checksums are computed over a [pseudo header that contains the IP source and destination address](#) as well, they too must be recalculated each time a translation is made.

### ***ICMP Manipulations***

Since NAT works so intimately with IP headers, and since IP is closely related to its “assistant” protocol [ICMP](#), NAT must also look for certain ICMP messages and make changes to addresses contained within them. Many ICMP messages, such as *Destination Unreachable* and *Parameter Problem* contain as data the original IP header of the datagram that led to the ICMP message. Since NAT is translating addresses in IP headers it must watch for these messages and translate addresses in included headers as required.

### ***Applications That Embed IP Addresses***

A number of TCP/IP applications embed IP addresses within the actual application data payload. The most notorious example of this is the [TCP/IP File Transfer Protocol \(FTP\)](#), which actually sends address and port assignments as text information in datagrams between devices during a connection. In order for NAT to support FTP, it must be specifically programmed with algorithms to look for this information and make changes as needed.

---

The level of complication can go even beyond this. Consider what happens when an FTP message containing these text address or port numbers is *fragmented*—part of the address to be translated may be in two different IP datagrams, and hard to recognize!

### ***Additional Issues With Port Translation***

When [port-based NAT \(PAT\)](#) is used, the issues that apply to addresses now apply to ports as well, making even more work for the router to perform.

### ***Cascading Impact Of Changes To Address Or Port Numbers***

Take the example of an FTP datagram encoding an IP address that NAT must change. The address being substituted might require more characters than the original; in our first example, 10.0.0.207 (10 ASCII characters) is replaced by 194.54.21.11 (12 ASCII characters). Making this substitution changes the size of the payload! This means that [TCP sequence numbers](#) also must be modified.

In these situations, NAT itself is supposed to take care of any additional work that may be required. This is definitely a complication that does not occur without the use of NAT, and is an often-cited example of NAT's “kludginess”.

### ***Problems With IPSec***

When [IPSec](#) is used in [transport mode](#), both the [Authentication Header \(AH\)](#) and [Encapsulating Security Payload \(ESP\)](#) protocols use an integrity check that is based on the value of the entire payload. When NAT tries to update the TCP or UDP checksum in the IP datagram, this changes the value of data that the receiving device uses in performing the AH or ESP integrity check. The check will fail. Thus, NAT can't be used in IPSec transport mode. It may still work in [tunnel mode](#) but there can be complications here as well.

---

## IP Security (IPSec) Protocols

One of the weaknesses of the original Internet Protocol is that it lacks any sort of general purpose mechanism for ensuring the authenticity and privacy of data as it is passed over the internetwork. Since IP datagrams must usually be routed between two devices over unknown networks, any information in them is subject to being intercepted and even possibly changed. With the increased use of the Internet for critical applications, security enhancements were needed for IP. To this end, a set of protocols called *IP Security or IPSec* was developed.

In this section I provide a brief description of IPSec concepts and protocols. I begin with an overview of IPSec, including a discussion of the history of the technology and defining standards. I describe the main components and protocols of the IPSec suite, and its different architectures and methods for implementation. I then move to actually discussing how IPSec works, beginning with a description of the two IPSec modes (transport and tunnel) and how they differ. I describe security associations and related constructs such as the Security Parameter Index (SPI). The last three topics cover the three main IPSec protocols: IPSec Authentication Header (AH), IPSec Encapsulating Security Payload (ESP) and the IPSec Internet Key Exchange (IKE).

**Note:** IPSec was initially developed with IPv6 in mind, but has been engineered to provide security for both IPv4 and IPv6 networks, and operation in both versions is similar. There are some differences in the datagram formats used for AH and ESP depending on whether IPSec is used in IPv4 and IPv6, since the two versions have different datagram formats and addressing. I highlight these differences where appropriate.

**Note:** There are many subjects in this Guide that are so involved that many large books have been written about them. Security on IP networks and IPSec is definitely in this category. Due to the already large size of this Guide and the complexity of IPSec, I can only provide here a very limited description of how it works. For more comprehensive information you will need to supplement with a reference specific to this technology.

---

## IPSec Overview, History and Standards

The best-known problem with [the original Internet Protocol \(IPv4\)](#) is the pending exhaustion of its address space. This situation arose due to the rapid expansion of the Internet beyond anyone's expectations when IPv4 was developed. This same mismatch between how the Internet was when IPv4 was created and how it is now has led to another major problem with IP: the lack of a definitive means of ensuring security on IP internetworks.

---

The security problem arose because 25 years ago, the Internet was tiny and relatively “private”. Today it is enormous and truly “public”. As the Internet has grown, the need for security has grown with it. Consider that [TCP/IP and the early Internet precursors](#) were developed as very small networks used by government researchers at the United States Defense Advanced Research Projects Agency (*DARPA* or *ARPA*). All the hardware was controlled by people who were well known and would generally have had security clearance. In such a network, you don't need to build security in to the protocols—you build it into the building! It's easier to use locks and guards to ensure security than fancy encryption, when you can get away with it. After all, the easiest way to keep someone from snooping or tampering with data on the network is simply to deny them access to the hosts that connect to the network.

This worked fine at first when there were only a few dozen machines on the Internet. And even when the Internet first started to grow, it was used pretty much only to connect together researchers and other networking professionals. New sites were added to the network slowly at first, and at least someone knew the identity of each new site added to the growing internetwork. However, as the Internet continued to increase in size and eventually was opened to the public, maintaining security of the network as a whole became impossible. Today, the “great unwashed masses” are on the Internet. Many routers—owned by “who knows” and administered by “who knows”—stand between you and most other devices you want to connect with. You cannot assume that the data you send or receive is secure.

A number of methods have evolved over the years to address the need for security. Most of these are focused at [the higher layers of the OSI protocol stack](#), to compensate for IP's lack of security. These solutions are valuable for certain situations, but they can't be generalized easily because they are particular to various applications. For example, we can use [Secure Sockets Layer \(SSL\)](#) for certain applications like World Wide Web access or FTP, but there are dozens of applications that this type of security was never intended to work with.

What was really needed was a solution to allow security at the IP level so all higher-layer protocols in TCP/IP could take advantage of it. When the decision was made to develop a new version of IP ([IPv6](#)), this was the golden opportunity to resolve not just the addressing problems in the older IPv4, but the lack of security as well. New security technology was developed with IPv6 in mind, but since IPv6 has taken years to develop and roll out, and the need for security is *now*, the solution was designed to be usable for both IPv4 and IPv6.

The technology that brings secure communications to the Internet Protocol is called *IP Security*, commonly abbreviated *IPSec* (The capitalization of this abbreviation is variable, so *IPsec* and *IPSEC* are also seen. Though not *IpSeC* or *IPseC*, fortunately. ☺)

### **Overview of IPSec Services and Functions**

IPSec is not a single protocol, but rather a set of services and protocols that provide a complete security solution for an IP network. These services and protocols combine to provide various types of protection. Since IPSec works at the IP layer, it can provide these

---

protections for any higher layer TCP/IP application or protocol without the need for additional security methods, which is a major strength. Some of the kinds of protection services offered by IPSec include:

- ☉ Encryption of user data for privacy.
- ☉ Authentication of the integrity of a message to ensure that it is not changed en route.
- ☉ Protection against certain types of security attacks, such as replay attacks.
- ☉ The ability for devices to negotiate the security algorithms and keys required to meet their security needs.
- ☉ Two security modes, tunnel and transport, to meet different network needs.

**Key Concept:** *IPSec* is a contraction of *IP Security*, and consists of a set of services and protocols that provide security to IP networks. It is defined by a sequence of several Internet standards.

---

### **IPSec Standards**

Since IPSec is actually a collection of techniques and protocols, it is not defined in a single Internet standard. Instead, a collection of RFCs defines the architecture, services and specific protocols used in IPSec. Some of the most important of these are shown in [Table 79](#), all of which were published in November 1998:

**Table 79: Important IP Security (IPSec) Standards**

RFC Number	Name	Description
2401	<u><i>Security Architecture for the Internet Protocol</i></u>	The main IPSec document, describing the architecture and general operation of the technology, and showing how the different components fit together.
2402	<u><i>IP Authentication Header</i></u>	Defines the IPSec <a href="#">Authentication Header (AH)</a> protocol used for ensuring data integrity and origin verification.
2403	<u><i>The Use of HMAC-MD5-96 within ESP and AH</i></u>	Describes a particular encryption algorithm for use by AH and ESP called Message Digest 5 (MD5), HMAC variant. (Obviously. ☺)
2404	<u><i>The Use of HMAC-SHA-1-96 within ESP and AH</i></u>	Describes a particular encryption algorithm for use by AH and ESP called Secure Hash Algorithm 1 (SHA-1), HMAC variant. (Naturally. ☺)
2406	<u><i>IP Encapsulating Security Payload (ESP)</i></u>	Describes the IPSec <a href="#">Encapsulation Security Payload (ESP)</a> protocol that provides data encryption for confidentiality.
2408	<u><i>Internet Security Association and Key Management Protocol (ISAKMP)</i></u>	Defines methods for exchanging keys and negotiating security associations.

---

**Table 79: Important IP Security (IPSec) Standards**

RFC Number	Name	Description
2409	<u><i>The Internet Key Exchange (IKE)</i></u>	Describes the <a href="#">Internet Key Exchange (IKE)</a> protocol used to negotiate security associations and exchange keys between devices for secure communications. Based on ISAKMP and OAKLEY.
2412	<u><i>The OAKLEY Key Determination Protocol</i></u>	Describes a generic protocol for key exchange.

### ***The Future of IPSec***

Deployment of IPSec has only really started to take off in the last few years; a major use of the technology is in implementing virtual private networks (VPNs). It appears that the future IPSec is bright, as more and more individuals and companies decide that they need to take advantage of the power of the Internet, while also protecting the security of the data they transport over it.

### **IPSec General Operation, Components and Protocols**

I have a confession to make: I considered not writing about IPSec in this Guide. When you find yourself writing a tome as large as this one, you lose stamina sometimes and there's this urge to avoid writing about confusing subjects. ☺ IPSec isn't the only difficult topic in this Guide but it is definitely a subject that baffles many because it's hard to get your hands around. Most discussions of it jump straight to describing the mechanisms and protocols without providing a general description of what it does and how the pieces fit together. Well, I recognized that IPSec is important and I don't shy away from a challenge. Thus, here's my attempt to provide a framework for understanding IPSec's various bits and pieces.

So, what exactly does IPSec do and how does it do it? In general terms, it provides security services at the IP layer for other TCP/IP protocols and applications to use. What this means is that IPSec provides the tools that devices on a TCP/IP network need in order to communicate securely. When two devices (either end user hosts or intermediate devices such as routers or firewalls) want to engage in secure communications, they set up a *secure path* between themselves that may traverse across many insecure intermediate systems. To accomplish this, they must perform (at least) the following tasks:

1. They must agree on a set of security protocols to use, so that each one sends data in a format the other can understand.
2. They must decide on a specific encryption algorithm to use in encoding data.
3. They must exchange keys that are used “unlock” data that has been cryptographically encoded.
4. Once this background work is completed, each device must use the protocols, methods and keys previously agreed upon to encode data and send it across the network.

---

## IPSec Core Protocols

To support the activities above, a number of different components comprise the total package known as “IPSec”, as shown in [Figure 116](#). The two main pieces are a pair of technologies sometimes called the *core protocols* of IPSec. These are the ones that actually do the work of encoding information to ensure security. They are:

- 🕒 **IPSec Authentication Header (AH):** This protocol provides authentication services for IPSec. What this means is that it allows the recipient of a message to verify that the supposed originator of a message was in fact the one that sent it. It also allows the recipient to verify that none of the data in the datagram has been changed by any intermediate devices en route. It also provides protection against so-called “replay” attacks, where a message is captured by an unauthorized user and re-sent.
- 🕒 **Encapsulating Security Payload (ESP):** The Authentication Header ensures integrity of the data in datagram, but not its privacy. When the information in a datagram is “for your eyes only”, it can be further protected using the ESP protocol, which encrypts the payload of the IP datagram.

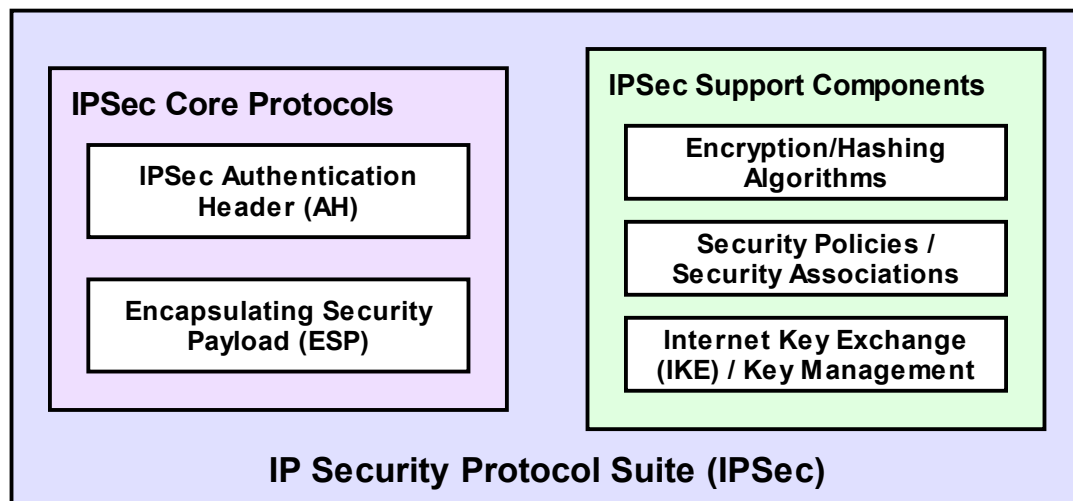

Figure 116: Overview of IPSec Protocols and Components

### IPSec Support Components

[AH](#) and [ESP](#) are commonly called “protocols”, though this is another case where the validity of this term is debatable. They are not really distinct protocols but are implemented as headers that are inserted into IP datagrams, as we will see. They thus do the “grunt work” of IPSec, and can be used together to provide both authentication and privacy. However, they cannot operate on their own. For them to function properly they need the support of several other protocols and services. The most important of these include:

- 
- 🔊 **Encryption/Hashing Algorithms:** AH and ESP are generic and do not specify the exact mechanism used for encryption. This gives them the flexibility to work with a variety of such algorithms, and to negotiate which is used as needed. Two common ones used with IPsec are *Message Digest 5 (MD5)* and *Secure Hash Algorithm 1 (SHA-1)*. These are also called *hashing* algorithms because they work by computing a formula called a *hash* based on input data and a key.
  - 🔊 **Security Policies and Associations, and Management Methods:** Since IPsec provides flexibility in letting different devices decide how they want to implement security, some means is required to keep track of the security relationships between devices. This is done in IPsec using constructs called *security policies* and *security associations*, and by providing ways to exchange security association information (see below).
  - 🔊 **Key Exchange Framework and Mechanism:** For two devices to exchange encrypted information they need to be able to share keys for unlocking the encryption. They also need a way to exchange security association information. In IPsec, a protocol called the *Internet Key Exchange (IKE)* provides these capabilities.

**Key Concept:** IPsec consists of a number of different components that work together to provide security services. The two main ones are protocols called the *Authentication Header (AH)* and *Encapsulating Security Payload (ESP)*, which provide authenticity and privacy to IP data in the form of special headers added to IP datagrams.

---

Well, that's at least a start at providing a framework for understanding what IPsec is all about and how the pieces fit together. We'll examine these components and protocols in more detail as we proceed through this section.

## **IPsec Architectures and Implementation Methods**

The main reason that IPsec is so powerful is that it provides security to IP, the basis for all other TCP/IP protocols. In protecting IP, we are protecting pretty much everything else in TCP/IP as well. An important issue, then, is how exactly we get IPsec into IP? There are several implementation methods for deploying IPsec, which represent different ways that IPsec may modify the overall [layer architecture of TCP/IP](#).

### ***IPsec Implementation Methods***

Three different implementation architectures are defined for IPsec in RFC 2401. Which one we use depends on various factors including the version of IP used (v4 versus v6), the requirements of the application and other factors. These in turn rest on a primary implementation decision: whether IPsec should be programmed into all hosts on a network, or just into certain routers or other “intermediate devices”.

This implementation decision is one that must be based on the requirements of the network. There are two options: to implement IPsec in end hosts, or in routers.

---

## End Host Implementation

Putting IPSec into all host devices provides the most flexibility and security. It enables “end-to-end” security between any two devices on the network. However, there are many hosts on a typical network, so this means far more work than just implementing IPSec in routers.

## Router Implementation

This option is much less work because it means we only make changes to a few routers instead of hundreds or thousands of clients. It only provides protection between pairs of routers that implement IPSec, but this may be sufficient for certain applications such as virtual private networks (VPNs). The routers can be used to provide protection only for the portion of the route that datagrams take outside the organization, leaving connections between routers and local hosts unsecured (or possibly, secured by other means).

## *IPSec Architectures*

Three different architectures are defined that describe methods for how to get IPSec into the TCP/IP protocol stack.

### Integrated Architecture

Under ideal circumstances, we would integrate IPSec's protocols and capabilities directly into IP itself. This is the most elegant solution, as it allows all IPSec security modes and capabilities to be provided just as easily as regular IP. No extra hardware or architectural layers are needed.

[IPv6](#) was designed to support IPSec, making this a viable option for hosts or routers. With IPv4, integration would require making changes to the IP implementation on each device, which is often impractical (to say the least!)

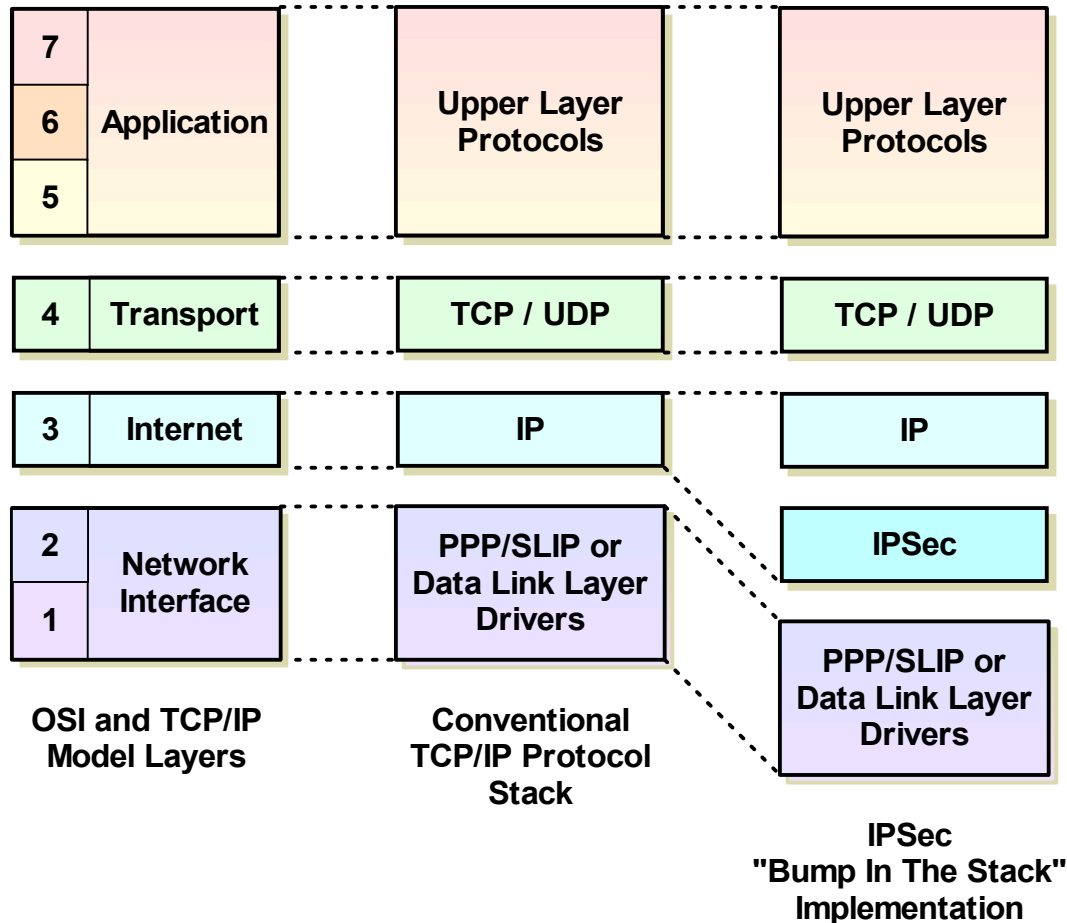

### “Bump In The Stack” (BITS) Architecture

In this technique, IPSec is made a separate architectural layer between IP and the data link layer; the cute name refers to the fact that IPSec is an extra element in the networking protocol stack, as you can see in [Figure 117](#). IPSec intercepts IP datagrams as they are passed down the protocol stack, processes them to provide security, and then passes them through to the data link layer.

The advantage of this is technique is that IPSec can be “retrofitted” to any IP device, since the IPSec functionality is separate from IP. The disadvantage is that there is duplication of effort compared to the integrated architecture. BITS is generally used for IPv4 hosts.

### “Bump In The Wire” (BITW) Architecture

In this method we add a hardware device that provides IPSec services. For example, suppose we have a company with two sites. Each has a network that connects to the Internet using a router that is not capable of IPSec functions. We can interpose a special

**Figure 117: IPSec “Bump In The Stack” (BITS) Architecture**

In this type of IPSec implementation, IPSec becomes a separate layer in the TCP/IP stack. It is implemented as software that sits below IP and adds security protection to datagrams created by the IP layer.

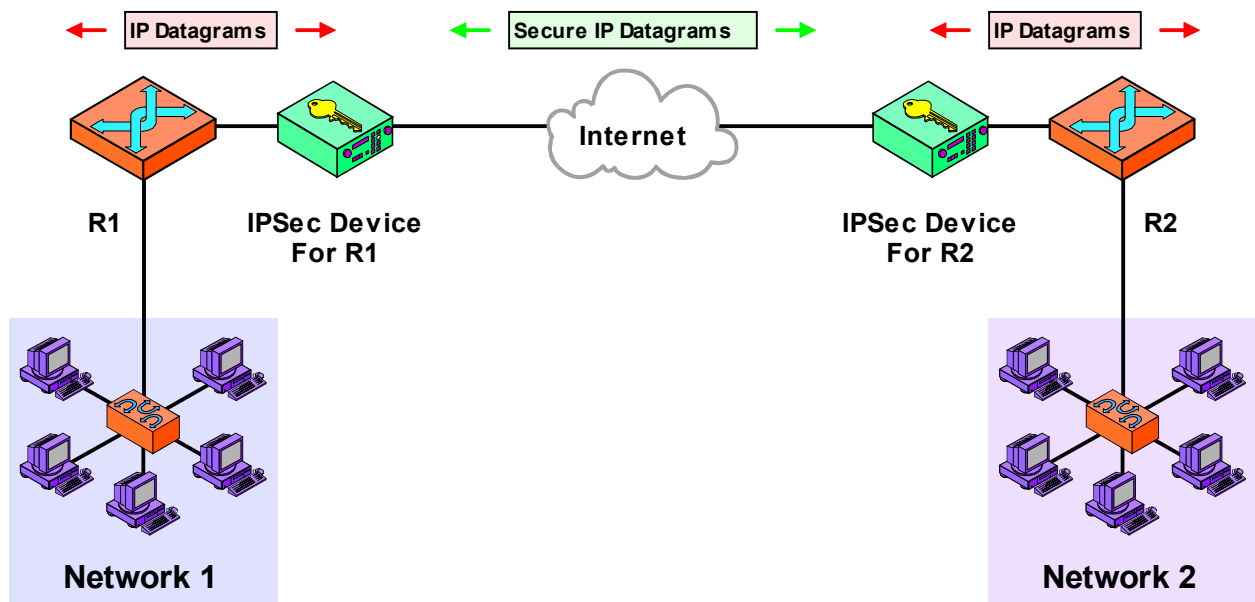

“IPSec” device between the router and the Internet at both sites, as shown in [Figure 118](#). These devices will then intercept outgoing datagrams and add IPSec protection to them, and strip it off incoming datagrams.

Just as BITS lets us add IPSec to legacy hosts, BITW can “retrofit” non-IPSec routers to provide security benefits. The disadvantages are complexity and cost.

### ***Parallels Between BITS and BITW***

Incidentally, even though BITS and BITW seem quite different, they are really different ways of doing the same thing. In the case of BITS we add an extra software layer that adds security to existing IP datagrams; in BITW this same job is done by distinct hardware devices. In both cases the result is the same, and the implications on the choice of IPSec mode is likewise the same.

As we will see in the next topic, the choice of architecture has an important impact on which of the two IPSec modes can be used.

**Figure 118: IPsec “Bump In The Wire” (BITW) Architecture**

In this IPsec architecture, IPsec is actually implemented in separate devices that sit between the devices that wish to communicate securely. These repackage insecure IP datagrams for transport over the public Internet.

**Key Concept:** Three different architectures or implementation models are defined for IPsec. The best is *integrated* architecture, where IPsec is built into the IP layer of devices directly. The other two are “*Bump In The Stack*” (BITS) and “*Bump In The Wire*” (BITW), which both are ways of layering IPsec underneath regular IP, using software and hardware solutions respectively.

## IPsec Modes: Transport and Tunnel

Three different basic implementation architectures can be used to provide IPsec facilities to TCP/IP networks. The choice of which implementation we use, as well as whether we implement in end hosts or routers, impacts the specific way that IPsec functions. Two specific *modes* of operation are defined for IPsec that are related to these architectures, called *transport mode* and *tunnel mode*.

IPsec modes are closely related to the function of the two core protocols, the [Authentication Header \(AH\)](#) and [Encapsulating Security Payload \(ESP\)](#). Both of these protocols provide protection by adding to a datagram a header (and possibly other fields) containing security information. The choice of mode does not affect the method by which each generates its header, but rather, changes what specific parts of the IP datagram are protected and how the headers are arranged to accomplish this. In essence, the mode really **describes**, not **prescribes** how AH or ESP do their thing. It is used as the basis for defining other constructs, such as [security associations \(SAs\)](#).

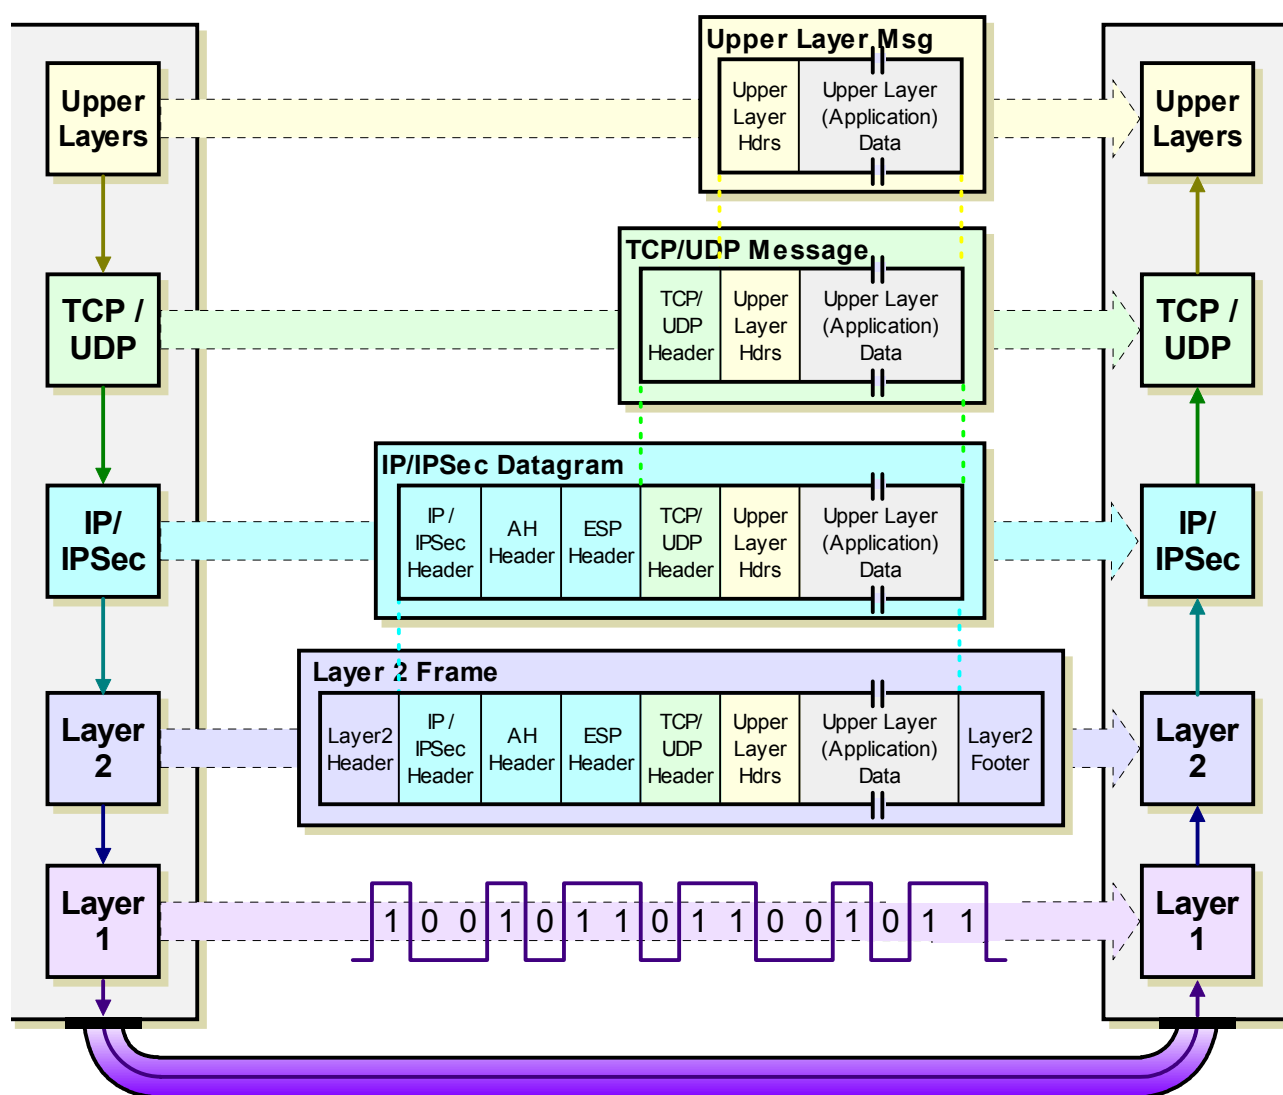

Let’s take a look at how the two modes work.

## Transport Mode

As its name suggests, in transport mode, the protocol protects the message passed down to IP from the transport layer. The message is processed by AH/ESP and the appropriate header(s) added in front of the transport (UDP or TCP) header. The IP header is then added in front of that by IP.

Another way of looking at this is as follows. Normally the transport layer packages data for transmission and sends it to IP. From IP's perspective, this transport layer message is the payload of the IP datagram. When IPSec is used in transport mode, the IPSec header is applied only over this IP payload, **not** the IP header. The AH and/or ESP headers appears between the original, single IP header and the IP payload. This is illustrated in [Figure 119](#).

**Figure 119: IPSec Transport Mode Operation**

When IPSec operates in transport mode, it is integrated with IP and used to transport the upper layer (TCP/UDP) message directly. After processing, the datagram has just one IP header that contains the AH and/or ESP IPSec headers. Contrast to [Figure 120](#).

---

## ***Tunnel Mode***

In this mode, IPSec is used to protect a complete **encapsulated** IP datagram after the IP header has already been applied to it. The IPSec headers appear in front of the original IP header, and then a **new** IP header is added in front of the IPSec header. That is to say, the entire original IP datagram is secured and then encapsulated within another IP datagram. This is shown in [Figure 120](#).

## ***Comparing Transport and Tunnel Modes***

The bottom line in understanding the difference between these two is this: tunnel mode protects the original IP datagram as a whole, header and all, while transport mode does not. Thus, in general terms, the order of the headers is as follows:

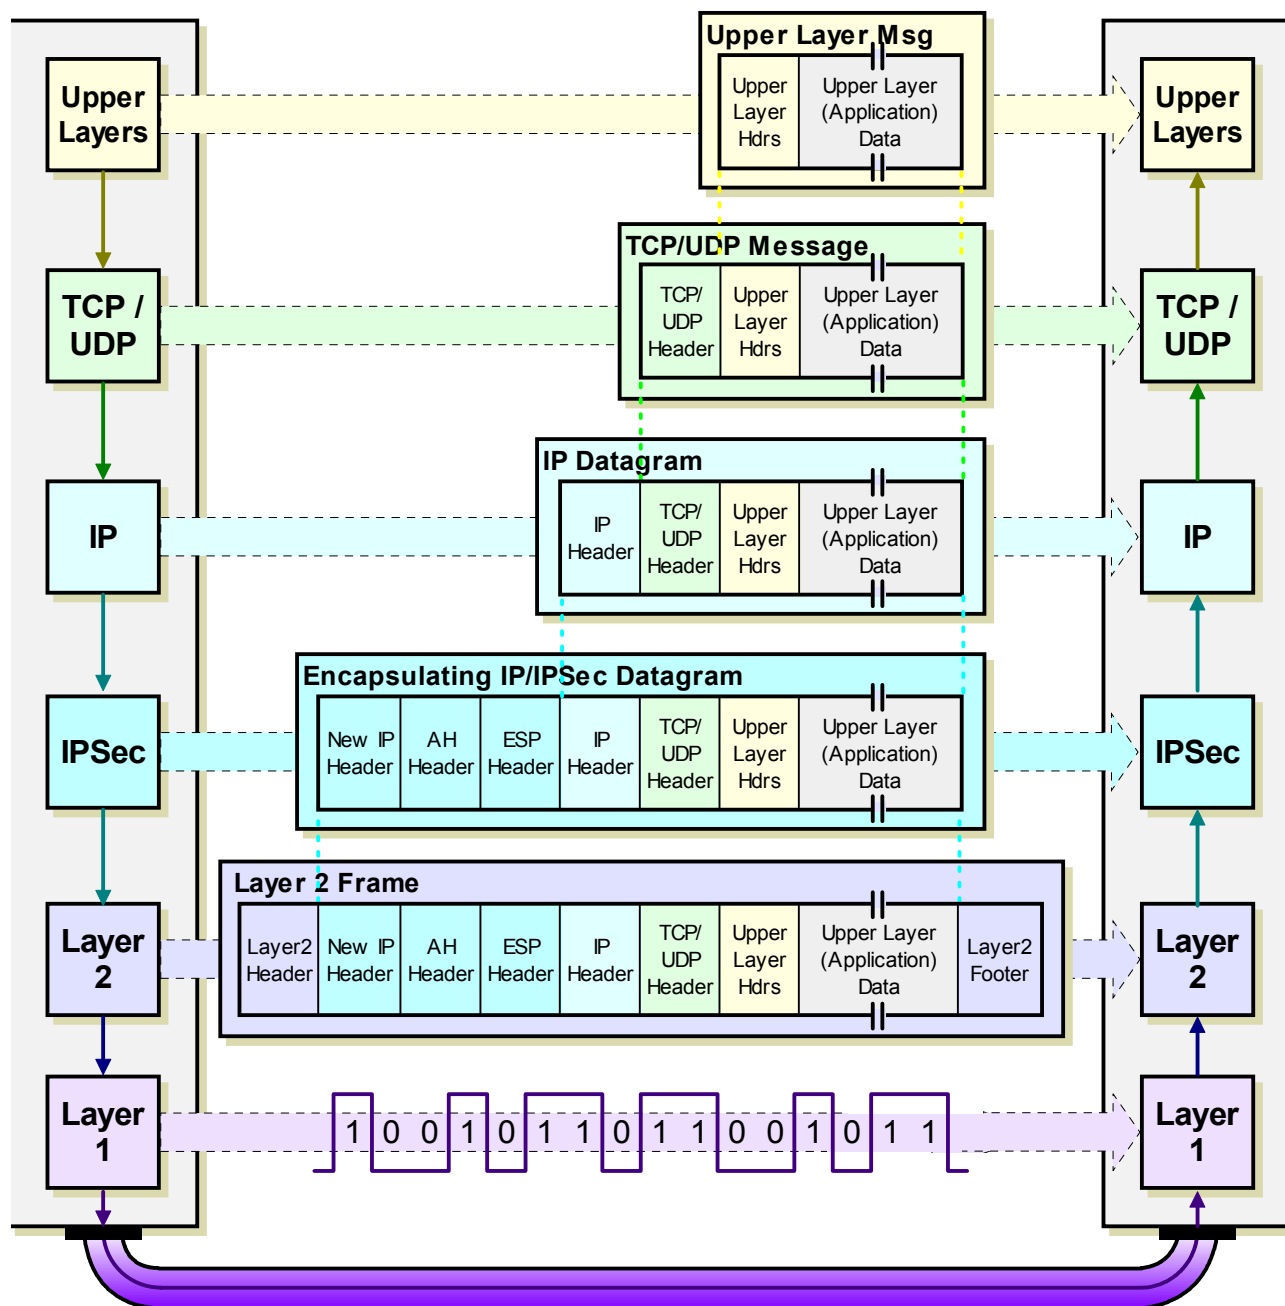

- ☉ **Transport Mode:** IP header, IPSec headers (AH and/or ESP), IP payload (including transport header).
- ☉ **Tunnel Mode:** New IP header, IPSec headers (AH and/or ESP), old IP header, IP payload.

Again, this is a simplified view of how IPSec datagrams are constructed; the reality is significantly more complex. The exact way that the headers are arranged in an IPSec datagram in both transport and tunnel modes depends on which version of IP is being used; IPv6 uses extension headers which must be arranged in a particular way when IPSec is used. The header placement also depends on which IPSec protocol is being used: AH or ESP. Note that it is also possible to apply both AH and ESP to the same datagram; if so, the AH header always appears before the ESP header.

There are thus three variables and eight basic combinations of mode (tunnel or transport), IP version (IPv4 or IPv6) and protocol (AH or ESP). The two topics on [AH](#) and [ESP](#) describe the four format combinations of transport/tunnel mode and IPv4/IPv6 applicable to each protocol. Note that ESP also includes an ESP trailer that goes **after** the data protected.

You could probably tell by reading these descriptions how the two modes relate to the choice of IPSec architecture from [the preceding topic](#). Transport mode requires that IPSec be integrated into IP, because AH/ESP must be applied as the original IP packaging is performed on the transport layer message. This is often the choice for implementations requiring end-to-end security with hosts that run IPSec directly.

Tunnel mode represents an encapsulation of IP within the combination of IP+IPSec. Thus, it corresponds with the BITS and BITW implementations, where IPSec is applied after IP has processed higher-layer messages and already added its header. Tunnel mode is a common choice for VPN implementations, which are based on tunneling of IP datagrams through an unsecured network such as the Internet.

**Figure 120: IPsec Tunnel Mode Operation**

IPsec *tunnel mode* is so named because it represents an encapsulation of a complete IP datagram, forming a virtual tunnel between IPsec-capable devices. The IP datagram is passed to IPsec, where a new IP header is created with the AH and/or ESP IPsec headers added. Contrast to [Figure 119](#).

**Key Concept:** IPSec has two basic modes of operation. In *transport mode*, IPSec AH and/or ESP headers are added as the original IP datagram is created; this mode is associated with integrated IPSec architectures. In *tunnel mode*, the original IP datagram is created normally, then the entire datagram is encapsulated into a new IP datagram containing the AH/ESP IPSec headers. This mode is most commonly used with “Bump In The Stack” and “Bump In The Wire” implementations.

---

## **IPSec Security Associations and the Security Association Database (SAD); Security Policies and the Security Policy Database (SPD); Selectors; the Security Parameter Index (SPI)**

Woah, there sure is a lot of "security" stuff in that topic title. Those items are all closely related, and important to understand before we proceed to looking at the core IPSec protocols themselves. These constructs are used to guide the operation of IPSec in a general way and also in particular exchanges between devices. They control how IPSec works and ensure that each datagram coming into or leaving an IPSec-capable device is properly treated.

Where to start... where to start. ☺ Let's begin by considering the problem of how to apply security in a device that may be handling many different exchanges of datagrams with others. There is overhead involved in providing security, so we do not want to do it for every message that comes in or out. Some types of messages may need more security, others less. Also, exchanges with certain devices may require different processing than others.

### ***Security Policies, Security Associations and Associated Databases***

To manage all of this complexity, IPSec is equipped with a flexible, powerful way of specifying how different types of datagrams should be handled. To understand how this works, we must first define two important logical concepts:

- ☛ **Security Policies:** A *security policy* is a rule that is programmed into the IPSec implementation that tells it how to process different datagrams received by the device. For example, security policies are used to decide if a particular packet needs to be processed by IPSec or not; those that do not bypass AH and ESP entirely. If security is required, the security policy provides general guidelines for how it should be provided, and if necessary, links to more specific detail.

Security policies for a device are stored in the device's *Security Policy Database (SPD)*.

- ☛ **Security Associations:** A *Security Association (SA)* is a set of security information that describes a particular kind of secure connection between one device and another. You can consider it a "contract", if you will, that specifies the particular security mechanisms that are used for secure communications between the two.

A device's security associations are contained in its *Security Association Database (SAD)*.

---

It's often hard to distinguish the SPD and the SAD, since they are similar in concept. The main difference between them is that security policies are general while security associations are more specific. To determine what to do with a particular datagram, a device first checks the SPD. The security policies in the SPD may reference a particular security association in the SAD. If so, the device will look up that security association and use it for processing the datagram.

## Selectors

One issue we haven't covered yet is how a device determines what policies or SAs to use for a specific datagram. Again here, IPSec defines a very flexible system that lets each security association define a set of rules for choosing datagrams that the SA applies to. Each of these rule sets is called a *selector*. For example, a selector might be defined that says that a particular range of values in the *Source Address* of a datagram, combined with another value in the *Destination Address*, means a specific SA must be used for the datagram.

Let's now come back to security associations, which are a very important concept in IPSec. Each secure communication that a device makes to another requires that an SA be established. SAs are unidirectional, so each one only handles either inbound or outbound traffic for a particular device. This allows different levels of security to be implemented for a flow from device *A* to device *B*, than for traffic coming from device *B* to device *A*. In a bidirectional communication of this sort, both *A* and *B* would have two SAs; *A* would have SAs we could call "SAdeviceBin" and "SAdeviceBout". Device *B* would have SAs "SAdeviceAin" and "SAdeviceAout".

## Security Association Triples and the Security Parameter Index (SPI)

Security associations don't actually have names, however. They are instead defined by a set of three parameters, called a *triple*:

- ① **Security Parameter Index (SPI):** A 32-bit number that is chosen to uniquely identify a particular SA for any connected device. The SPI is placed in AH or ESP datagrams and thus links each secure datagram to the security association. It is used by the recipient of a transmission so it knows what SA governs the datagram.
- ② **IP Destination Address:** The address of the device for whom the SA is established.
- ③ **Security Protocol Identifier:** Specifies whether this association is for AH or ESP. If both are in use with this device they have separate SAs.

As you can see, the two security protocols AH and ESP are dependent on security associations and policies and the various databases that control their operation. Management of these databases is important, but another whole complex subject. Generally, SAs can either be set up manually (which is of course extra work) or an automated system can be deployed using a protocol like [IKE](#).

Confused? I don't blame you, despite my best efforts, and remember that this is all *highly* simplified. Welcome to the wonderful world of networking security. If you are ever besieged by insomnia, I *highly* recommend RFC 2401. ☺

---

## **IPSec Authentication Header (AH)**

One of the two core security protocols in IPSec is the *Authentication Header (AH)*. This is another protocol whose name has been well chosen: AH is a protocol that provides *authentication* of either all or part of the contents of a datagram through the addition of a *header* that is calculated based on the values in the datagram. What parts of the datagram are used for the calculation, and the placement of the header, depends on the mode ([tunnel or transport](#)) and the version of IP (IPv4 or IPv6).

The operation of the AH protocol is surprisingly simple—especially for any protocol that has anything to do with network security. It can be considered analogous to the algorithms used to calculate checksums or perform CRC checks for error detection. In those cases, a standard algorithm is used by the sender to compute a checksum or CRC code based on the contents of a message. This computed result is transmitted along with the original data to the destination, which repeats the calculation and discards the message if any discrepancy is found between its calculation and the one done by the source.

This is the same idea behind AH, except that instead of using a simple algorithm known to everyone, we use a special hashing algorithm and a specific key known only to the source and the destination. A [security association](#) between two devices is set up that specifies these particulars so that the source and destination know how to perform the computation but nobody else can. On the source device, AH performs the computation and puts the result (called the *Integrity Check Value* or *ICV*) into a special header with other fields for transmission. The destination device does the same calculation using the key the two devices share, which enables it to see immediately if any of the fields in the original datagram were modified (either due to error or malice).

It's important that I point out explicitly that just as a checksum doesn't change the original data, neither does the ICV calculation change the original data. The presence of the AH header allows us to verify the integrity of the message, but doesn't encrypt it. Thus, AH provides **authentication** but not **privacy** (that's what ESP is for. No, I don't mean using a psychic, I mean [the other IPSec core protocol](#)!)

### ***Authentication Header Datagram Placement and Linking***

The calculation of the authentication header is similar for both IPv4 and IPv6. One difference is in the exact mechanism used for placing the header into the datagram and for linking the headers together. I'll describe IPv6 first since it is simpler, as AH was really designed to fit into IPv6's mechanism for this.

#### **IPv6 Authentication Header Placement and Linking**

The AH is inserted into the IP datagram as an extension header, following the [normal IPv6 rules for extension header linking](#). It is linked by the previous header (extension or main) putting into its *Next Header* field the assigned value for the AH header (51). The AH header then links to the next extension header or the transport layer header using its *Next Header* field.

---

In transport mode, the AH is placed into the main IP header and appears before any *Destination Options* header containing options intended for the final destination, and before an *ESP* header if present, but after any other extension headers. In tunnel mode, it appears as an extension header of the new IP datagram that encapsulates the original one being tunneled. This is shown graphically in [Figure 121](#).

### IPv4 Authentication Header Placement and Linking

A method that is similar to the IPv6 header linking technique is employed. In an IPv4 datagram, the *Protocol* field indicates the identity of the higher layer protocol (typically TCP or UDP) carried in the datagram. As such, this field “points” to the next header, which is at the front of the IP payload. AH takes this value and puts it into its *Next Header* field, and then places the protocol value for AH itself (51 decimal) into the IP *Protocol* field. This makes the IP header “point” to the AH, which then “points” to whatever the IP datagram pointed to before.

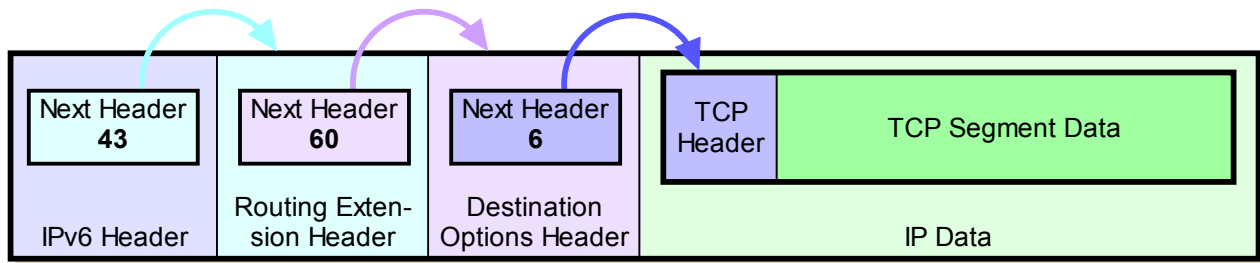

Again, in transport mode, the authentication header is added after the main IP header of the original datagram; in tunnel mode it is added after the new IP header that encapsulates the original datagram being tunneled. This is shown in [Figure 122](#).

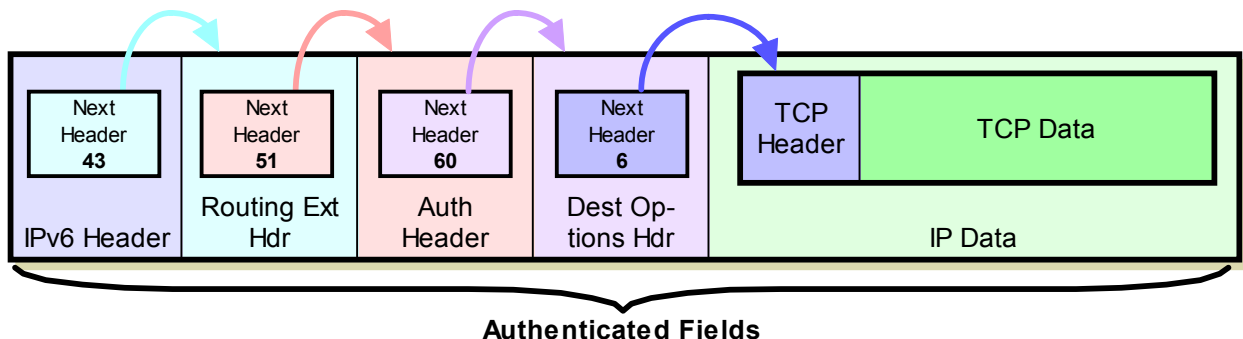

**Key Concept:** The IPsec *Authentication Header (AH)* protocol allows the recipient of a datagram to verify its authenticity. It is implemented as a header added to an IP datagram that contains an *integrity check value* computed based on the values of the fields in the datagram. This value can be used by the recipient to ensure that the data has not been changed in transit. The Authentication Header does not encrypt data and thus does not ensure the privacy of transmissions.

---

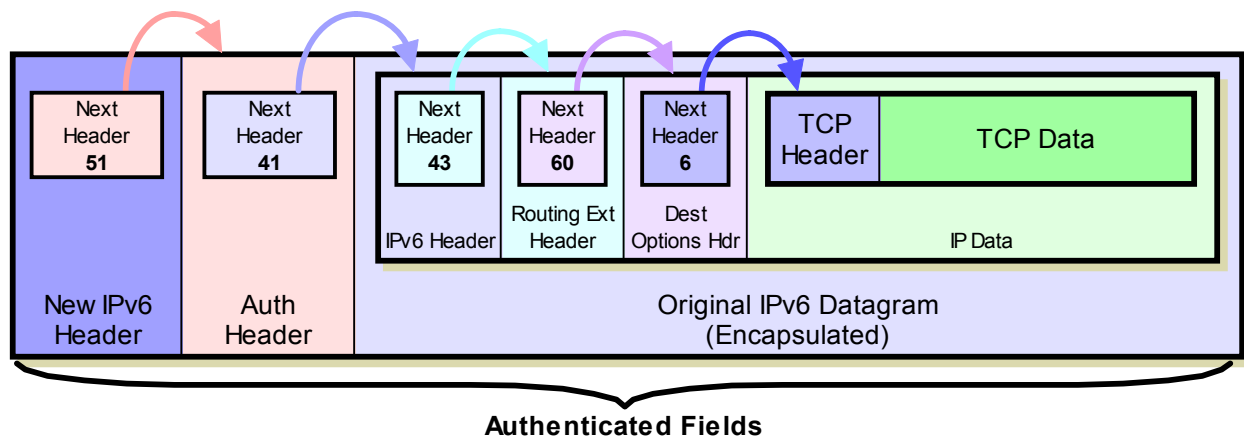

**Original IPv6 Datagram Format (Including Routing Extension Header and Destination-Specific Destination Options Extension Header)**

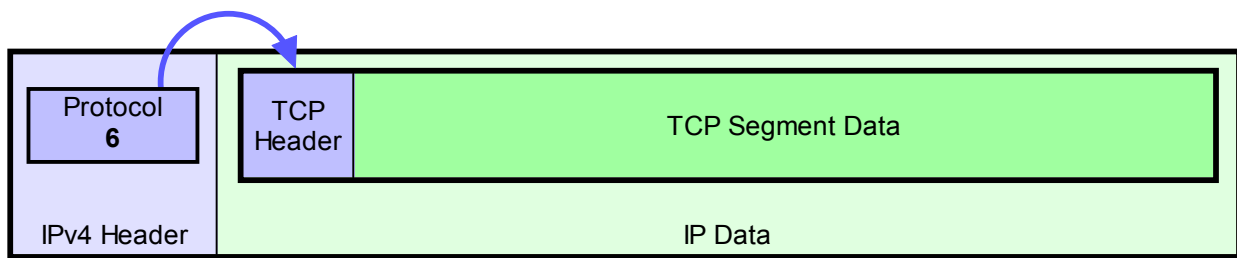

**IPv6 AH Datagram Format - IPsec Transport Mode**

**IPv6 AH Datagram Format - IPsec Tunnel Mode**

**Figure 121: IPv6 Datagram Format With IPsec Authentication Header (AH)**

At top is an example IPv6 datagram with two extension headers linked using the standard IPv6 mechanism (see [Figure 106](#).) When AH is applied in transport mode, it is simply added as a new extension header (shown in pink) that goes between the *Routing* extension header and the *Destination Options* header. In tunnel mode, the entire original datagram is encapsulated into a new IPv6 datagram that contains the Authentication Header. In both cases the *Next Header* fields are used to link each header one to the next. Note the use of Next Header value 41 in tunnel mode, which is the value for the encapsulated IPv6 datagram.

**Original IPv4 Datagram Format**

**IPv4 AH Datagram Format - IPsec Transport Mode**

**IPv4 AH Datagram Format - IPsec Tunnel Mode**

**Figure 122: IPv4 Datagram Format With IPsec Authentication Header (AH)**

At top is an example IPv4 datagram; it may or may not contain IPv4 options (which are not distinct entities as they are in IPv6). In transport mode, the authentication header is added between the IP header and the IP data; the *Protocol* field of the IP header points to it, while its *Next Header* field contains the IP header's prior protocol value (in this case 6, for TCP.) In tunnel mode the IPv4 datagram is encapsulated into a new IPv4 datagram that includes the AH header. Note in tunnel mode, the AH header's use of the value 4 (which means IPv4) in its *Next Header*.

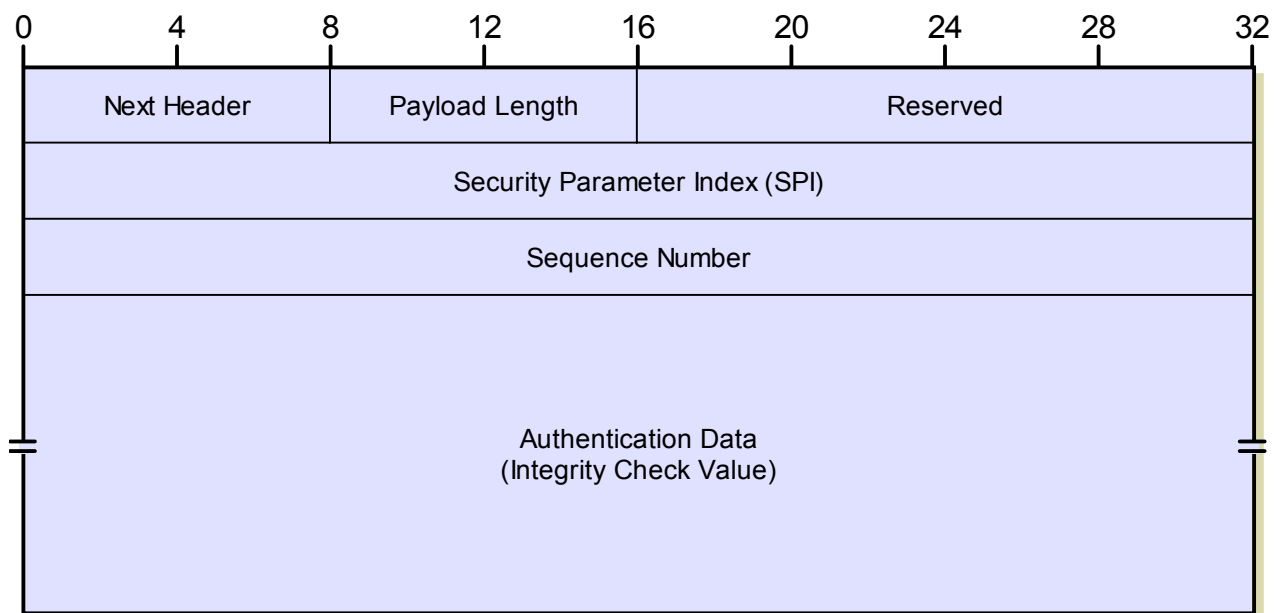

---

## Authentication Header Format

The format of the Authentication Header itself is described in [Table 80](#) and shown in [Figure 123](#).

**Table 80: IPSec Authentication Header (AH) Format**

Field Name	Size (bytes)	Description
<b>Next Header</b>	1	<b>Next Header:</b> Contains the protocol number of the next header after the AH. Used to link headers together.
<b>Payload Len</b>	1	<b>Payload Length:</b> Despite its name, this field measures the length of the authentication header itself, not the payload. (I wonder what the history is behind that!) It is measured in 32 bit units, with 2 subtracted for consistency with how header lengths are normally calculated in IPv6.
<b>Reserved</b>	2	<b>Reserved:</b> Not used; set to zeroes.
<b>SPI</b>	4	<b>Security Parameter Index (SPI):</b> A 32-bit value that when combined with the destination address and security protocol type (which here is obviously the one for AH) identifies the security association to be used for this datagram. <a href="#">See the topic on security associations for more details.</a>
<b>Sequence Number</b>	4	<b>Sequence Number:</b> This is a counter field that is initialized to zero when a security association is formed between two devices, and then incremented for each datagram sent using that SA. This uniquely identifies each datagram on an SA and is used to provide protection against replay attacks by preventing the retransmission of captured datagrams.
<b>Authentication Data</b>	Variable	<b>Authentication Data:</b> This field contains the result of the hashing algorithm performed by the AH protocol, the Integrity Check Value (ICV).

**Figure 123: IPSec Authentication Header (AH) Format**

---

The size of the *Authentication Data* field is variable to support different datagram lengths and hashing algorithms. Its total length must be a multiple of 32 bits. Also, the entire header must be a multiple of either 32 bits (for IPv4) or 64 bits (for IPv6), so additional padding may be added to the *Authentication Data* field if necessary.

You may also notice that no IP addresses appear in the header, which is a prerequisite for it being the same for both IPv4 and IPv6.

## **IPSec Encapsulating Security Payload (ESP)**

The IPSec [Authentication Header \(AH\)](#) provides integrity authentication services to IPSec-capable devices, so they can verify that messages are received intact from other devices. For many applications, however, this is only one piece of the puzzle. We want to not only protect against intermediate devices changing our datagrams, we want to protect against them examining their contents as well. For this level of private communication, AH is not enough; we need to use the *Encapsulating Security Payload (ESP)* protocol.

The main job of ESP is to provide the privacy we seek for IP datagrams by *encrypting* them. An encryption algorithm combines the data in the datagram with a key to transform it into an encrypted form. This is then repackaged using a special format that we will see shortly, and transmitted to the destination, which decrypts it using the same algorithm. ESP also sports Encapsulating Security Payload Fields its own authentication scheme like that used in AH, or can be used in conjunction with AH.

### ***Encapsulating Security Payload Fields***

ESP has several fields that are the same as those used in AH, but packages its fields in a very different way. Instead of having just a header, it divides its fields into three components:

- ☉ **ESP Header:** This contains two fields, the *SPI* and *Sequence Number*, and comes before the encrypted data. Its placement depends on whether ESP is used in transport mode or tunnel mode, as explained in [the topic on IPSec modes](#).
- ☉ **ESP Trailer:** This section is placed after the encrypted data. It contains padding that is used to align the encrypted data, through a *Padding* and *Pad Length* field. Interestingly, it also contains the *Next Header* field for ESP.
- ☉ **ESP Authentication Data:** This field contains an *Integrity Check Value (ICV)*, computed in a manner similar to how the AH protocol works, for when ESP's optional authentication feature is used.

There are two reasons why these fields are broken into pieces like this. The first is that some encryption algorithms require the data to be encrypted to have a certain block size, and so padding must appear after the data and not before it. That's why padding appears in the ESP Trailer. The second is that the *ESP Authentication Data* appears separately because it is used to authenticate the rest of the encrypted datagram **after encryption**. This means it cannot appear in the ESP Header or ESP Trailer.

---

## Encapsulating Security Payload Operations and Field Use

Let's try to explain this procedurally, by considering three basic steps performed by ESP.

### 1. Header Calculation and Placement

The first thing to consider is how the ESP header is placed; this is similar to how AH works:

- ☛ **IPv6:** The *ESP Header* is inserted into the IP datagram as an extension header, following [the normal IPv6 rules for extension header linking](#). In transport mode, it appears before a *Destination Options* header containing options intended for the final destination, but after any other extension headers, if present. In tunnel mode, it appears as an extension header of the new IP datagram that encapsulates the original one being tunneled. This can be seen in [Figure 124](#).
- ☛ **IPv4:** As with the AH, the *ESP Header* is placed after the normal IPv4 header. In transport mode, it appears after the original IP header; in tunnel mode, after the IP header of the new datagram encapsulating the original. This is shown in [Figure 125](#).

### 2. Trailer Calculation and Placement

The *ESP Trailer* is appended to the data to be encrypted. ESP then performs the encryption. The payload (TCP/UDP message or encapsulated IP datagram) and the ESP trailer are both encrypted, but the *ESP Header* is not. Note again that any other IP headers that appear between the ESP header and the payload are also encrypted. In IPv6 this can include a *Destination Options* extension header.

Normally, the *Next Header* field would appear in the ESP header and would be used to link the ESP header to the header that comes after it. However, the *Next Header* field in ESP appears in the trailer and not the header, which makes the linking seem a bit strange in ESP. The method is the same as that used in AH and in IPv6 in general, with the *Next Header* and/or *Protocol* fields used to tie everything together. However, in ESP the *Next Header* field appears *after* the encrypted data, and so “points back” to one of the following: a *Destination Options* extension header (if present), a TCP/UDP header (in transport mode) or an IPv4/IPv6 header (in tunnel mode). This too is shown in [Figure 124](#) and [Figure 125](#).

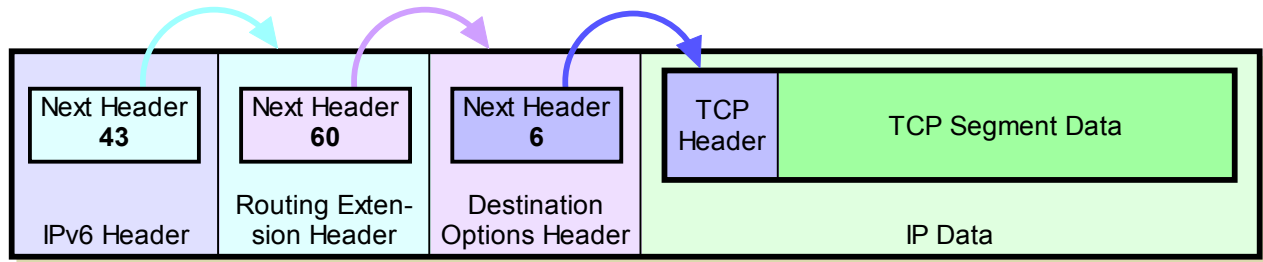

### 3. ESP Authentication Field Calculation and Placement

If the optional ESP authentication feature is used, the authentication field is computed over the entire ESP datagram (except the *Authentication Data* field itself, of course). This includes the ESP header, payload and trailer.

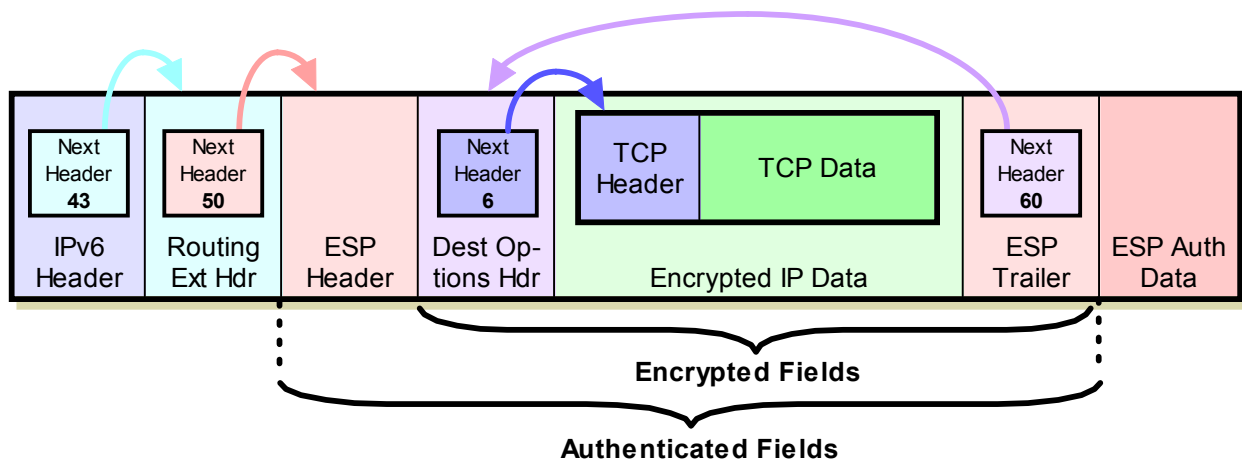

**Key Concept:** The IPsec *Encapsulating Security Payload* protocol allows the contents of a datagram to be encrypted, to ensure that only the intended recipient is able to see the data. It is implemented using three components: an *ESP Header* added to the front of a protected datagram, an *ESP Trailer* that follows the protected data, and an optional *ESP Authentication Data* field that provides authentication services similar to those provided by the [Authentication Header \(AH\)](#).

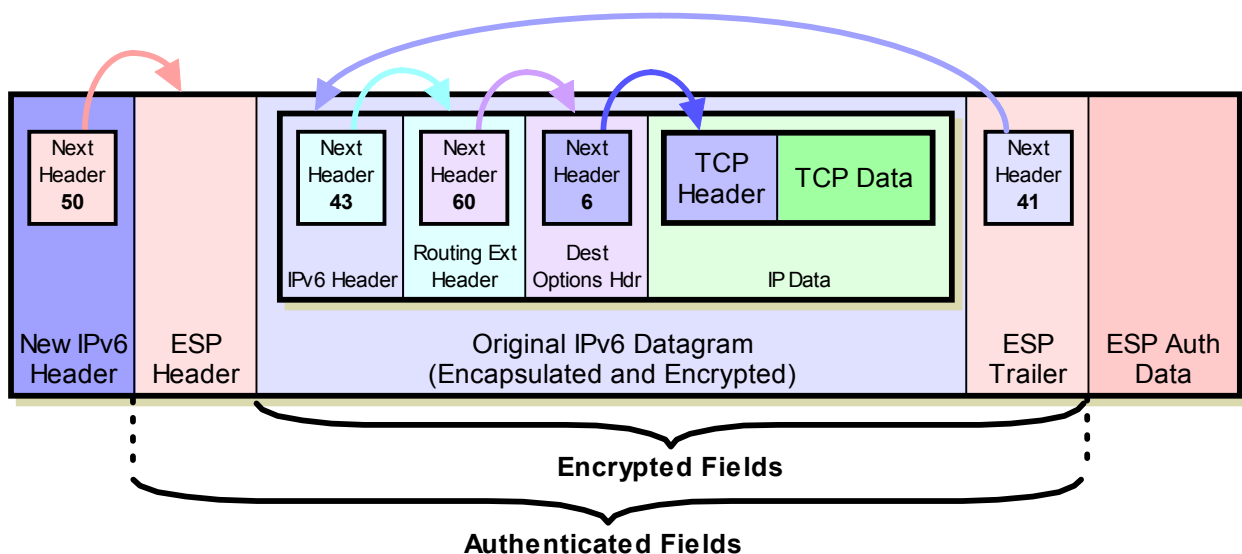

---

**Original IPv6 Datagram Format (Including Routing Extension Header and Destination-Specific Destination Options Extension Header)**

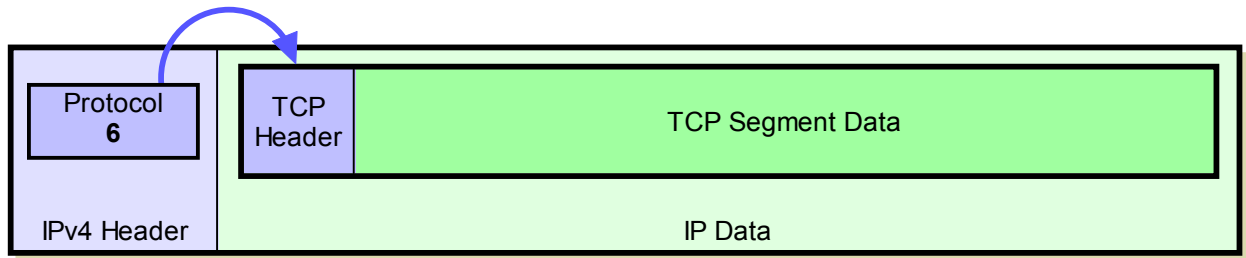

**IPv6 ESP Datagram Format - IPSec Transport Mode**

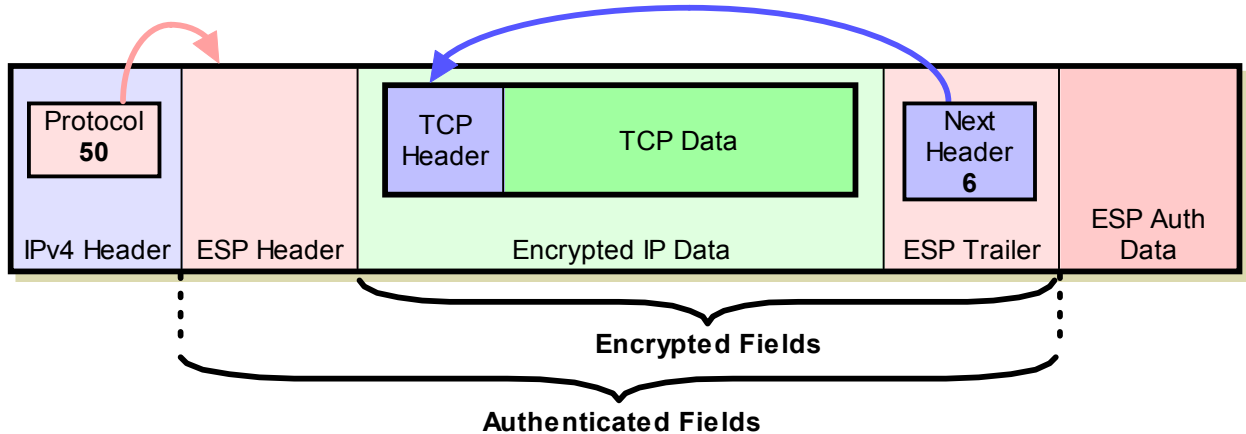

**IPv6 ESP Datagram Format - IPSec Tunnel Mode**

**Figure 124: IPv6 Datagram Format With IPSec Encapsulating Security Payload (ESP)**

At top is the same example IPv6 datagram with two extension headers shown in Figure 121. When ESP is applied in transport mode, the *ESP Header* is added to the existing datagram as in AH, and the *ESP Trailer* and *ESP Authentication Data* are placed at the end. In tunnel mode, the *ESP Header* and *Trailer* bracket the entire encapsulated IPv6 datagram. Note the encryption and authentication coverage in each case, and also how the *Next Header* field “points back” into the datagram since it appears in the ESP Trailer.

**Original IPv4 Datagram Format**

**IPv4 ESP Datagram Format - IPSec Transport Mode**

**IPv4 ESP Datagram Format - IPSec Tunnel Mode**

**Figure 125: IPv4 Datagram Format With IPSec Authentication Header (AH)**

At top is the same sample IPv4 datagram shown in [Figure 122](#). When this datagram is processed by ESP in transport mode, the ESP Header is placed between the IPv4 header and data, with the ESP Trailer and ESP Authentication Data following. In tunnel mode, the entire original IPv4 datagram is surrounded by these ESP components, rather than just the IPv4 data. Again, as in [Figure 124](#), note the encryption and authentication coverage, and how the Next Header field “points back” to specify the identity of the encrypted data/datagram.

---

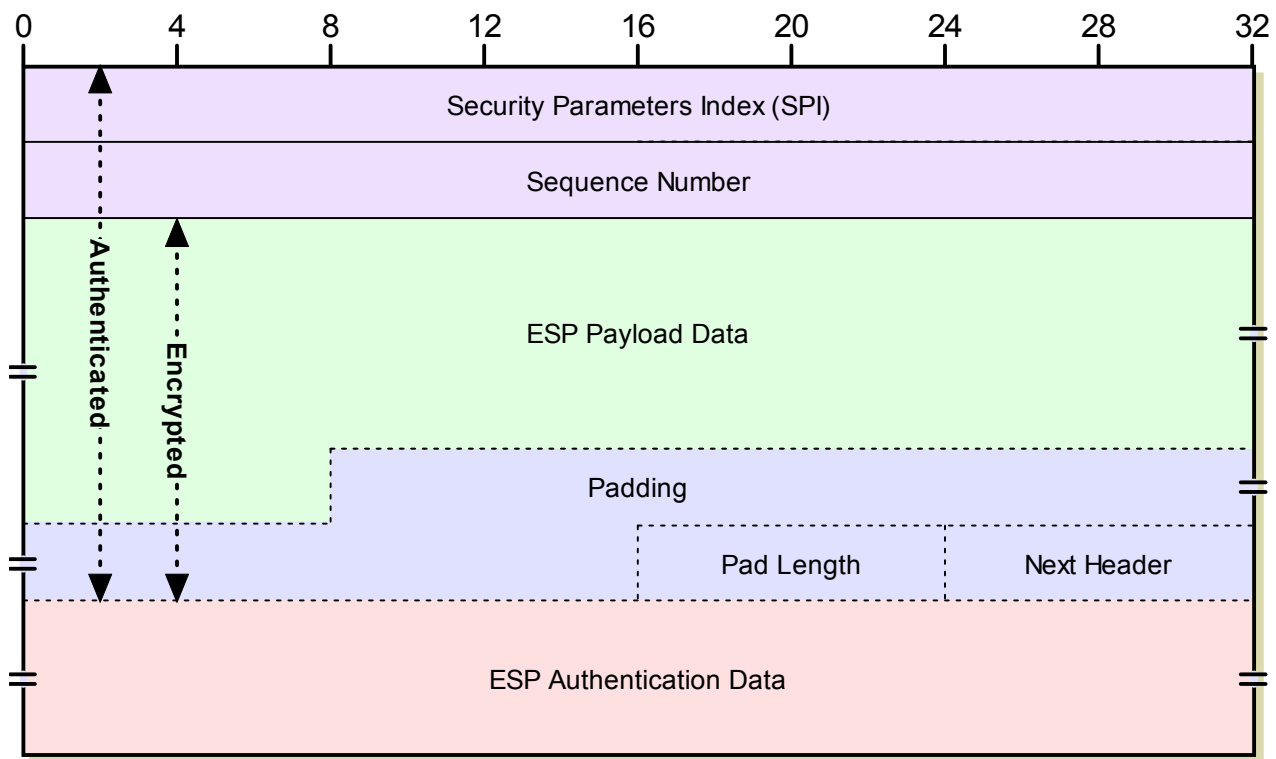

## Encapsulating Security Payload Format

The format of the ESP sections and fields is described in [Table 81](#) and shown in [Figure 126](#). I have shown explicitly in each the encryption and authentication coverage of the fields, which will hopefully cause all that stuff I just wrote to make at least a bit more sense.

**Table 81: IPSec Encapsulating Security Payload (ESP) Format**

Section	Field Name	Size (bytes)	Description	Encryption Coverage	Authentication Coverage
ESP Header	<i>SPI</i>	4	<b>Security Parameter Index (SPI):</b> A 32-bit value that is combined with the destination address and security protocol type to identify the security association to be used for this datagram. <a href="#">See the topic on security associations for more details.</a>		
	<i>Sequence Number</i>	4	<b>Sequence Number:</b> A counter field initialized to zero when a security association is formed between two devices, and then incremented for each datagram sent using that SA. This is used to provide protection against replay attacks.		
Payload	<i>Payload Data</i>	Variable	<b>Payload Data:</b> The encrypted payload data, consisting of a higher layer message or encapsulated IP datagram. May also include support information such as an initialization vector, required by certain encryption methods.		
ESP Trailer	<i>Padding</i>	Variable (0 to 255)	<b>Padding:</b> Additional padding bytes included as needed for encryption or for alignment.		
	<i>Pad Length</i>	1	<b>Pad Length:</b> The number of bytes in the preceding Padding field.		
	<i>Next Header</i>	1	<b>Next Header:</b> Contains the protocol number of the next header in the datagram. Used to chain together headers.		
ESP Authentication Data		Variable	<b>ESP Authentication Data:</b> This field contains the <i>Integrity Check Value (ICV)</i> resulting from the application of the optional ESP authentication algorithm.		

The *Padding* field is used when encryption algorithms require it. *Padding* is also used to make sure that the *ESP Trailer* ends on a 32-bit boundary. That is, the size of the *ESP Header* plus *Payload* plus *ESP Trailer* must be a multiple of 32 bits. The *ESP Authentication Data* must also be a multiple of 32 bits.

**Figure 126: IPsec Encapsulating Security Payload (ESP) Format**

Note that most of the fields and sections in this format are variable length. The exceptions are the *SPI* and *Sequence Number* fields, which are 4 bytes long, and the *Pad Length* and *Next Header* fields, 1 byte each.

## IPsec Key Exchange (IKE)

IPsec, like many secure networking protocol sets, is based on the concept of a “shared secret”. Two devices that want to send information securely encode and decode it using a piece of information that only they know. Anyone who isn’t “in” on the secret is able to intercept the information but is prevented either from reading it (if [ESP](#) is used to encrypt the payload) or from tampering with it undetected (if [AH](#) is used). Before either AH or ESP can be used, however, it is necessary for the two devices to exchange the “secret” that the security protocols themselves will use. The primary support protocol used for this purpose in IPsec is called *Internet Key Exchange (IKE)*.

IKE is defined in RFC 2409, and is one of the more complicated of the IPsec protocols to comprehend. In fact, it is simply impossible to truly understand more than a real simplification of its operation without significant background in cryptography. I don’t have a background in cryptography and I must assume that you, my reader, do not either. So rather than fill this topic with baffling acronyms and unexplained concepts, I will just provide a brief outline of IKE and how it is used.

---

## ***IKE Overview and Relationship to Other Key Exchange Methods***

The purpose of IKE is to allow devices to exchange information required for secure communication. As the title suggests, this includes cryptographic keys used for encoding authentication information and performing payload encryption. IKE works by allowing IPSec-capable devices to exchange [security associations \(SAs\)](#), to populate their security association databases (SADs). These are then used for the actual exchange of secured datagrams with the AH and ESP protocols.

IKE is considered a “hybrid” protocol because it combines (and supplements) the functions of three other protocols. The first of these is the *Internet Security Association and Key Management Protocol (ISAKMP)*. This protocol provides a framework for exchanging encryption keys and security association information. It operates by allowing security associations to be negotiated through a series of phases.

ISAKMP is a generic protocol that supports many different key exchange methods. In IKE, the ISAKMP framework is used as the basis for a specific key exchange method that combines features from two key exchange protocols:

- ☉ **OAKLEY:** Describes a specific mechanism for exchanging keys through the definition of various key exchange “modes”. Most of the IKE key exchange process is based on OAKLEY.
- ☉ **SKEME:** Describes a different key exchange mechanism than OAKLEY. IKE uses some features from SKEME, including its method of public key encryption and its fast re-keying feature.

### ***IKE Operation***

So, IKE doesn't strictly implement either OAKLEY or SKEME but takes bits of each to form its own method of using ISAKMP. Clear as mud, I know. Since IKE functions within the framework of ISAKMP, its operation is based on the ISAKMP phased negotiation process. There are two phases:

- ☉ **ISAKMP Phase 1:** The first phase is a “setup” stage where two devices agree on how to exchange further information securely. This negotiation between the two units creates a security association for ISAKMP itself; an *ISAKMP SA*. This security association is then used for securely exchanging more detailed information in Phase 2.
- ☉ **ISAKMP Phase 2:** In this phase the ISAKMP SA established in Phase 1 is used to create SAs for other security protocols. Normally, this is where the parameters for the “real” SAs for the AH and ESP protocols would be negotiated.

An obvious question is why IKE bothers with this two-phased approach; why not just negotiate the security association for AH or ESP in the first place? Well, even though the extra phase adds overhead, multiple Phase 2 negotiations can be conducted after one Phase 1, which amortizes the extra “cost” of the two-phase approach. It is also possible to use a simpler exchange method for Phase 2 once the ISAKMP security association has been established in Phase 1.

---

The ISAKMP security association negotiated during Phase 1 includes the negotiation of the following attributes used for subsequent negotiations:

- ☉ An encryption algorithm to be used, such as the *Data Encryption Standard (DES)*.
- ☉ A hash algorithm (*MD5* or *SHA*, as used by AH or ESP).
- ☉ An authentication method, such as authentication using previously shared keys.
- ☉ A *Diffie-Hellman* group. Diffie and Hellman were two pioneers in the industry who invented public-key cryptography. In this method, instead of encrypting and decrypting with the same key, data is encrypted using a public key knowable to anyone, and decrypted using a private key that is kept secret. A Diffie-Hellman group defines the attributes of how to perform this type of cryptography. Four predefined groups derived from OAKLEY are specified in IKE and provision is allowed for defining new groups as well.

Note that even though security associations in general are unidirectional, the ISAKMP SA is established bidirectionally. Once Phase 1 is complete, then, either device can set up a subsequent SA for AH or ESP using it.

---

## **Internet Protocol Mobility Support (Mobile IP)**

The [Internet Protocol \(IP\)](#) is the most successful network layer protocol in computing due to its many strengths, but it also has some weaknesses, most of which have become more important as networks have evolved over time. Technologies like [classless addressing](#) and [Network Address Translation](#) combat the exhaustion of the IPv4 address space, while IPSec provides it with secure communications it lacks. Another weakness of IP is that it was not designed with mobile computers in mind.

While mobile devices can certainly use IP, the way that devices are addressed and datagrams routed causes a problem when they are moved from one network to another. At the time IP was developed, computers were large and rarely moved. Today, we have millions of notebook computers and smaller devices, some of which even use wireless networking to connect to the wired network. The importance of providing full IP capabilities for these mobile devices has grown dramatically. To support IP in a mobile environment, a new protocol called *IP Mobility Support*, or more simply, *Mobile IP*, was developed.

In this section I describe the special protocol developed to overcome the problems with mobile computers attaching to IP internetworks. I begin with an overview of Mobile IP and a more detailed description of why it was created. I discuss important concepts that define Mobile IP and its general mode of operation. I then move on to some of the specifics of how Mobile IP works. This includes a description of the special mobile IP addressing scheme, an explanation of how agents are discovered by mobile devices, the process of registration with the device's home agent, and how data is encapsulated and routed. I discuss the impact that Mobile IP has on the operation of the TCP/IP Address Resolution Protocol (ARP). I end the section by examining some of the efficiency and security issues that come into play when Mobile IP is used.

**Note:** This section describes specifically how IP mobility support is provided for IPv4 networks. In the future I may add more specific details for how mobility is implemented in [IPv6](#).

---

**Background Information:** If you are not familiar with the basics of [IP addressing](#) and [routing](#), I strongly suggest at least skimming those sections before attempting to read about Mobile IP.

---

### **Mobile IP Overview, History and Motivation**

Mobile computing has greatly increased in popularity over the past several years, due largely to advances in miniaturization. Today we can get in a notebook PC or even a hand-held computer the power that once required a hulking behemoth of a machine. We also have wireless LAN technologies that easily let a device move from place to place and retain networking connectivity at the data link layer. Unfortunately, the Internet Protocol was

---

developed back in the era of the behemoths, and isn't designed to deal gracefully with computers that move around. To understand why IP doesn't work well in a mobile environment, we must take a look back at how IP addressing and routing function.

### ***The Problem With Mobile Nodes in TCP/IP***

If you've read any of [the materials in this Guide on IP addressing](#)—and I certainly hope that you have—you know that IP addresses are [fundamentally divided into two portions](#): a network identifier (network ID) and a host identifier (host ID). The network ID specifies which network a host is on, and the host ID uniquely specifies hosts within a network. This structure is fundamental to datagram routing, because devices use the network ID portion of the destination address of a datagram to [determine if the recipient is on a local network or a remote one](#), and routers use it to determine how to route the datagram.

This is a great system, but it has one critical flaw: the IP address is tied tightly to the network where the device is located. Most devices never (or at least rarely) change their attachment point to the network, so this is not a problem, but it is certainly an issue for a mobile device. When the mobile device travels away from its home location, the system of routing based on IP address “breaks”. This is illustrated in [Figure 127](#).

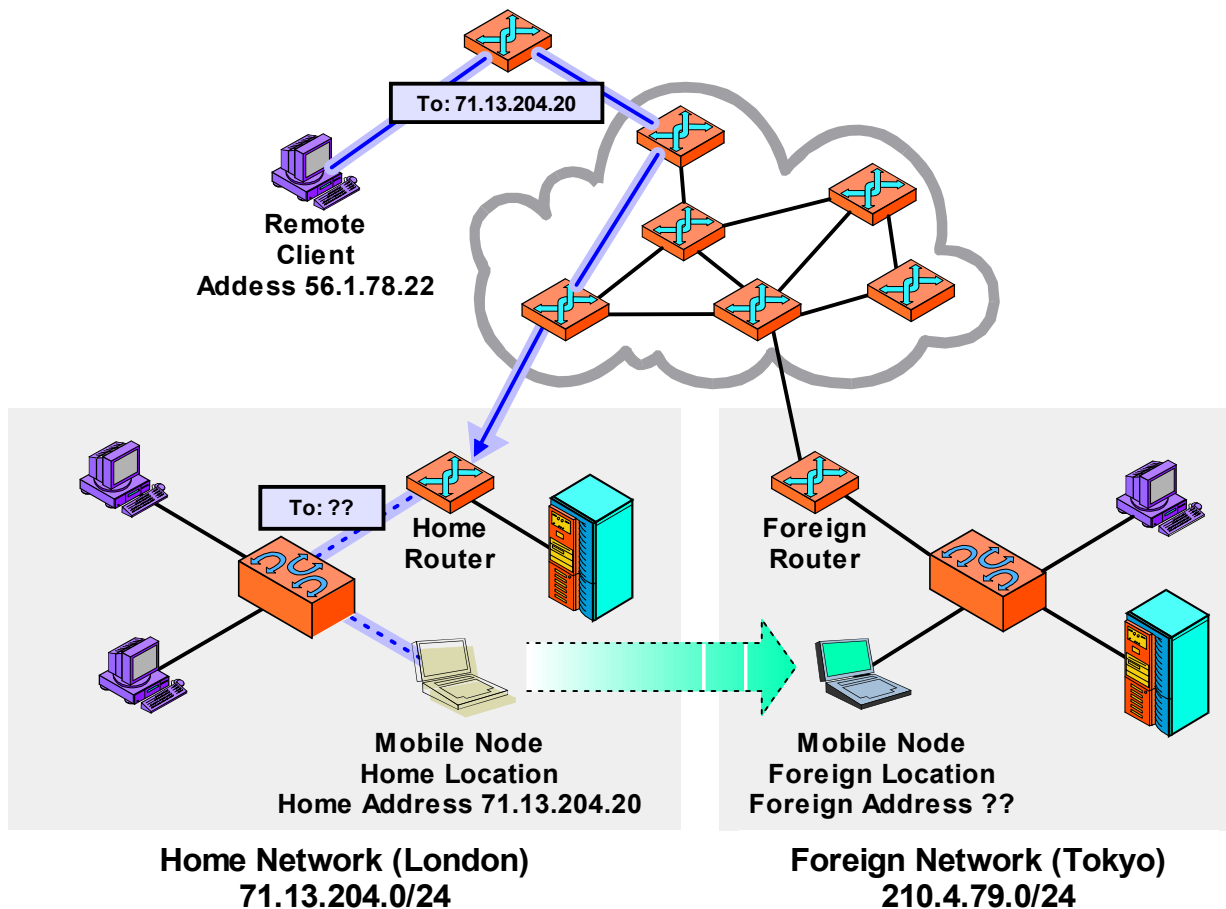

### ***Difficulties with Older Mobile Node Solutions***

The tight binding of network identifier and host IP address means that there are only two real options under conventional IP when a mobile device moves from one network to another:

- ☉ **Change IP Address:** We can change the IP address of the host to a new address that includes the network ID of the network to which it is moving.
- ☉ **Decouple IP Routing From Address:** We can change the way routing is done for the device, so that instead of routers sending datagrams to it based on its network ID, they route based on its entire address.

These both seem like viable options at first glance, and if only a few devices tried them they might work. Unfortunately, they are both inefficient, often impractical, and neither is **scalable**, meaning, practical when thousands or millions of devices try them:

- ☉ Changing the IP address each time a device moves is time-consuming and normally requires manual intervention. In addition, the entire TCP/IP stack would need to be restarted, breaking any existing connections.
- ☉ If we change the mobile device's IP address, how do we communicate the change of address to other devices on the Internet? These devices will only have the mobile node's original home address, which means they won't be able to find it even if we give it a new address matching its new location.
- ☉ Routing based on the entire address of a host would mean the entire Internet would be flooded with routing information for each and every mobile computer. Considering how much trouble has gone into developing technologies like classless addressing to reduce routing table entries, it's obvious this is a Pandora's Box nobody wants to touch.

**Figure 127: The Main Problem With Mobile Devices on IP Internetworks**

In this example, a mobile device (the notebook PC) has been moved from its home network in London to another network in Tokyo. A remote client (upper left) decides to send a datagram to the mobile device. However, it has no idea the device has moved. Since it sends using the mobile node's home address, 71.13.204.20, its request is routed to the router responsible for that network, which is in London. Of course the mobile device isn't there, so the router can't deliver it. Mobile IP solves this problem by giving mobile devices and routers the capability to forward datagrams from one location to another.

**Key Concept:** The basic problem with supporting mobile devices in IP internetworks is that routing is performed using the IP address, which means the IP address of a device is tied to the network where that the device is located. If a device changes networks, data sent to its old address cannot be delivered by conventional means. Traditional workarounds such as routing by the full IP address or changing IP addresses manually often create more problems.

### ***A Better Solution: Mobile IP***

The solution to these difficulties was to define a new protocol especially to support mobile devices, which adds to the original Internet Protocol. This protocol, called *IP Mobility Support for IPv4*, was first defined in RFC 2002, updated in RFC 3220, and is now

---

described in RFC 3344. The formal name as given in that document title is rather long; the technology is more commonly called *Mobile IP* both in the RFC itself and by networking people.

To ensure its success, Mobile IP's designers had to meet a number of important goals. The resulting protocol has these key attributes and features:

- ☉ **Seamless Device Mobility Using Existing Device Address:** Mobile devices can change their physical network attachment method and location while continuing to use their existing IP address.
- ☉ **No New Addressing or Routing Requirements:** The overall scheme for addressing and routing as in regular IP is maintained. IP addresses are still assigned in the conventional way, by the owner of each device. No new routing requirements are placed on the internetwork, such as host-specific routes.
- ☉ **Interoperability:** Mobile IP devices can still send to and receive from existing IP devices that do not know how Mobile IP works, and vice-versa.
- ☉ **Layer Transparency:** The changes made by Mobile IP are confined to the network layer. Transport layer and higher layer protocols and applications are able to function as in regular IPv4, and existing connections can even be maintained across a move.
- ☉ **Limited Hardware Changes:** Changes are required to the software in the mobile device, as well as to routers used directly by the mobile device. Other devices, however, do not need changes, including routers between the ones on the home and visited networks.
- ☉ **Scalability:** Mobile IP allows a device to change from any network to any other, and supports this for an arbitrary number of devices. The scope of the connection change can be global; you could detach a notebook from an office in London and move it to Australia or Brazil, for example, and it will work the same as if you took it to the office next door.
- ☉ **Security:** Mobile IP works by redirecting messages, and includes authentication procedures to prevent an unauthorized device from causing problems.

Mobile IP accomplishes these goals by implementing a *forwarding system* for mobile devices. When a mobile unit is on its “home” network, it functions normally. When it moves to a different network, datagrams are sent from its home network to its new location. This allows normal hosts and routers that don't know about Mobile IP to continue to operate as if the mobile device had not moved. Special support services are required to implement Mobile IP, to allow activities such as letting a mobile device determine where it is, telling the home network where to forward messages and more. I explore Mobile IP operation more in [the next topic](#), and the implementation specifics in the rest of this section.

**Key Concept:** *Mobile IP* solves the problems associated with devices that change network locations, by setting up a system where datagrams sent to the mobile node's home location are forwarded to it wherever it may be located. It is particularly useful for wireless devices but can be used for any device that moves between networks periodically.

---

---

Mobile IP is often associated with wireless networks, since devices using WLAN technology can move so easily from one network to another. However, it wasn't designed specifically for wireless. It can be equally useful for moving from an Ethernet network in one building to a network in another building, city or country. Mobile IP can be of great benefit in numerous applications, including traveling salespeople, consultants who visit client sites, administrators that walk around a campus troubleshooting problems, and much more.

### ***Limitations of Mobile IP***

It's important to realize that Mobile IP has certain limitations in its usefulness in a wireless environment. It was designed to handle mobility of devices, but only relatively ***infrequent*** mobility. This is due to the work involved with each change. This overhead isn't a big deal when you move a computer once a week, a day or even an hour. It can be an issue for "real-time" mobility such as roaming in a wireless network, where hand-off functions operating at the data link layer may be more suitable. Mobile IP was designed under the specific assumption that the attachment point would not change more than once per second.

I should also point out that Mobile IP is intended to be used with devices that maintain a static IP configuration. Since the device needs to be able to always know the identity of its home network and normal IP address, it is much more difficult to use it with a device that obtains an IP address dynamically, using something like DHCP.

## **Mobile IP Concepts and General Operation**

I like analogies, as they provide a way of explaining often dry technical concepts in terms we can all relate to. The problem of mobile devices in an IP internetwork can easily be compared to a real-life mobility and information transmission problem: mail delivery for those who travel. To help explain how Mobile IP works, I will set up this analogy and use it as the basis for a look at Mobile IP's general operation. I will also refer back to it in explaining certain concepts in the remaining topics in this section.

### ***Mobile IP Overview: "Address Forwarding" for the Internet***

Suppose you are a consultant working for a large corporation with many offices. Your home office is in London, England, and you spend about half your time there. The rest of the time is split between other offices in say, Rome, Tokyo, New York City and Toronto. You also occasionally visit client sites that can be just about anywhere in the world. You may be at these remote locations for weeks at a time.

The problem is: how do you arrange things so that you can receive your mail regardless of your location? You have the same problem that regular IP has with a mobile device, and without taking special steps, the same two unsatisfactory options for resolving it: address changing or decoupling routing from your address. You can't change your address each time you move because you would be modifying it constantly; by the time you told everyone about your new address it would change again. And you certainly can't "decouple" the routing of mail from your address, unless you want to set up your own postal system!

---

The solution to this dilemma of course is *mail forwarding*. Let's say that you leave London for Tokyo for a couple of months. You tell the London post office (PO) that you will be in Tokyo. They intercept mail headed for your normal London address, relabel it, and forward it to Tokyo. Depending on where you are staying, this mail might be redirected either straight to a new address in Tokyo, or to a Tokyo PO where you can pick it up. If you leave Tokyo to go to another city, you just call the London PO and tell them your new location. When you come home, you cancel the forwarding and get your mail as always. (Yes, I'm assuming London and Tokyo each have only one post office. You mean they don't? Yeah, whatever. ☺)

The advantages of this system are many. It is relatively simple to understand and implement. It is also transparent to everyone who sends you mail; they still send to you in London and it gets wherever it needs to go. And handling of the forwarding mechanism is done only by the London PO and possibly the PO where you are presently located; the rest of the postal system doesn't even know anything out of the ordinary is going on.

There are some disadvantages of course too. The London PO may allow occasional forwarding for free, but would probably charge you if you did this on a regular basis. You might also need a special arrangement in the city you travel to. You have to keep communicating with your home PO each time you move. And perhaps most importantly, every piece of mail has to be sent through the system twice—first to London and then to wherever you are located—which is inefficient.

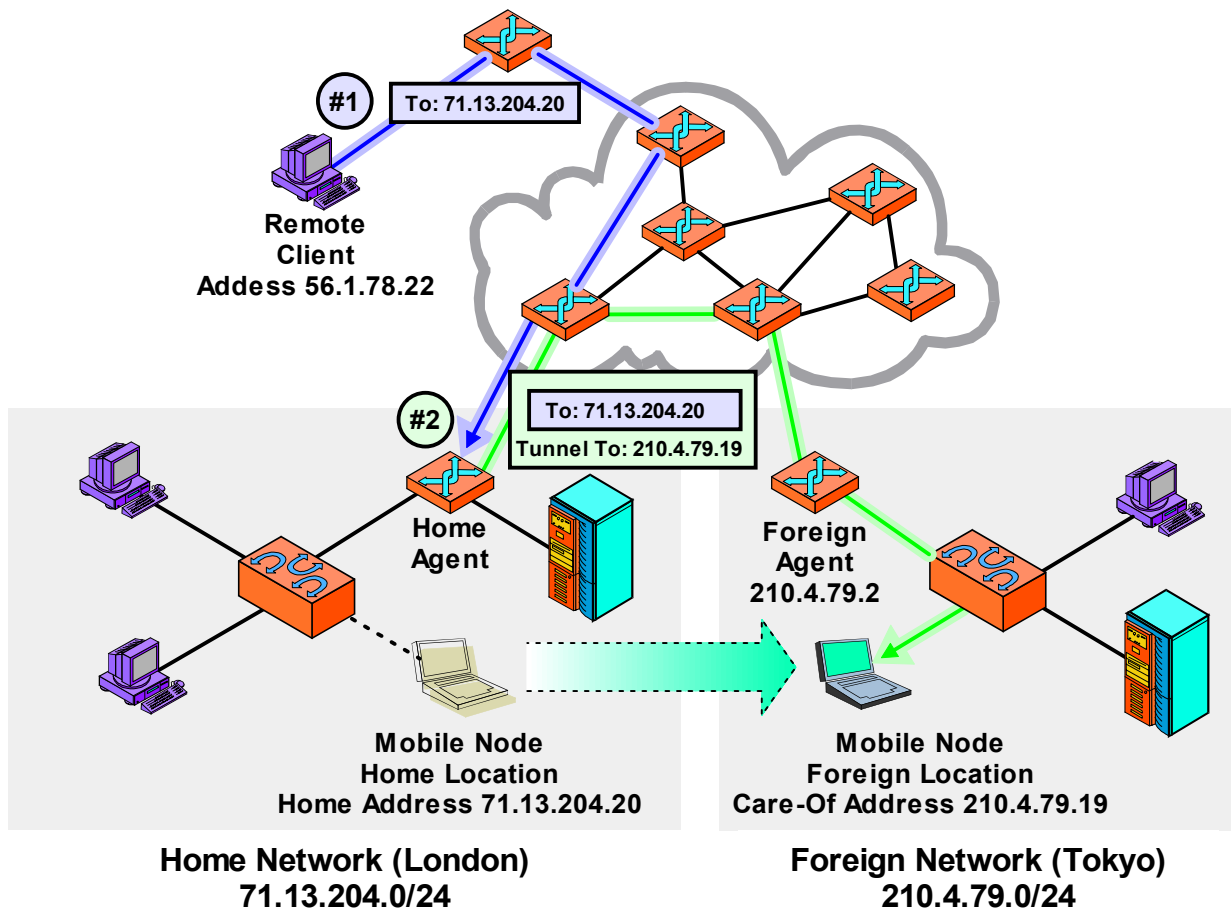

Mobile IP works in a manner very similar to the mail forwarding system I just described. The “traveling consultant” is the device that goes from network to network. Each network can be considered like a different “city”, and the internetwork of routers is like the postal system. The router that connects any network to the Internet is like that network's “post office”, from an IP perspective.

The mobile node is normally resident on its home network, which is the one that is indicated by the network ID in its IP address. Devices on the internetwork always route using this address, so the pieces of “mail” (datagrams) always arrive at a router at the device's “home”. When the device “travels” to another network, the home router (“post office”) intercepts these datagrams and forwards them to the device's current address. It may send them straight to the device using a new, temporary address, or it may send them to a router on the device's current network (the “other post office”, Tokyo in our analogy) for final delivery. An overview of Mobile IP operation can be seen in [Figure 128](#).

### **Mobile IP Device Roles**

As you can see, just as mail forwarding requires support from one or more post offices, Mobile IP requires the help of two routers. In fact, special names are given to the three main players that implement the protocol (also shown in [Figure 128](#)):

- ☉ **Mobile Node:** This is the mobile device, the one moving around the internetwork.
- ☉ **Home Agent:** This is a router on the home network that is responsible for catching datagrams intended for the mobile node and forwarding them to it when it is traveling. It also implements other support functions necessary to run the protocol.

**Figure 128: General Operation of the Mobile IP Protocol**

This diagram is like [Figure 127](#), but with Mobile IP implemented. The mobile node's home router serves as home agent and the router in Tokyo as the foreign agent. The mobile has been assigned a temporary, "care-of" address to use while in Tokyo (which in this case is a *co-located* care-of address, meaning that it is assigned directly to the mobile node; [Figure 129](#) shows the same example using the other type of care-of address). In step #1, the remote client sends a datagram to the mobile using its home address, as before. It arrives in London as usual. In step #2, the home agent encapsulates that datagram in a new one and sends it to the mobile node in Tokyo.

- Foreign Agent:** This is a router on the network to which the mobile node is currently attached. It serves as a "home away from home" for the mobile node, normally acting as its default router as well as implementing Mobile IP functions. Depending on the mode of operation, it may receive forwarded datagrams from the home agent and forward them to the mobile node. It also supports the sharing of mobility information to make Mobile IP operate. The foreign agent may not be required in some Mobile IP implementations but is usually considered part of how the protocol operates.

**Key Concept:** Mobile IP operates by setting up the TCP/IP equivalent of a mail forwarding system. A router on a *mobile node*'s home network serves as the mobile device's *home agent*, and one on its current network acts as the *foreign agent*. The home agent receives datagrams destined for the mobile's normal IP address and forwards them to the mobile node's current location, either directly or by sending to the foreign agent. The home agent and foreign agent are also responsible for various communication and setup activities that are required for Mobile IP work.

---

## Mobile IP Functions

An important difference between Mobile IP and our mail forwarding example is one that represents the classic distinction between people and computers: people are smart and computers are not. When our consultant is traveling in Tokyo, he always knows he's in Tokyo and that his mail is being forwarded. (Well, assuming he goes easy on the sake, but that's a different story. ☺) He knows to go deal with the Tokyo post office to get his mail. The post office in London knows what forwarding is all about and how to do it. The traveler and the post offices all can communicate easily using the telephone.

In contrast, in the computer world, when a device travels using Mobile IP, things are more complicated. Suppose our consultant flies to Tokyo, turns on his notebook and plugs it in to the network. When the notebook is first turned on, it has no clue what is going on. It has to figure out that it is in Tokyo. It needs find a foreign agent in Tokyo. It needs to know what address to use while in Tokyo. It needs to communicate back with its home agent back in London to tell it that it is in Tokyo and to start forwarding datagrams. Furthermore, it must accomplish its communication without any "telephone".

To this end, Mobile IP includes a host of special functions that are used to set up and manage datagram forwarding. To see how these support functions work, we can describe the general operation of Mobile IP as a simplified series of steps:

1. **Agent Communication:** The mobile node finds an agent on its local network by engaging in the *Agent Discovery* process. It listens for *Agent Advertisement* messages sent out by agents and from this can determine where it is located. If it doesn't hear these messages it can ask for one using an *Agent Solicitation* message.
2. **Network Location Determination:** The mobile node determines whether it is on its home network or a foreign one by looking at the information in the *Agent Advertisement* message.

If it is on its home network it functions using regular IP. To show how the rest of the process works, let's say the device sees that it just moved to a foreign network. The remaining steps are:

3. **Care-Of Address Acquisition:** The device obtains a temporary address called a *care-of address*. This either comes from the *Agent Advertisement* message from the foreign agent, or through some other means. This address is used only as the destination point for forwarding datagrams, and for no other purpose.

- 
4. **Agent Registration:** The mobile node informs the home agent on its home network of its presence on the foreign network and enables datagram forwarding, by *registering* with the home agent. This may be done either directly between the node and the home agent, or indirectly using the foreign agent as a conduit.
  5. **Datagram Forwarding:** The home agent captures datagrams intended for the mobile node and forwards them. It may send them either directly to the node or indirectly to the foreign agent for delivery, depending on the type of care-of address in use.

Datagram forwarding continues until the current agent registration expires. The device can then renew it. If it moves again, it repeats the process to get a new care-of address and then registers its new location with the home agent. When the mobile node returns back to its home network, it *deregisters* to cancel datagram forwarding and resumes normal IP operation.

The following topics look in more detail at the functions summarized in each of the steps above.

## **Mobile IP Addressing: Home and "Care-Of" Addresses**

Just as most of us have only a single address used for our mail, most IP devices have only a single address. Our traveling consultant, however, needs to have two addresses; a normal one and one that is used while he is away. Continuing our [earlier analogy](#), the Mobile-IP-equipped notebook our consultant carries needs to have two addresses as well:

- ☉ **Home Address:** The “normal”, permanent IP address assigned to the mobile node. This is the address used by the device on its home network, and the one to which datagrams intended for the mobile node are always sent.
- ☉ **Care-Of Address:** A secondary, temporary address used by a mobile node while it is “traveling” away from its home network. It is a normal 32-bit IP address in most respects, but is used only by Mobile IP for forwarding IP datagrams and for administrative functions. Higher layers never use it, nor do regular IP devices when creating datagrams.

### ***Mobile IP Care-Of Address Types***

The care-of address is a slightly tricky concept. There are two different types, which correspond to two distinctly different methods of forwarding datagrams from the home agent router.

#### **Foreign Agent Care-Of Address**

This is a care-of address provided by a foreign agent in its *Agent Advertisement* message. It is, in fact, the IP address of the foreign agent itself. When this type of care-of address is used, all datagrams captured by the home agent are not relayed directly to the mobile node, but indirectly to the foreign agent, which is responsible for final delivery. Since in this arrangement the mobile node has no distinct IP address valid on the foreign network, this is typically done using a layer two technology. This arrangement is illustrated in [Figure 129](#).

---

In our consultant analogy, this type of care-of address is like forwarding from the London post office to the Tokyo post office. The London personnel would take a letter for John Smith sent to his London address, and repackage it for delivery to “John Smith, care of the Tokyo post office”. The Tokyo post office (or John Smith himself) would need to worry about the last leg of the delivery.

### Co-Located Care-Of Address

This is a care-of address assigned directly to the mobile node using some means external to Mobile IP. For example, it may be assigned on the foreign network manually, or automatically using [DHCP](#). In this situation, the care-of address is used to forward traffic from the home agent directly to the mobile node. This was the type of address shown in [Figure 128](#).

In our consultant analogy, this is like John Smith obtaining a temporary address for his use while in Tokyo. The London post office would forward directly to his Tokyo address. They would not specifically send it to the Tokyo post office (though of course that PO would handle the mail at some point).

**Key Concept:** In Mobile IP, each mobile device uses a temporary, *care-of address* while on a foreign network. A *co-located* care-of address is one that is assigned directly to the mobile node, and enables direct delivery of datagrams to the node. The alternative is to use a *foreign agent* care-of address. In this situation the mobile node actually uses the IP address of the foreign agent; datagrams are sent to the foreign agent, which delivers them to the mobile node.

---

### Advantages and Disadvantages of the Care-Of Address Types

The foreign agent care-of address is considered the type used in “classical” Mobile IP, where there is both a home agent and a foreign agent. While it seems less efficient than the co-located address method, it offers some important advantages. A key one is that the same foreign agent care-of address can be used for all mobile nodes visiting that network. Datagrams for all mobile nodes on that network are sent to the foreign agent, which completes the delivery to the individual nodes. Since the mobile nodes use the foreign agent's address, no extra addresses or extra work are required for each mobile node.

The co-located care-of address has the advantage that traffic can be forwarded directly from the home agent to the mobile node. In this type of arrangement, it is possible for a Mobile IP device to travel to a foreign network where there is no Mobile-IP-aware router to act as a foreign agent. This does mean, however, that the Mobile IP implementation must include all the functions of communicating with the home agent that the foreign agent normally performs.

When co-located care-of addresses are used, an issue is how the temporary address is obtained. In many foreign networks automatic assignment of an IP address using something like DHCP may be possible, but if not, a temporary IP address would need to be

**Figure 129: Mobile IP Operation With A Foreign Agent "Care-Of" Address**

This diagram is similar to [Figure 128](#), except that instead of the mobile node having a co-located (distinct) IP address as in that example, here the mobile node is using a foreign agent care-of address. This means that the node's care-of address is actually that of the foreign agent itself. Step #1 is the same as in [Figure 128](#), but in step #2 the home agent forwards not to the mobile node directly, but to the foreign agent (since that router is the one whose IP address the mobile is using). In step #3 the foreign agent strips off the home agent's packaging and delivers the original datagram to the mobile node. This is typically done using whatever layer two (LAN or wireless LAN) technology connects the mobile node and foreign agent together.

assigned. Either way, some of the foreign network's limited IP address space would need to be set aside for mobile nodes, each of which would use an address while present on the network. In some cases this could lead to an address depletion issue.

Foreign agent care-of addressing is usually preferred due to its more automatic nature, when a foreign agent is present on the visited network. Considering that all datagrams will need to go through some router on the foreign network to reach the mobile node anyway, we might as well save the extra IP addresses. Co-located care-of addresses would be used when there is no foreign agent, or might be practical for long term connections even when a foreign agent is present.

---

Remember that the care-of address represents only the destination to which mobile node datagrams are forwarded. Foreign agents provide services other than forwarding, so it is possible for a mobile node to use a co-located care-of address even when a foreign agent is present, while continuing to take advantage of the other foreign agent services.

**Key Concept:** In Mobile IP, co-located care-of addresses have the advantage of flexibility, but require each device to have a unique IP address on the remote network. Foreign agent care-of addresses have the chief advantage of allowing many mobile devices on a foreign network without each requiring a distinct IP address.

---

For more information on how datagrams are forwarded between the home agent and the mobile node's care-of address, see [the topic on Mobile IP encapsulation and tunneling](#).

## **Mobile IP Agent Discovery, and Agent Advertisement and Solicitation Messages**

When a mobile node is first turned on, it cannot assume that it is still “at home” the way normal IP devices do. It must first determine where it is, and if it is not at home, begin the process of setting up datagram forwarding from its home network. This process is accomplished by communicating with a local router serving as an agent, through the process called *agent discovery*.

### ***Agent Discovery Process***

Agent discovery encompasses the first three steps in the simplified five-step Mobile IP operational summary I gave in [the topic on general operation](#). The main goals of agent discovery include the following:

- 🕒 **Agent/Node Communication:** Agent discovery is the method by which a mobile node first establishes contact with an agent on the local network to which it is attached. Messages are sent from the agent to the node containing important information about the agent; a message can also be sent from the node to the agent asking for this information to be sent.
- 🕒 **Orientation:** The node uses the agent discovery process to determine where it is. Specifically, it learns whether it is on its home network or a foreign network by identifying the agent that sends it messages.
- 🕒 **Care-Of Address Assignment:** The agent discovery process is the method used to tell a mobile node the [care-of address](#) it should use, when foreign agent care-of addressing is used.

Mobile IP agents are routers that have been given additional programming to make them “Mobile IP aware”. The communication between a mobile node and the agent on its local network is basically the same as the normal communication required between a device on an IP network and its local router, except more information needs to be sent when the router is an agent.

---

## Agent Advertisement and Agent Solicitation Messages

Provision already exists for exchanges of data between a router and a node, in the form of ICMP messages that are used for the regular IP *router discovery* process. Two messages are used for this purpose: *Router Advertisement* messages that let routers tell local nodes that they exist and describe their capabilities, and *Router Solicitation* messages that let a node prompt a router to send an advertisement. [These are described in their own topic in the ICMP section.](#)

Given the similarity to normal router discovery, it made sense to implement agent discovery as a modification to the existing process rather than set up a whole new system. The messages used in the agent discovery process are:

- ☛ **Agent Advertisement:** This is a message transmitted regularly by a router acting as a Mobile IP agent. It consists of a regular *Router Advertisement* message that has one or more *extensions* added that contain Mobile-IP-specific information for mobile nodes.
- ☛ **Agent Solicitation:** This message can be sent by a mobile IP device to nudge a local agent to send an *Agent Advertisement*.

The use of these messages is described in the Mobile IP standard in detail, and unsurprisingly, is very similar to how regular *Router Advertisement* and *Router Solicitation* messages are employed. Agents are normally configured to send out *Agent Advertisements* on a regular basis, with the rate set to ensure reasonably fast contact with mobile nodes without consuming excessive network bandwidth. They are required to respond to any *Agent Solicitation* messages they receive by sending an *Advertisement*. It is possible that some agents may be configured to send *Advertisements* only upon receipt of a *Solicitation*.

Mobile nodes are required to accept and process *Agent Advertisements*. They distinguish these from regular *Router Advertisements* by looking at the size of the message. They then parse the extension(s) to learn the capabilities of the local agent. They determine whether they are on their home network or a foreign network, and in the case of a foreign agent, how the agent should be used. Mobile nodes are required to use *Agent Advertisements* to detect when they have moved, using one of two algorithms defined in the standard, and also to detect when they have returned back to their home network after they have been traveling. They are also required to be able to send *Agent Solicitation* messages if they don't receive an *Agent Advertisement* after a certain period of time. They are restricted to sending these only infrequently, however, again to keep traffic manageable.

Now let's look at the formats of the two message types.

### Agent Solicitation Message Format

Let's start with the *Agent Solicitation* message because it is much simpler. In fact, there is no new message format defined for this at all; it is identical to the format of a [Router Solicitation message](#).

---

The reason no new message type is required here is that a solicitation is an extremely simple message: “hey, if there are any routers out there, please tell me who you are and what you can do”. No extra Mobile IP information needs to be sent. When a regular IP router receives a *Router Solicitation* it will send a *Router Advertisement*, but a Mobile IP router automatically sends the longer *Agent Advertisement* instead when prompted by any solicitation, whether it comes from a Mobile IP node or a regular IP device.

### ***Agent Advertisement Message Format***

The *Agent Advertisement* begins with the normal fields of an [ICMP Router Advertisement message](#). The destination of the message is either the “[all devices](#)” multicast address (224.0.0.1) if multicast is supported on the local network, or the broadcast address (255.255.255.255) otherwise. The *Router Address* fields are filled in with the address(es) of the agent.

---

**Note:** It is possible that a device may wish to advertise its ability to handle Mobile IP messages, but not act as a regular router. In this case it changes the normal *Code* field in the header of the *Router Advertisement* message from 0 to 16.

---

Following the regular fields, one or more *extensions* are added to the message format. There are three extensions defined: the *Mobility Agent Advertisement Extension*, *Prefix-Lengths Extension*, and *One-Byte Padding Extension*.

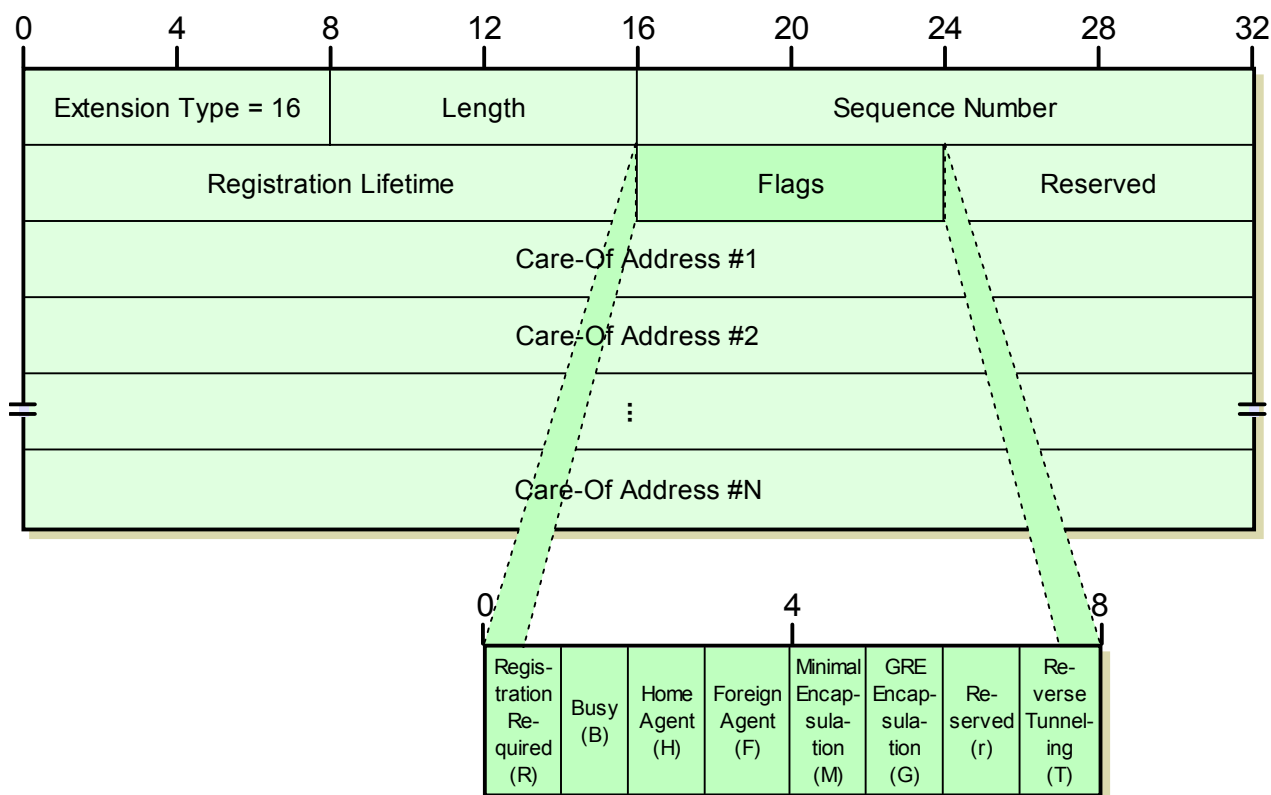

### ***Mobility Agent Advertisement Extension***

This is the main extension used to convey Mobile IP capabilities of the agent to mobile nodes on the local network. It contains numerous fields used as part of the various processes described in this overall section on Mobile IP.

The structure of the *Mobility Agent Advertisement Extension* is described in [Table 82](#) and shown graphically in [Figure 130](#).

**Table 82: Mobile IP *Mobility Agent Advertisement Extension* Format**

Field Name	Size (bytes)	Description																											
<b>Type</b>	1	<b>Extension Type:</b> Identifies the <i>Agent Advertisement</i> extension type. For the <i>Mobility Agent Advertisement Extension</i> , it is set to 16.																											
<b>Length</b>	1	<b>Length:</b> Length of the extension in bytes, excluding the <i>Type</i> and <i>Length</i> fields. Thus, it is equal to 6 plus 4 for each care-of address in the message.																											
<b>Sequence Number</b>	2	<b>Sequence Number:</b> A sequential counter set to zero when the router initializes and then incremented for each advertisement sent out.																											
<b>Registration Lifetime</b>	2	<b>Registration Lifetime:</b> The maximum length of time, in seconds, the agent is willing to accept for <a href="#">registration requests</a> . A value of 65,535 (all ones) means “infinite”. Note that this field is for registration only and has no relation to the regular Lifetime field in the regular Router Advertisement part of the message.																											
<b>Flags</b>	1	<p><b>Flags:</b> A one-byte field containing several informational flags that convey specific information about the agent's capabilities and status. There are seven one-bit flags, which when set to one convey the meanings given in the table below:</p> <table> <tr> <th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr> <tr> <td><b>R</b></td><td>1/8 (1 bit)</td><td><b>Registration Required:</b> The mobile node must register through the foreign agent, even when using a co-located care-of address.</td></tr> <tr> <td><b>B</b></td><td>1/8 (1 bit)</td><td><b>Busy:</b> The agent is currently too busy to accept further registrations from mobile nodes.</td></tr> <tr> <td><b>H</b></td><td>1/8 (1 bit)</td><td><b>Home Agent:</b> The agent is willing to function as a home agent on this link (it will forward datagrams, etc.) Note that a device can offer services as both a home agent and a foreign agent.</td></tr> <tr> <td><b>F</b></td><td>1/8 (1 bit)</td><td><b>Foreign Agent:</b> The agent is willing to function as a foreign agent. Again, a device can act as both a home agent and a foreign agent simultaneously.</td></tr> <tr> <td><b>M</b></td><td>1/8 (1 bit)</td><td><b>Minimal Encapsulation:</b> The agent can receive tunneled datagrams using minimal encapsulation.</td></tr> <tr> <td><b>G</b></td><td>1/8 (1 bit)</td><td><b>GRE Encapsulation:</b> The agent can receive tunneled datagrams using GRE encapsulation.</td></tr> <tr> <td><b>r</b></td><td>1/8 (1 bit)</td><td><b>Reserved:</b> Not used; sent as zero.</td></tr> <tr> <td><b>T</b></td><td>1/8 (1 bit)</td><td><b>Reverse Tunneling:</b> The agent supports reverse tunneling.</td></tr> </table>	Subfield Name	Size (bytes)	Description	<b>R</b>	1/8 (1 bit)	<b>Registration Required:</b> The mobile node must register through the foreign agent, even when using a co-located care-of address.	<b>B</b>	1/8 (1 bit)	<b>Busy:</b> The agent is currently too busy to accept further registrations from mobile nodes.	<b>H</b>	1/8 (1 bit)	<b>Home Agent:</b> The agent is willing to function as a home agent on this link (it will forward datagrams, etc.) Note that a device can offer services as both a home agent and a foreign agent.	<b>F</b>	1/8 (1 bit)	<b>Foreign Agent:</b> The agent is willing to function as a foreign agent. Again, a device can act as both a home agent and a foreign agent simultaneously.	<b>M</b>	1/8 (1 bit)	<b>Minimal Encapsulation:</b> The agent can receive tunneled datagrams using minimal encapsulation.	<b>G</b>	1/8 (1 bit)	<b>GRE Encapsulation:</b> The agent can receive tunneled datagrams using GRE encapsulation.	<b>r</b>	1/8 (1 bit)	<b>Reserved:</b> Not used; sent as zero.	<b>T</b>	1/8 (1 bit)	<b>Reverse Tunneling:</b> The agent supports reverse tunneling.
Subfield Name	Size (bytes)	Description																											
<b>R</b>	1/8 (1 bit)	<b>Registration Required:</b> The mobile node must register through the foreign agent, even when using a co-located care-of address.																											
<b>B</b>	1/8 (1 bit)	<b>Busy:</b> The agent is currently too busy to accept further registrations from mobile nodes.																											
<b>H</b>	1/8 (1 bit)	<b>Home Agent:</b> The agent is willing to function as a home agent on this link (it will forward datagrams, etc.) Note that a device can offer services as both a home agent and a foreign agent.																											
<b>F</b>	1/8 (1 bit)	<b>Foreign Agent:</b> The agent is willing to function as a foreign agent. Again, a device can act as both a home agent and a foreign agent simultaneously.																											
<b>M</b>	1/8 (1 bit)	<b>Minimal Encapsulation:</b> The agent can receive tunneled datagrams using minimal encapsulation.																											
<b>G</b>	1/8 (1 bit)	<b>GRE Encapsulation:</b> The agent can receive tunneled datagrams using GRE encapsulation.																											
<b>r</b>	1/8 (1 bit)	<b>Reserved:</b> Not used; sent as zero.																											
<b>T</b>	1/8 (1 bit)	<b>Reverse Tunneling:</b> The agent supports reverse tunneling.																											
<b>Reserved</b>	1	<b>Reserved:</b> Sent as zero and ignored by recipient.																											
<b>Care-Of Addresses</b>	Variable (4 per address)	<b>Care-Of Addresses:</b> Zero or more addresses provided by a foreign agent for a mobile node to use as a foreign agent care-of address. A foreign agent must always provide at least one address in its advertisement; a router that cannot act as a foreign agent will typically omit this field.																											

**Figure 130: Mobile IP *Mobility Agent Advertisement* Extension Format**

This extension appears after the normal fields of a *Router Advertisement* message, as shown in [Figure 148](#).

**Related Information:** See [the topic on Mobile IP encapsulation](#) for more on minimal and GRE encapsulation and reverse tunneling.

### ***Prefix-Lengths Extension***

This is an optional extension that tells a mobile node the prefix length(s) of the router address(es) contained in the regular portion of the *Agent Advertisement* message; that is, the *Router Address* field in the regular *Router Advertisement* part of the message. The [prefix length](#) is another term for the number of bits in an IP address is the network ID, so this tells the node the network ID in each of the router's addresses

The format of the *Prefix-Lengths Extension* is shown in [Table 83](#) and also in [Figure 131](#).

**Table 83: Mobile IP *Prefix-Lengths Extension* Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Extension Type:</b> Identifies the <i>Agent Advertisement</i> extension type. For the <i>Prefix-Lengths Extension</i> , it is set to 19.
<b>Length</b>	1	<b>Length:</b> Length of the extension in bytes, excluding the <i>Type</i> and <i>Length</i> fields. Thus, it is equal to the number of prefix lengths (since each takes 1 byte).
<b>Prefix Lengths</b>	Variable (1 per length)	<b>Prefix Lengths:</b> One prefix length number for each router address in the regular, <i>Router Advertisement</i> portion of the <i>Agent Advertisement</i> .

**Figure 131: Mobile IP *Prefix-Lengths Extension* Format**

This extension appears after the normal fields of a *Router Advertisement* message, as shown in [Figure 148](#).

### **One-Byte Padding Extension**

Some implementations require ICMP messages to be an even number of bytes, so a byte of padding is needed. (The *One-Byte Padding Extension* is just a single byte of all zeroes. No tables or figures needed for that!)

**Key Concept:** Mobile IP *agent discovery* is the process by which a mobile node determines where it is located and establishes contact with a home or foreign agent. Routers that can function as agents regularly send *Agent Advertisement* messages to indicate their capabilities, which are modified versions of regular *Router Advertisements*. A mobile node can also send an *Agent Solicitation* to request the sending of an *Advertisement*, which is the same as regular *Router Solicitation*.

**Note:** Mobile IP does not include any provisions for authentication of *Agent Advertisement* and *Agent Solicitation* messages. They may be authenticated using **IPSec**, of course, if that has been implemented.

---

## **Mobile IP Home Agent Registration and Registration Messages**

Once a mobile node has completed [agent discovery](#), it knows whether it is on its home network or a foreign network. If on its home network it communicates as a regular IP device, but if on a foreign network it must activate Mobile IP. This requires that it communicate with its home agent so information and instructions can be exchanged between the two. This process is called *home agent registration*, or more simply, just *registration*.

The main purpose of registration is to actually start Mobile IP working. The mobile node must contact the home agent and tell it that it is on a foreign network and request that datagram forwarding be turned on. It also must let the home agent know its [care-of address](#) so the home agent knows where to send the forwarded datagrams. The home agent in turn needs to communicate various types of information back to the mobile node when registration is performed. Note that the foreign agent is not really involved in registration, except perhaps to relay messages, as we will see.

### ***Mobile Node Registration Events***

Successful registration establishes what is called in the standard a *mobility binding* between a home agent and a mobile node. For the duration of the registration, the mobile node's regular home address is tied to its current care-of address and the home agent will encapsulate and forward datagrams addressed to the home address over to the care-of address. The mobile node is supposed to manage its registration and handle various events using several actions:

- ☉ **Registration:** The mobile node initiates a registration when it first detects it has moved from its home network to a foreign network.
- ☉ **Deregistration:** When the mobile node returns home, it should tell the home agent to cancel forwarding, a process called *deregistration*.
- ☉ **Reregistration:** If the mobile node moves from one foreign network to another, or if its care-of address changes, it must update its registration with the home agent. It also must do so if its current registration is about to expire, even if it remains stationary on one foreign network.

Each registration is established only for a specific length of time, which is why regular reregistration is required whether the device moves or not. Registrations are time-limited to ensure that they do not become stale. If, for example, a node forgets to deregister when it returns home, the datagram forwarding will eventually stop when the registration expires.

### ***New Registration Request and Registration Reply Messages***

To perform registration, two new message types have been defined in Mobile IP: the *Registration Request* and the *Registration Reply*. Each of these does what you would expect from its name. Interestingly, these are not ICMP messages like the ones used in agent discovery; they are [User Datagram Protocol \(UDP\)](#) messages. Thus, technically speaking, registration is performed at a higher layer than the rest of Mobile IP communication. Agents listen for *Registration Requests* on well-known UDP port #434, and respond back to mobile nodes using whatever [ephemeral port](#) the node used to send the message.

---

The formats of these two messages are described later in this topic.

## **Registration Procedures**

There are two different procedures defined for registration, depending on the type of care-of address used by the mobile node and other specifics we will get into shortly. The first is the direct registration method, which has just two steps:

1. Mobile node sends *Registration Request* to home agent.
2. Home agent sends *Registration Reply* back to mobile node.

In some cases, however, a slightly more complex process is required, where the foreign agent conveys messages between the home agent and the mobile node. In this situation, the process has four steps:

1. Mobile node sends *Registration Request* to foreign agent.
2. Foreign agent processes *Registration Request* and forwards to home agent.
3. Home agent sends *Registration Reply* to foreign agent.
4. Foreign agent processes *Registration Reply* and sends back to mobile node.

The first, simpler method is normally used when a mobile node is using a co-located care-of address. In that situation, the node can easily communicate directly with the home agent, and the mobile node is also set up to directly receive information and datagrams from the home agent. When there is no foreign agent, this is obviously the method that **must** be used. It is also obviously the method used when a mobile node is deregistering with its home agent after it arrives back on the home network.

The second method is required when a mobile node is using a foreign care-of address. Recall that in this situation, the mobile node doesn't have its own unique IP address at all; it is using a shared address given it by the foreign agent, which precludes direct communication between the node and the home agent. Also, if a mobile node receives an *Agent Advertisement* with the “R” flag set, it also should go through the foreign agent, even if it has a co-located care-of address.

Note that the foreign agent really is just a “middleman”; the exchange is still really between the home agent and the mobile node. However, the foreign agent can deny registration if the request violates whatever rules are in place for using the foreign network. It is for this reason that some foreign agents may require that they be the conduit for registrations even if the mobile node has a co-located care-of address. Of course, if the foreign agent can't contact the home agent the registration will not be able to proceed.

The description above is really a highly simplified explanation of the basics of registration. The Mobile IP standard specifies many more details on exactly how agents and nodes perform registration, including particulars on when requests and replies are sent, how to handle various special conditions such as invalid requests, rules for how home agents maintain a table of mobility bindings, and much more. The standard covers the definition of extensions to the regular registration messages to support authentication, which is required

for secure communications ([see the topic on security issues for more details](#)). It also includes the ability to have a mobile node maintain more than one concurrent binding, when needed.

**Key Concept:** Mobile IP *home agent registration* is the process by which a *mobility binding* is created between a home agent and a traveling mobile node to enable datagram forwarding to be performed. Registration is performed by the mobile node sending a *Registration Request* message, and the home agent returning a *Registration Reply*. The foreign agent may be required to act as a “middleman” to facilitate the transaction, but is otherwise not involved.

### Registration Request Message Format

Registration Request messages have the format shown in [Table 84](#) and [Figure 132](#).

**Figure 132: Mobile IP Registration Request Message Format**

This message is carried in the payload of a User Datagram Protocol (UDP) message, the headers of which are not shown.

**Table 84: Mobile IP Registration Request Message Format (Page 1 of 2)**

Field Name	Size (bytes)	Description																											
<b>Type</b>	1	<b>Type:</b> Identifies the registration message type. For a request, this field is 1.																											
<b>Flags</b>	1	<p><b>Flags:</b> A one-byte field containing several informational flags that convey specific requests being made by the mobile node to the home agent. When set, a flag conveys the meanings given in the appropriate entry below:</p> <table> <tr> <th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr> <tr> <td><b>S</b></td><td>1/8 (1 bit)</td><td><b>Simultaneous Bindings:</b> Mobile node requests that prior mobility bindings be retained in addition to the one in the current request.</td></tr> <tr> <td><b>B</b></td><td>1/8 (1 bit)</td><td><b>Broadcast Datagrams:</b> Mobile node requests that broadcasts on the home network be forwarded to it.</td></tr> <tr> <td><b>D</b></td><td>1/8 (1 bit)</td><td><b>Decapsulation By Mobile Node:</b> Mobile node is telling the home agent that it will itself decapsulate encapsulated datagrams, as opposed to a foreign agent. In other words, when this is one, the mobile node is using a co-located care-of address; when zero, it is using a foreign agent care-of address.</td></tr> <tr> <td><b>M</b></td><td>1/8 (1 bit)</td><td><b>Minimal Encapsulation:</b> Mobile node requests that home agent use minimal encapsulation for forwarded datagrams.</td></tr> <tr> <td><b>G</b></td><td>1/8 (1 bit)</td><td><b>GRE Encapsulation:</b> Mobile node requests that home agent use GRE encapsulation for forwarded datagrams.</td></tr> <tr> <td><b>r</b></td><td>1/8 (1 bit)</td><td><b>Reserved:</b> Not used; sent as zero.</td></tr> <tr> <td><b>T</b></td><td>1/8 (1 bit)</td><td><b>Reverse Tunneling:</b> Mobile node requests that reverse tunneling be used by the home agent.</td></tr> <tr> <td><b>x</b></td><td>1/8 (1 bit)</td><td><b>Reserved:</b> Not used; sent as zero.</td></tr> </table>	Subfield Name	Size (bytes)	Description	<b>S</b>	1/8 (1 bit)	<b>Simultaneous Bindings:</b> Mobile node requests that prior mobility bindings be retained in addition to the one in the current request.	<b>B</b>	1/8 (1 bit)	<b>Broadcast Datagrams:</b> Mobile node requests that broadcasts on the home network be forwarded to it.	<b>D</b>	1/8 (1 bit)	<b>Decapsulation By Mobile Node:</b> Mobile node is telling the home agent that it will itself decapsulate encapsulated datagrams, as opposed to a foreign agent. In other words, when this is one, the mobile node is using a co-located care-of address; when zero, it is using a foreign agent care-of address.	<b>M</b>	1/8 (1 bit)	<b>Minimal Encapsulation:</b> Mobile node requests that home agent use minimal encapsulation for forwarded datagrams.	<b>G</b>	1/8 (1 bit)	<b>GRE Encapsulation:</b> Mobile node requests that home agent use GRE encapsulation for forwarded datagrams.	<b>r</b>	1/8 (1 bit)	<b>Reserved:</b> Not used; sent as zero.	<b>T</b>	1/8 (1 bit)	<b>Reverse Tunneling:</b> Mobile node requests that reverse tunneling be used by the home agent.	<b>x</b>	1/8 (1 bit)	<b>Reserved:</b> Not used; sent as zero.
Subfield Name	Size (bytes)	Description																											
<b>S</b>	1/8 (1 bit)	<b>Simultaneous Bindings:</b> Mobile node requests that prior mobility bindings be retained in addition to the one in the current request.																											
<b>B</b>	1/8 (1 bit)	<b>Broadcast Datagrams:</b> Mobile node requests that broadcasts on the home network be forwarded to it.																											
<b>D</b>	1/8 (1 bit)	<b>Decapsulation By Mobile Node:</b> Mobile node is telling the home agent that it will itself decapsulate encapsulated datagrams, as opposed to a foreign agent. In other words, when this is one, the mobile node is using a co-located care-of address; when zero, it is using a foreign agent care-of address.																											
<b>M</b>	1/8 (1 bit)	<b>Minimal Encapsulation:</b> Mobile node requests that home agent use minimal encapsulation for forwarded datagrams.																											
<b>G</b>	1/8 (1 bit)	<b>GRE Encapsulation:</b> Mobile node requests that home agent use GRE encapsulation for forwarded datagrams.																											
<b>r</b>	1/8 (1 bit)	<b>Reserved:</b> Not used; sent as zero.																											
<b>T</b>	1/8 (1 bit)	<b>Reverse Tunneling:</b> Mobile node requests that reverse tunneling be used by the home agent.																											
<b>x</b>	1/8 (1 bit)	<b>Reserved:</b> Not used; sent as zero.																											
<b>Lifetime</b>	2	<b>Lifetime:</b> Length of time, in seconds, that the mobile node requests from the home agent for this registration.																											
<b>Home Address</b>	4	<b>Home Address:</b> The home (normal) IP address of the mobile node when on its home network. Uniquely identifies the device regardless of how the request is conveyed to the home agent.																											
<b>Home Agent</b>	4	<b>Home Agent:</b> The IP address of the device acting as the mobile node's home agent.																											
<b>Care-Of Address</b>	4	<b>Care-Of Address:</b> The IP address being used by the mobile node as its care-of address.																											

**Table 84: Mobile IP Registration Request Message Format (Page 2 of 2)**

Field Name	Size (bytes)	Description
<b>Identification</b>	8	<b>Identification:</b> A 64-bit number that uniquely identifies the <i>Registration Request</i> and is used to match requests to replies. It also provides protection against replay attacks; <a href="#">see the topic on Mobile IP security issues for more</a> .
<b>Extensions</b>	Variable	<b>Extensions:</b> Extension fields are included here for authentication of the request. Other extensions may also be included.

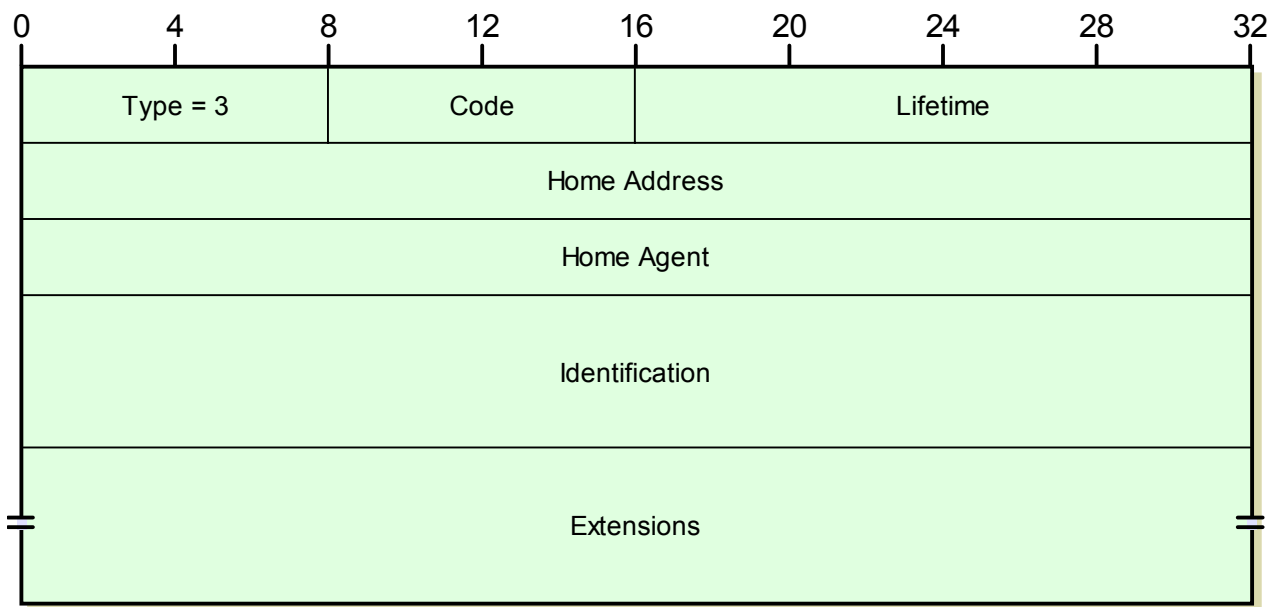

**Related Information:** See [the topic on Mobile IP encapsulation](#) for more on minimal and GRE encapsulation and reverse tunneling.

### Registration Reply Message Format

Registration Reply messages are formatted as shown in [Table 85](#) and [Figure 133](#).

**Table 85: Mobile IP Registration Reply Message Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the registration message type. For a reply, this field is 3.
<b>Code</b>	1	<b>Code:</b> Indicates the result of the registration request. This field is set to 0 if the registration was accepted, 1 if it was accepted but simultaneous bindings were requested and are not supported. If the registration was denied, a different reason code is provided that indicates the reason for the rejection, as well as whether it was the home agent or foreign agent that denied it.
<b>Lifetime</b>	2	<b>Lifetime:</b> If the registration was accepted, the length of time in seconds until the registration expires. This may of course be a different value than the mobile node requested.
<b>Home Address</b>	4	<b>Home Address:</b> The home (normal) IP address of the mobile node when on its home network. Uniquely identifies the device regardless of how the request is conveyed to the home agent, so the message can be delivered to it if multiple mobile nodes are served by the same foreign agent.
<b>Home Agent</b>	4	<b>Home Agent:</b> The IP address of the device acting as the mobile node's home agent.
<b>Identification</b>	8	<b>Identification:</b> A 64-bit number that uniquely identifies the <i>Registration Reply</i> and is matched to the Identification field of the request that precipitated it.
<b>Extensions</b>	Variable	<b>Extensions:</b> Extension fields are included here for authentication of the reply. Other extensions may also be included.

**Figure 133: Mobile IP Registration Reply Message Format**

This message is carried in the payload of a User Datagram Protocol (UDP) message, the headers of which are not shown.

## **Mobile IP Data Encapsulation and Tunneling**

Once a mobile node on a foreign network has completed a successful [registration](#) with its home agent, the Mobile IP datagram forwarding process described in [the general operation topic](#) will be fully “activated”. The home agent will intercept datagrams intended for the mobile node as they are routed to its home network, and forward them to the mobile node. This is done by *encapsulating* the datagrams and then sending them to the node's care-of address.

### ***Mobile IP Data Encapsulation Techniques***

Encapsulation is required because each datagram we intercept and forward needs to be resent over the network to the device's care-of address. In theory, the designers might conceivably have done this by just having the home agent change the destination address and stick it back out on the network, but there are various complications that make this unwise. It makes more sense to take the entire datagram and wrap it in a new set of headers before retransmitting. In our [mail analogy](#), this is comparable to taking a letter received for our traveling consultant and putting it into a fresh envelope for forwarding, as opposed to just crossing off the original address and putting a new one on.

The default encapsulation process used in Mobile IP is called *IP Encapsulation Within IP*, defined in RFC 2003 and commonly abbreviated *IP-in-IP*. It is a relatively simple method that describes how to take an IP datagram and make it the payload of another IP datagram. In Mobile IP, the new headers specify how to send the encapsulated datagram to the mobile node's care-of address.

---

In addition to IP-in-IP, two other encapsulation methods may be optionally used: *Minimal Encapsulation Within IP*, defined in RFC 2004, and *Generic Routing Encapsulation (GRE)*, defined in RFC 1701. To use either of these, the mobile node must request the appropriate method in its *Registration Request* and the home agent must agree to use it. If foreign agent care-of addressing is used, the foreign agent also must support the method desired.

### ***The Mobile IP Data Delivery Tunnel***

The encapsulation process creates a logical construct called a *tunnel* between the device that encapsulates and the one that decapsulates. This is the same idea of a tunnel used in discussions of virtual private networks (VPNs), [IPSec tunnel mode](#), or the various other tunneling protocols used for security. The tunnel represents a conduit over which datagrams are forwarded across an arbitrary internetwork, with the details of the encapsulated datagram (meaning the original IP headers) temporarily hidden.

In Mobile IP, the start of the tunnel is the home agent, which does the encapsulation. The end of the tunnel depends on what sort of care-of address is being used:

- ☉ **Foreign Agent Care-Of Address:** The foreign agent is the end of the tunnel. It receives encapsulated messages from the home agent, strips off the outer IP header and then delivers the datagram to the mobile node. This is generally using layer two, because the mobile node and foreign agent are on the same local network, and of course, the mobile node does not have its own IP address on that network (it is using that of the foreign agent.)
- ☉ **Co-Located Care-Of Address:** The mobile node itself is the end of the tunnel and strips off the outer header.

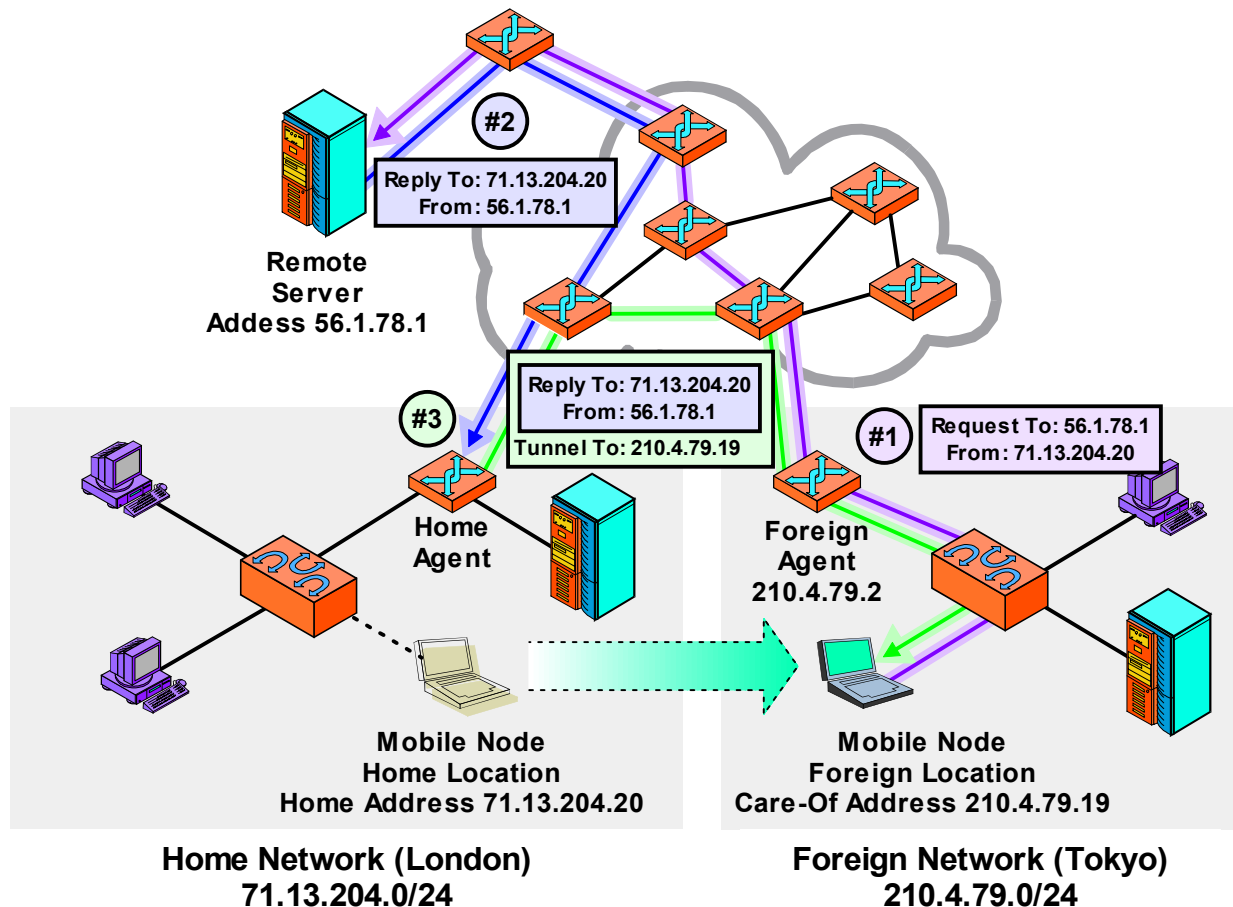

### ***Mobile IP Conventional Tunneling***

Normally, the tunnel described above is used only for datagrams that have been sent to the mobile node and captured by the home agent. When the mobile node wants to send a datagram, it doesn't tunnel it back to the home agent; this would be needlessly inefficient. Instead it just sends out the datagram directly using whatever router it can find on its current network, which may or may not be a foreign agent. When it does this, it uses its own home address as the source address for any requests it sends. As a result, any response to those requests will go back to the home network. This sets up a “triangle” of sorts for these kinds of transactions:

1. The mobile node sends a request from the foreign network to some third party device somewhere on the internetwork.
2. The third party device responds back to the mobile node. However, this sends the reply back to the mobile node's home address on its home network.
3. The home agent intercepts the response on the home network and tunnels it back to the mobile node.

This process is illustrated in [Figure 134](#). The reverse transaction would be pretty much the same, just in the reverse order. In that case the third party (Internet) device would send a request to mobile node, which would be received and forwarded by the home agent. The mobile node would reply back directly to the Internet host.

**Figure 134: Mobile IP Encapsulation and Tunneling**

This example illustrates how a typical request/reply message exchange in Mobile IP results in a “triangle” of communication. In step #1, the mobile node sends a request to a remote server somewhere on the Internet. It uses its own home address as the source for this request, so in step #2 the reply goes back to the home agent. Step #3 consists of the home agent tunneling the reply back to the mobile node.

**Key Concept:** Once Mobile IP is set up and operational, it works by having the home agent *encapsulate* and *tunnel* received datagrams to the mobile node. The mobile device normally sends datagrams directly to Internet hosts, which respond back to the mobile’s home agent which forwards those datagrams to the mobile node. This means a request/reply communication takes three transmissions.

---

## Mobile IP Reverse Tunneling

There may be situations where it is not feasible or desired to have the mobile node send datagrams directly to the internetwork using a router on the foreign network as we just saw. In this case, an optional feature called *reverse tunneling* may be deployed, if it is supported by the mobile node, the home agent and if relevant, the foreign agent.

When this is done, a reverse tunnel to complement the normal one is set up between the mobile node and the home agent, or between the foreign agent and the home agent, depending on care-of address type. All transmissions from the mobile node are tunneled back to the home network where the home agent transmits them over the internetwork, resulting in a more symmetric operation rather than the “triangle” just described. This is basically what I described earlier as being “needlessly inefficient”, because it means each communication requires four steps. Thus, it is used only when necessary.

One situation where reverse tunneling may be required is if the network where the mobile node is located has implemented certain security measures that prohibit the node from sending datagrams using its normal IP address. In particular, a network may be set up to disallow outgoing datagrams with a source address that doesn’t match its network prefix. This is often done to prevent “spoofing” (impersonating another’s IP address.)

**Key Concept:** An optional feature called *reverse tunneling* may be used in certain cases, such as when a network does not allow outgoing datagrams with a foreign source IP address. When enabled, rather than sending datagrams directly, the mobile node tunnels all transmissions back to the home agent, which sends them on the Internet.

---

Note that everything I’ve just discussed is applicable to “normal”—meaning unicast—datagrams sent to and from the mobile node. Broadcast datagrams on the home network, which would normally be intended for the mobile node if it were at home, are not forwarded unless the node specifically asks for this service during registration. Multicast operation on the foreign network is also supported, but extra work is required by the mobile node to set it up.

## Mobile IP and TCP/IP Address Resolution Protocol (ARP) Operation

Mobile IP is a protocol that does a good job of implementing a difficult function: transparently allowing an IP device to travel to a different network. Unfortunately, a problem with any protocol that tries to change how IP works is dealing with “special cases”. Having a home agent [intercept datagrams and tunnel them to the mobile node](#) works well in general terms, but there are some places where extra work is required. One of these is the use of the [TCP/IP Address Resolution Protocol \(ARP\)](#), which under Mobile IP “breaks” unless we take special steps.

**Background Information:** Some understanding of how ARP works in general terms is assumed in this topic. This includes [ARP proxying](#).

---

### ***Difficulties With Mobile IP and ARP***

To understand the problem with ARP, consider a mobile node that is on a foreign network and has successfully [registered](#) with its home agent. The home agent will intercept all datagrams that come onto the home network intended for the mobile node, and then encapsulate and forward them. For this to happen, though, the home agent (home router) must see the datagram. This normally only occurs when a datagram comes onto the home network from the “outside” and is processed by the router.

What happens when a local device on the home network itself wants to transmit to a mobile node that has traveled elsewhere? Remember that this device may not be mobile itself and probably knows nothing about Mobile IP. It will follow the standard process for deciding what to do with a datagram it needs to send as explained in [the topic discussing direct and indirect delivery of IP datagrams](#). It will compare its network ID to that of the mobile node and realize it doesn't need to route its datagram; it can send it directly to the mobile node.

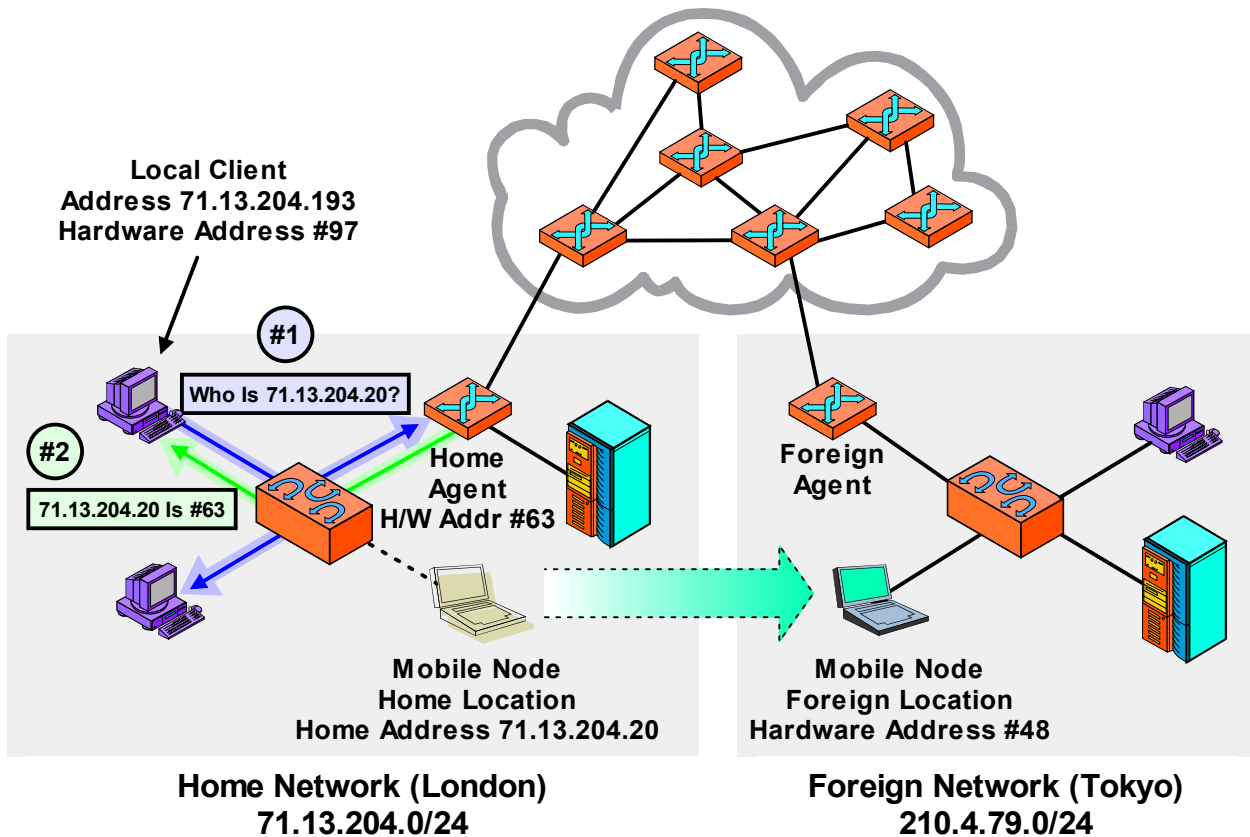

The local host will attempt to use ARP to find the data link layer address of the mobile node so it can send the datagram to it directly. It will start by looking in its ARP cache and if it finds the node's data link layer address there, will use it to send at layer two. Of course the mobile node is no longer on the local network segment so the message will never be received. If there is no ARP cache entry, the host on the home network will attempt to send an *ARP Request* to the mobile node to determine its layer two address. Again, the mobile node has traveled away, so this request will go unanswered.

### ***Additional Home Agent Tasks To Deal With ARP***

Solving this problem requires the intervention of, you guessed it, the home agent. It must perform two tasks to enable local hosts to send to the mobile node:

- 🕒 **ARP Proxying:** The home agent must listen for any *ARP Requests* sent by nodes on the same network as any of the mobile nodes that are currently registered to it. When it hears one, it replies in the mobile node's stead, and specifies ***its own*** data link layer address as the binding for the mobile node's IP address. This will cause hosts on the home network to send any datagrams intended for the mobile node to the home agent where they can be forwarded. This process is illustrated in [Figure 135](#).
- 🕒 **“Gratuitous” ARP:** Proxying helps with *ARP Requests* but what about devices that already have cache entries for the mobile node? As soon as the mobile node leaves the network, these become automatically stale. To correct them, the home agent sends what is called a *gratuitous* ARP message that tells devices on the local network to associate the mobile node's IP address with the home agent's data link layer

address. The term “gratuitous” refers to the fact that the message isn't being sent in order to perform an actual address resolution but merely to cause caches to be updated. It may be sent more than once to ensure that every device “gets the message”.

**Figure 135: ARP Proxying By Mobile IP Home Agent**

The home agent must take special steps to deal with transmissions from devices on the local network to the mobile node. In this example (using short hardware addresses for simplicity) the hardware address of the mobile node is #48 and that of the home agent #63. A local client on the home network with hardware address #97 sends an *ARP Request* to find out the hardware address of the mobile node. The home agent responds on the mobile's behalf, specifying not hardware address #48 but rather its own, #63. The client will thus send to the home agent, which can then forward the data to the mobile node on the foreign network.

Once this is done, ARP should function normally on the home link. Of course, when the mobile device returns back to the home network, the process must be reversed. Upon deregistration with the home agent, it will stop proxying for the mobile node. Both the mobile node and the home agent will also send gratuitous ARP broadcasts that update local device caches to again associate the mobile node's IP address with its own layer two address, instead of that of the home agent.

**Key Concept:** To avoid problems with hosts on the mobile node's home network trying to send datagrams to it at layer two, the home agent is required to use proxy ARP to direct such devices to send to the home agent so they can be forwarded. It must also use "gratuitous" ARP to update any existing ARP caches to that effect.

---

## **Mobile IP Efficiency Issues**

Having the [home agent forward all datagrams to the mobile node wherever it may be](#) is a convenient solution to mobility, but is also a rather inefficient one. Since every datagram must be sent first to the home network and then be forwarded to the mobile node, datagrams are going to travel over some part of the internetwork twice. The degree of inefficiency represented by forwarding can be significant, and may lead to problems with certain applications.

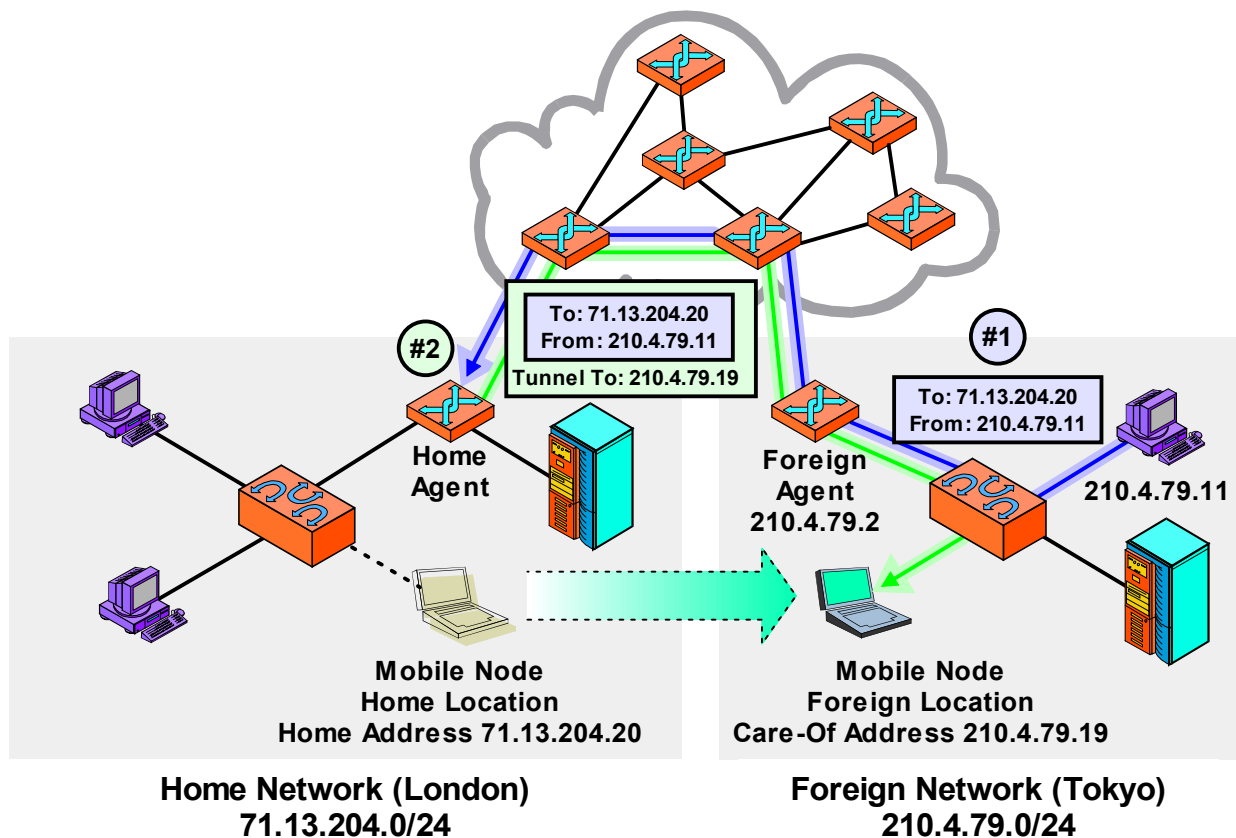

To see what the problem is, let's consider a traveling mobile node *M* and a regular device that wants to send to it, device *A*. The degree of the inefficiency of Mobile IP is a function of the internetwork distance between device *A* and *M*'s home network, compared to the internetwork distance between device *A* and *M*'s current network. By distance here, I mean the term as it is used in determining routes on an internetwork; two devices are "closer" when it takes less time and/or fewer hops to communicate between them, and "farther" when it takes more. (I use geography in my examples below to represent this notion of distance, but remember that geographical distance is only one factor in internetwork distance.)

### ***The Impact on Efficiency of Sending Device Location***

Let's consider the case where mobile node *M* is on a foreign network quite far from home, and a sending device, device *A*, wants to send a datagram using node *M*'s home IP address. Suppose the home network is in London and the device is again in Tokyo, Japan. The following examples are arranged in order of increasing inefficiency of Mobile IP, compared to the alternative of having the mobile node just get a new temporary IP address on the foreign network and not use Mobile IP:

- 🕒 **Sending Device On Home Network:** In this situation, device *A* will send a datagram that is immediately intercepted by the home agent on the home network and forwarded to the mobile node. There is really no inefficiency here at all (except for overhead for encapsulation and such) because even if *A* sent directly to the mobile node with a new foreign address, it would probably be routed through the home agent router anyway.
- 🕒 **Sending Device On Network Close To Home Network:** Here, let's say a device in Paris, France wants to send to the mobile node. The datagram goes from Paris to London and then to Tokyo. That's not too bad.
- 🕒 **Sending Device On Network Close To Foreign Network:** Now, suppose the sending device is in Taipei, Taiwan. In this situation, Mobile IP becomes **quite** inefficient. The datagram must be sent from Taipei all the way to London, and then all the way back to Tokyo.

- ☛ **Sending Device On Foreign Network:** The greatest inefficiency results when the sending device is actually on the foreign network that the mobile node is visiting. If device A is on the mobile node's current network in Tokyo, it must send all the way to London and then have the result forwarded all the way back again to Tokyo. Without Mobile IP, all we would need to do is use ARP and then deliver directly at layer two without routing needed at all! This scenario is illustrated in [Figure 136](#).

**Figure 136: A Mobile IP Inefficiency “Worst Case Scenario”**

This diagram shows the worst possible case of Mobile IP inefficiency: when a device on the foreign network where the mobile is located tries to send to it. The sender here, 210.4.79.11, uses the mobile node's home address, so the transmission must be routed all the way back to London and then forwarded back to Tokyo, even though the two devices might be sitting on the same desk!

Unfortunately, the “worst case scenario” outlined in the last bullet point is one that occurs quite often. It's common for a mobile device to connect with a foreign network specifically to communicate with the hosts on that network

### ***Implications of Reverse Tunneling***

To make matters worse, consider what happens if [reverse tunneling](#) is used! Here, tunneling is done not just for datagrams sent to the mobile node but sent from it as well. In our “worst case” example, a request/reply pair from the mobile node to another device on the foreign network requires **two** complete round-trips from Tokyo to London and back. Clearly, this is far from ideal.

---

## ***Inefficiency is an Inherent Part of Mobile IP***

There really isn't any solution to this problem within Mobile IP itself; it's just a natural consequence of how the protocol works. The only way to really improve things is to “hack in” a solution that ultimately boils down to one of the two options we always have in IP without mobility support: we either decide to give the mobile device a temporary real IP address on the foreign network, or we use a host-specific route for the mobile device while on the foreign network.

We've already seen that these both have problems, which is why Mobile IP was created in the first place. There may be situations, however, where efficiency is more important than the transparent portability that Mobile IP provides. For a long-term deployment on a foreign network far from the home network, or for applications where efficiency is paramount, it may make sense to employ one of these techniques. For example, a corporation that has a small number of offices in different cities connected using the Internet might set up special routing. This would let mobile devices visiting from other cities can talk directly to nodes local to the foreign part of the network without being routed across the Internet.

**Key Concept:** Since datagrams are sent to a mobile node at its home address, each datagram sent to the mobile device must first go back to its home network and then be forwarded to its current location. The level of inefficiency that results depends on how far the sender is from the mobile's home network. The worst case actually occurs if the sender and mobile are on the same foreign network, in which case each transmission must make a round-trip to the mobile's home network and then back again. This is an inherent part of how Mobile IP and cannot readily be rectified.

---

## **Mobile IP Security Considerations**

Security is always a concern in any internetworking environment these days, but is especially important with Mobile IP. There are a number of reasons for this, which are related to both how the protocol is used and the specific mechanisms by which it is implemented.

In terms of use, security was kept in mind during Mobile IP's development because mobile devices often use wireless networking technologies. Wireless communication is inherently less secure than wired communication, because transmissions are sent “out in the open” where they can be intercepted. It's also easier for malicious users to possibly disrupt the operation of wireless devices than when they connect using wires.

In terms of operation, Mobile IP has a number of risks due to it using a registration system and then forwarding datagrams across an unsecured internetwork. A malicious device could interfere with [registration process](#), causing the datagrams intended for a mobile device to be diverted. A “bad guy” might also interfere with the [data forwarding process](#) itself, by encapsulating a bogus datagram to trick a mobile node into thinking it was sent something that it never was.

---

## **Mobile IP Security Provisions**

For these reasons, the Mobile IP standard includes a limited number of explicit provisions to safeguard against various security risks. One security measure was considered sufficiently important that it was built into the Mobile IP standard directly: authentication of *Registration Request* and *Registration Reply* messages. This authentication process is accomplished in a manner somewhat similar to how the IPsec [Authentication Header \(AH\)](#) operates. Its goal is to prevent unauthorized devices from intercepting traffic by tricking an agent into setting up, renewing or canceling a registration improperly.

All Mobile IP devices are required to support authentication. Nodes must use it for requests and agents must use it for replies. Keys must be assigned manually as there is no automated system for secure key distribution. The default authentication method uses *HMAC-MD5* (specified in RFC 2403), which is one of two hashing algorithms used by [IPsec](#).

### **Protecting Against Replay Attacks**

Another concern is a security problem called a *replay attack*. In this type of attack, a third party intercepts a datagram, holds onto it and then re-sends it later on. This seems fairly harmless, but consider the importance of timing. Imagine a mobile node registers with its home agent, then later returns home and deregisters. If a malicious device captures a copy of the original *Registration Request* and re-sends it, the home agent might be fooled into thinking the node has traveled away from home when it has not. It could then intercept the forwarded datagrams.

The *Identification* field used in *Registration Request* and *Registration Reply* messages is designed to prevent replay attacks. Since each request has a different *Identification* number, nodes and agents can match up requests with replies and reject any datagrams they receive that are repeats of ones they have seen already. The Mobile IP standard also specifies alternative methods for protecting against replays.

### **Limitations of Mobile IP Authentication**

While Mobile IP includes authentication measures for registration messages, it does not for other types of messages. It also doesn't specify authentication of encapsulated datagrams being forwarded from the home agent to the mobile node. Encryption is also not provided to safeguard the privacy of either control messages or forwarded datagrams. The obvious solution when stronger assurances of privacy or authenticity are required is to make use of the IPsec [Authentication Header \(AH\)](#) and/or [Encapsulating Security Payload \(ESP\)](#) protocols.

---

## Internet Control Message Protocol (ICMP/ICMPv4 and ICMPv6)

---

The [Internet Protocol \(IP\)](#) is the key network layer protocol that implements the [TCP/IP protocol suite](#). Since IP is the protocol that provides the mechanism for delivering datagrams between devices, it is designed to be relatively basic, and to function with few “bells and whistles”. One of the provisions it lacks is some way to allow errors to be reported back to a transmitting device, and for tests and special tasks to be accomplished. However, these capabilities are necessary for the operation of an internetwork, so TCP/IP defines an adjunct protocol for IP that provides them: the *Internet Control Message Protocol (ICMP)*

In this section I describe the operation of ICMP using two main subsections. The first subsection describes ICMP concepts and operation in general terms, including a look at the overall method by which ICMP messages are packaged and the circumstances under which they are sent. The second subsection provides detailed descriptions of each of the individual message types supported by ICMP.

ICMP was developed to be a companion to the [original Internet Protocol, version 4](#). With the creation of [IP version 6 \(IPv6\)](#), a new version of ICMP called (ta-da) *ICMP version 6 (ICMPv6)* was created as well, and the original ICMP is now sometimes called *ICMPv4* to differentiate it, just as the “old” IP is now often called “IPv4”. These two versions have some differences in their specifics, but really are very similar in overall operation. For this reason, I decided to integrate the general operation description of both versions of ICMP, and just point out where the differences are between them. The area where IPv4 and IPv6 most differ is in specific message types and formats, so these have been described separately in the second subsection.

**Background Information:** Due to the close relationship between ICMP and IP, this section assumes familiarity with basic IP concepts, including [IP addressing](#), the [general format of IP datagrams](#) and [how they are routed](#). To better understand ICMPv6 details, you may also want to reference the IPv6 [addressing](#) and [datagram encapsulation](#) topics, and especially the [IPv6 Neighbor Discovery \(ND\) protocol](#).

---

---

## **ICMP Concepts and General Operation**

The Internet Control Message Protocol (ICMP) is one of the under-appreciated “worker bees” of the networking world. Everyone knows how important key protocols such as the Internet Protocol are to TCP/IP, but few realize that the suite as a whole relies on many functions that ICMP provides. Originally created to allow the reporting of a small set of error conditions, ICMP messages are now used to implement a wide range of error-reporting, feedback and testing capabilities. While each message type is unique, they are all implemented using a common message format, sent and received based on relatively simple protocol rules. This makes ICMP one of the easiest TCP/IP protocols to understand. (Yes, I actually said something in this Guide was **easy**!)

In this section I provide a general description of ICMP. I begin with an overview of ICMP, discussing its purpose, history, and the versions and standards that define it. I describe the general method by which ICMP operates, and also discuss the rules that govern how and when ICMP messages are created and processed. I then outline the common format used for ICMP messages in ICMPv4 and ICMPv6, and how data is encapsulated in them in general terms. I conclude with a discussion of ICMP message classifications, and a summary of different message types and codes for both version 4 and version 6.

### **ICMP Overview, History, Versions and Standards**

The Internet Protocol is the foundation of the TCP/IP protocol suite, since it is the mechanism responsible for delivering datagrams. Three of the main [characteristics that describe IP's datagram delivery method](#) are *connectionless*, *unreliable* and *unacknowledged*. This means that datagrams are “just sent” over the internetwork with no prior connection established, no assurance they will show up, and no acknowledgement sent back to the sender that they arrived. On the surface, this seems like it would result in a protocol that is difficult to use and impossible to rely on, and therefore a poor choice for designing a protocol suite. However, even though IP “makes no guarantees”, it works very well because most of the time, IP internetworks are sufficiently robust that messages get where they need to go.

Even the best-designed system still encounters problems, of course. Incorrect packets are occasionally sent, hardware devices have problems, routes are found to be invalid, and so forth. IP devices also often need to share specific information to guide them in their operation, and to perform tests and diagnostics. However, IP itself includes no provision to allow devices to exchange low-level control messages. Instead, these features are provided in the form of a “companion” protocol to IP called the *Internet Control Message Protocol (ICMP)*.

#### ***The Relationship Between IP and ICMP***

I think a good analogy for the relationship between IP and ICMP is to consider the one between a high-powered executive, and her experienced administrative assistant. The executive is busy and her time is very expensive. She is paid to do a specific job and to do it well, and not to spend time on administrative tasks. However, without **someone** doing

---

those tasks, the executive could not do her job properly. The administrative assistant does the also-important support jobs that make it possible for the executive to focus on her work. The working relationship between them is very important; a good pair will work together like a cohesive team, even anticipating each others' needs.

In TCP/IP, the [Internet Protocol](#) is the executive, and ICMP is its “administrative assistant”. IP focuses on its core activities, such as addressing, datagram packaging and routing. ICMP provides critical support to IP in the form of *ICMP messages* that allow different types of communication to occur between IP devices. These messages use a common general format, and are encapsulated in IP datagrams for transmission. They are divided into different categories, and each type has a specific use and internal field format.

Just as an administrative assistant often has a special location in an organization chart, usually connecting with a “dotted line” directly to the executive he or she assists, ICMP occupies a unique place in the [TCP/IP protocol architecture](#). Technically, one might consider ICMP to belong to layer four, since it creates messages that are encapsulated in IP datagrams and sent using IP at layer three. However, in the standard that first defined it, ICMP is specifically declared to be not only part of the network layer, but:

“actually an integral part of IP, [that] must be implemented by every IP module”.

### ***ICMP Standards for IPv4 and IPv6***

The defining standard I just quoted, by the way, is RFC 792. This was the initial defining standard for ICMP, titled simply *Internet Control Message Protocol*. It was published at the same time as the standard for IP, which was RFC 791. This is further indication that IP and ICMP really are a “team” of sorts.

Due to the close relationship between the two, when the [new version 6 of the Internet Protocol \(IPv6\)](#) was developed in the mid-1990s, it was necessary to define a new version of ICMP as well. This was of course called the *Internet Control Message Protocol (ICMPv6) for the Internet Protocol Version 6 (IPv6) Specification*, first published as RFC 1885 in 1995, and revised in RFC 2463 in 1998. Just as the original IP is now often called IPv4 to differentiate it from IPv6, the original ICMP is now also called *ICMPv4*.

These two RFCs, 792 and 2463, define the basic operation of ICMPv4 and ICMPv6 respectively, and also describe some of the ICMP message types supported by each version of the protocol. ICMPv4 and ICMPv6 are very similar in most general respects, though they have some differences, most of which are a direct result of the changes made to IP itself. Another document, RFC 1122 (*Requirements for Internet Hosts - Communication Layers*) contains rules for how ICMPv4 is used, as we will see in [the topic on ICMP message creation and processing conventions](#). RFC 1812 (*Requirements for IP Version 4 Routers*) is also relevant.

**Key Concept:** In TCP/IP, diagnostic, test and error-reporting functions at the internet/network layer are performed by the *Internet Control Message Protocol (ICMP)*, which is like the Internet Protocol's “administrative assistant”. The original version, now called *ICMPv4*, is used with IPv4, and the newer *ICMPv6* with IPv6.

### Other Standards That Define ICMP Messages

Both versions of the protocol define a general messaging system that was designed to be expandable. This means that in addition to the messages defined in the ICMP standards themselves, other protocols may also define message types used in ICMP. Some of the more important of these are shown in [Table 86](#).

**Table 86: Non-ICMP Internet Standards That Define ICMP Messages**

ICMP Version of Message Types Defined	RFC Number	Name	ICMP Message Types Defined
ICMPv4	950	<u>Internet Standard Subnetting Procedure</u>	Address Mask Request, Address Mask Reply
	1256	<u>ICMP Router Discovery Messages</u>	Router Advertisement, Router Solicitation
	1393	<u>Traceroute Using an IP Option</u>	Traceroute
	1812	<u>Requirements for IP Version 4 Routers</u>	Defines three new codes (subtypes) for the Destination Unreachable message.
ICMPv6	2461	<u>Neighbor Discovery for IP Version 6 (IPv6)</u>	Router Advertisement, Router Solicitation, Neighbor Advertisement, Neighbor Solicitation, Redirect
	2894	<u>Router Renumbering for IPv6</u>	Router Renumbering

The topic on [ICMP message classifications, types and codes](#) includes a full list of the ICMPv4/ICMPv6 message types covered in this Guide and the standards that define each.

### ICMP General Operation

ICMP is one of the simplest protocols in the TCP/IP protocol suite. Most protocols implement a particular type of functionality to either facilitate basic operation of a part of the network stack, or an application. To this end they include many specific algorithms and tasks that define the protocol, which is where most of the complexity lies. ICMP, in contrast, is exactly what its name suggests: a protocol that defines control messages. As such, pretty much all of what ICMP is about is providing a mechanism for any IP device to send control messages to another device.

---

## The ICMP Message-Passing Service

Various message types are defined in ICMP that allow different types of information to be exchanged. These are usually either generated for the purpose of reporting errors, or for exchanging important information of different sorts that is needed to keep IP operating smoothly. ICMP itself doesn't define how all the different ICMP messages are used; this is done by the protocols that use the messages. In this manner, ICMP describes a simple message-passing service to other protocols.

**Key Concept:** ICMP is not like most other TCP/IP protocols in that it does not perform a specific task. It defines a mechanism by which various control messages can be transmitted and received to implement a variety of functions.

---

As mentioned in [the preceding overview topic](#), ICMP is considered an integral part of IP, even though it uses IP to send its messages. Typically, the operation of ICMP involves some portion of the TCP/IP protocol software on a machine detecting a condition that causes it to generate an ICMP message. This is often the IP layer itself, though it may be some other part of the software. The message is then encapsulated and transmitted like any other TCP/IP message, and is given no special treatment compared to other IP datagrams. The message is sent over the internetwork to the IP layer at the receiving device, as shown in [Figure 137](#).

Again, since many of the ICMP messages are actually intended to convey information to a device's IP software, the IP layer itself may be the “ultimate destination” of an ICMP message once a recipient gets it. In other cases, the ultimate destination may be some other part of the TCP/IP protocol software, which is determined by the type of message received. ICMP does not use [ports](#) like [UDP](#) or [TCP](#) to direct its messages to different applications on a host; the software recognizes the message type and directs it accordingly within the software.

ICMP was originally designed with the idea that most messages would be sent by routers, but they can be sent by both routers and by regular hosts as well, depending on the message type. Some are obviously only sent by routers, such as *Redirect* messages, while others may be sent by either routers or hosts. Many of the ICMP messages are used in matched pairs, especially various kinds of *Request* and *Reply* messages, and *Advertisement* and *Solicitation* messages.

### ICMP Error-Reporting Limitations

One interesting general characteristic of ICMP's operation is that when errors are detected, they can be reported using ICMP, but only back to the original source of a datagram. This is actually a big drawback in how ICMP works. Refer back to [Figure 137](#) and consider again client host *A* sending a message to server host *B*, with a problem detected in the datagram

**Figure 137: ICMP General Operation**

A typical use of ICMP is to provide a feedback mechanism when an IP message is sent. In this example, device A is trying to send an IP datagram to device B. However, when it gets to router R3 a problem of some sort is detected that causes the datagram to be dropped. R3 sends an ICMP message back to A to tell it that something happened, hopefully with enough information to let A correct the problem, if possible. R3 can only send the ICMP message back to A, not to R2 or R1.

by router R3. Even if R3 suspects that the problem was caused by one of the preceding routers that handled the message, such as R2, it **cannot** send a problem report to R2. It can only send an ICMP message back to host A.

This limitation is an artifact of how the Internet Protocol works. You may recall from looking at [the IP datagram format](#) that the only address fields are for the original source and ultimate destination of the datagram. (The only exception is if the *IP Record Route* [option](#) is used, but devices cannot count on this.) When R3 receives a datagram from R2 that R2 in turn received from R1 (and prior to that, from A), it is only A's address in the datagram. Thus, R3 **must** send a problem report back to A, and A must decide what to do with it. Device A may decide to change the route it uses, or to generate an error report that an administrator can use to troubleshoot the R2 router.

In addition to this basic limitation, several [special rules and conventions](#) have been put in place to govern the circumstances under which ICMP messages are generated, sent and processed.

**Key Concept:** ICMP error-reporting messages sent in response to a problem seen in an IP datagram can only be sent back to the originating device. Intermediate devices cannot be the recipient of an ICMP message because their addresses are normally not carried in the IP datagram's header.

---

## **ICMP Message Classes, Types and Codes**

ICMP messages are used to allow the communication of different types of information between IP devices on an internetwork. The messages themselves are used for a wide variety of purposes, and are organized into general categories, as well as numerous specific types and subtypes.

### ***ICMP Message Classes***

At the highest level, ICMP messages are divided into two classes:

- ☉ **Error Messages:** These messages are used to provide feedback to a source device about an error that has occurred. They are usually generated specifically in response to some sort of action, usually the transmission of a datagram, as shown in the example of [Figure 137](#). Errors are usually related to the structure or content of a datagram, or to problem situations on the internetwork encountered during datagram routing.
- ☉ **Informational (or Query) Messages:** These are messages that are used to let devices exchange information, implement certain IP-related features, and perform testing. They do not indicate errors and are typically not sent in response to a regular datagram transmission. They are generated either when directed by an application, or on a regular basis to provide information to other devices. An informational ICMP message may also be sent in reply to another informational ICMP message, since they often occur in request/reply or solicitation/advertisement functional pairs.

**Key Concept:** ICMP messages are divided into two general categories: *error messages* that are used to report problem conditions, and *informational messages* that are used for diagnostics, testing and other purposes.

---

### ***ICMP Message Types***

Each individual kind of message in ICMP is given its own unique *Type* value, which is put into the field of that name in the ICMP common message format. This field is 8 bits wide, so a theoretical maximum of 256 message types can be defined. A separate set of *Type* values is maintained for each of ICMPv4 and ICMPv6.

In ICMPv4, *Type* values were assigned sequentially, to both error and informational messages, on a “first come, first served” basis (sort of) so one cannot tell just by the *Type* value what type of message each is. One minor improvement made in ICMPv6 was that the

---

message types were separated. In IPv6, error messages have *Type* values from 0 to 127, and informational messages have values from 128 to 255. Of course, only some of the *Type* values are currently defined.

**Key Concept:** A total of 256 different possible message types can be defined for each of ICMPv4 and ICMPv6. The *Type* field that appears in the header of each message specifies the kind of ICMP message. In ICMPv4 there is no relationship between *Type* value and message type; in ICMPv6 error messages have a *Type* value of 0 to 127, informational messages 128 to 255.

---

### ***ICMP Message Codes***

The message type indicates the general purpose of each kind of ICMP message. ICMP also provides an additional level of detail within each message type in the form of a *Code* field, which is also 8 bits. You can consider this field as a message “subtype”. Thus, each message type can have up to 256 subtypes that are more detailed subdivisions of the message's overall functionality. A good example is the *Destination Unreachable* message, which is generated [when a datagram cannot be delivered](#). In this message type, the *Code* value provides more information on exactly why the delivery was not possible.

### ***ICMP Message Class and Type Summary***

A complete section describing all of the major ICMP message types for both ICMPv4 and ICMPv6 has been included in this Guide. For convenience, I have summarized all these message types in [Table 87](#), which shows each of the *Type* values for the messages covered in this Guide, the name of each message, a very brief summary of its purpose, and the RFC that defines it. (To keep the table from being egregiously large I have not shown each of the *Code* values for each *Type* value; these can be found in the individual message

type descriptions.) The table is organized into sections in the same way as the [ICMP Message Types and Formats section](#), except this table is sorted by ascending *Type* value within each category, for easier reference.

**Table 87: ICMP Message Classes, Types and Codes (Page 1 of 2)**

Message Class	Type Value	Message Name	Summary Description of Message Type	Defining RFC Number
ICMPv4 Error Messages	3	<b><i>Destination Unreachable</i></b>	Indicates that a datagram could not be delivered to its destination. The <i>Code</i> value provides more information on the nature of the error.	792
	4	<b><i>Source Quench</i></b>	Lets a congested IP device tell a device that is sending it datagrams to slow down the rate at which it is sending them.	792
	5	<b><i>Redirect</i></b>	Allows a router to inform a host of a better route to use for sending datagrams.	792
	11	<b><i>Time Exceeded</i></b>	Sent when a datagram has been discarded prior to delivery due to expiration of its <i>Time To Live</i> field.	792
	12	<b><i>Parameter Problem</i></b>	Indicates a miscellaneous problem (specified by the <i>Code</i> value) in delivering a datagram.	792
ICMPv4 Informational Messages (part 1 of 2)	0	<b><i>Echo Reply</i></b>	Sent in reply to an <i>Echo (Request)</i> message; used for testing connectivity.	792
	8	<b><i>Echo (Request)</i></b>	Sent by a device to test connectivity to another device on the internetwork. The word “Request” sometimes appears in the message name.	792
	9	<b><i>Router Advertisement</i></b>	Used by routers to tell hosts of their existence and capabilities.	1256
	10	<b><i>Router Solicitation</i></b>	Used by hosts to prompt any listening routers to send a <i>Router Advertisement</i> .	1256
	13	<b><i>Timestamp (Request)</i></b>	Sent by a device to request that another send it a timestamp value for propagation time calculation and clock synchronization. The word “Request” sometimes appear in the message name.	792
	14	<b><i>Timestamp Reply</i></b>	Sent in response to a <i>Timestamp (Request)</i> to provide time calculation and clock synchronization information.	792
	15	<b><i>Information Request</i></b>	Originally used to request configuration information from another device. Now obsolete.	792

Table 87: ICMP Message Classes, Types and Codes (Page 2 of 2)

Message Class	Type Value	Message Name	Summary Description of Message Type	Defining RFC Number
ICMPv4 Informational Messages (part 2 of 2)	16	<b>Information Reply</b>	Originally used to provide configuration information in response to an <i>Information Request</i> message. Now obsolete.	792
	17	<b>Address Mask Request</b>	Used to request that a device send a subnet mask.	950
	18	<b>Address Mask Reply</b>	Contains a subnet mask sent in reply to an <i>Address Mask Request</i> .	950
	30	<b>Traceroute</b>	Used to implement the experimental “enhanced” <i>traceroute</i> utility.	1393
ICMPv6 Error Messages	1	<b>Destination Unreachable</b>	Indicates that a datagram could not be delivered to its destination. <i>Code</i> value provides more information on the nature of the error.	2463
	2	<b>Packet Too Big</b>	Sent when a datagram cannot be forwarded because it is too big for the <a href="#">maximum transmission unit (MTU)</a> of the next hop in the route. This message is needed in IPv6 and not IPv4 because in IPv4, routers can fragment oversized messages, while in IPv6 they cannot.	2463
	3	<b>Time Exceeded</b>	Sent when a datagram has been discarded prior to delivery due to the <i>Hop Limit</i> field being reduced to zero.	2463
	4	<b>Parameter Problem</b>	Indicates a miscellaneous problem (specified by the <i>Code</i> value) in delivering a datagram.	2463
ICMPv6 Informational Messages	128	<b>Echo Request</b>	Sent by a device to test connectivity to another device on the internetwork.	2463
	129	<b>Echo Reply</b>	Sent in reply to an <i>Echo (Request)</i> message; used for testing connectivity.	2463
	133	<b>Router Solicitation</b>	Prompts a router to send a <i>Router Advertisement</i> .	2461
	134	<b>Router Advertisement</b>	Sent by routers to tell hosts on the local network the router exists and describe its capabilities.	2461
	135	<b>Neighbor Solicitation</b>	Sent by a device to request the layer two address of another device while providing its own as well.	2461
	136	<b>Neighbor Advertisement</b>	Provides information about a host to other devices on the network.	2461
	137	<b>Redirect</b>	Redirects transmissions from a host to either an immediate neighbor on the network or a router.	2461
	138	<b>Router Renumbering</b>	Conveys renumbering information for router renumbering.	2894

---

You can see that several of the message types are quite similar in ICMPv4 and ICMPv6, but there are some slight differences. An obvious one is that *Redirect* is considered an error message in ICMPv4, but an informational message in ICMPv6. The way that the messages is used also often different. In IPv6, the use of many of the ICMP informational messages is described in the [Neighbor Discovery \(ND\) protocol](#), which is new to IPv6.

Note that the *Information Request* and *Information Reply* messages were originally created to allow devices to determine an IP address and possibly other configuration information. This function was later implemented using protocols such as [RARP](#), [BOOTP](#) and [DHCP](#), and these message types obsoleted.

## **ICMP Message Creation and Processing Conventions and Rules**

In [the overview of ICMP](#) I compared the relationship between IP and ICMP to that between an executive and an administrative assistant. One of the characteristics that many executives value in a good assistant is that the assistant does his or her work independently, and without causing unnecessary disruption. A good assistant should save the executive time, not cost him or her time.

As the “assistant” to IP, ICMP must similarly help IP function without taking up too much of its “time”. Here, the resource being conserved is not so much “time” as **bandwidth**. ICMP messages are important, but must be considered part of the “overhead” of running a network. They carry no user data, so each one represents a small loss of overall end-user bandwidth on the network. For this reason, we want to send them only when necessary, and to carefully control the circumstances under which they are generated.

Now, administrative assistants have some serious advantages over networking protocols: common sense and experience. They usually know where the line is drawn between help and hindrance; computers don't. To partially compensate, ICMP's operation is guided by a set of *conventions* or *rules* for how messages are created and processed. For ICMPv4, these conventions are described in part in the defining RFC 792, but much more in RFC 1122 ([Requirements for Internet Hosts — Communication Layers](#)), which provides specific information on implementing TCP/IP in host devices. In ICMPv6, the information related to ICMP implementation that appears in RFC 1122 has been largely incorporated into the main document that defines ICMPv6, RFC 2463.

### ***Limitations on ICMP Message Responses***

Most of the issues related to message generation have to do with error messages, not informational messages. The latter class of messages usually don't cause problems because they are generated based on specific rules already established in the protocols that use them. For example, *Router Advertisement* messages are sent by routers on a regular basis, and the routers make sure this is infrequent. They are also sent in response to *Router Solicitation* messages sent on occasion by hosts, and as long as a host doesn't go haywire and start sending tons of *Solicitations*, there won't be a problem. Even then, a router can be given enough smarts not to send *Router Advertisements* too often.

---

The problem comes up with error messages specifically because they are sent *in response* to so many situations. Potentially, they may even be sent in response to each other. Without special care, loops or cascading message generation might occur. For example, consider a situation where device *A* encounters an error and sends an error report to device *B*. Device *B* finds an error in device *A*'s message and sends an error report back to device *A*. This could result in billions of messages being sent back and forth clogging the network, until a human figures out what is wrong and fixes it.

To prevent such problems, an ICMP error message **must not** be generated in response to any of the following:

- 🕒 **An ICMP Error Message:** This prevents loops of the type just mentioned. Note, however, that an ICMP error message **can** be generated in response to an ICMP informational message.
- 🕒 **A Broadcast or Multicast Datagram:** What would happen if a datagram were broadcast to 5,000 hosts and each of them found an error in it and tried to send a report back to the source? Something unpleasant.
- 🕒 **IP Datagram Fragments Except The First:** When a datagram is [fragmented](#), errors may only be sent in response to the first fragment. Often, errors that are generated due to a problem with one fragment would also be generated by each successive one, causing unnecessary ICMP traffic.
- 🕒 **Datagrams With Non-Unicast Source Address:** If a datagram's source address doesn't define a unique, unicast device address, an error message cannot be sent back to that source. This prevents ICMP messages from being broadcast, unicast, or sent to non-routable special addresses such as the [loopback address](#).

**Key Concept:** In order to prevent excessive numbers of ICMP messages from being sent on a network, a special set of rules is put into place to govern when and how they may be created. Most of these are designed to eliminate situations where very large numbers of ICMP error messages would be generated in response to certain occurrences.

---

These rules apply to both ICMPv4 and ICMPv6, but in ICMPv6 there are a couple of special cases. In certain circumstances an ICMPv6 *Packet Too Big* message may be sent to a multicast address, as this is required for [Path MTU Discovery](#) to work. Certain *Parameter Problem* messages may also be sent to multicast or broadcast addresses. Finally, in addition to the rules above, IPv6 implementations are specifically directed to limit the rate at which they send ICMPv6 messages overall.

### **ICMP Message Processing Conventions**

Message processing generally takes place as described in [the topic on general operation](#), with the ICMP message delivered either to the IP software or other protocol software implementation as required. What is done with the message usually depends on its type. Some are destined only for the IP software itself, but many are intended for the higher-layer

---

protocol that generated the datagram that led to the error. [In the next topic](#) we will see that ICMP error messages include information that allows the upper-layer protocol to be extracted for the purpose of passing the message to the appropriate software layer.

In IPv6, the class of message (error or informational) can be determined from the *Type* value. This knowledge can then be used to guide processing of ICMP messages with unknown *Type* values. The rule is that ICMP error messages with unknown *Type* values must be passed to the appropriate upper layer protocol. Informational messages with unknown *Type* values are discarded without taking action.

In addition to these general rules, there are specific rules put into place to guide the processing of some of the message types. I describe some of these conventions in the topics that discuss individual ICMP messages.

An important final point is that ICMP messages, especially error messages, are not considered "binding" on the device that processes them. To stick with the office analogy, they have the equivalent status in an office of only of an "FYI memo", not an "assignment". It is often the case that a device *should* take action upon processing an ICMP message, but the device is not required to. The exception, again, is when informational messages are used for specific purposes. For example, most of the messages that come in pairs are designed so that a *Request* results in the matching *Reply* and a *Solicitation* yields an *Advertisement*.

**Key Concept:** A device receiving an ICMP message is not required to take action unless a protocol using a message type dictates a specific response to a particular message type. In particular, devices are not mandated to perform any specific task when receiving an ICMP error message.

---

## **ICMP Common Message Format and Data Encapsulation**

As we have seen in the preceding topics, ICMP is not so much a protocol that performs a specific function as a [framework for the exchange of error reports and information](#). Since each of the message types is used for a different purpose, they differ in the types of information each contains. This means each ICMP message has a slightly different format. At the same time, however, ICMP message types also have a degree of commonality—a portion of each message is common between message types.

### ***ICMP Common Message Format***

The structure of an ICMP message can be generally thought of as having a *common part* and a *unique part*. The common part consists of three fields that have the same size and same meaning in all ICMP messages (though the values in the fields aren't the same for each ICMP message type, of course). The unique part contains fields that are specific to each type of message.

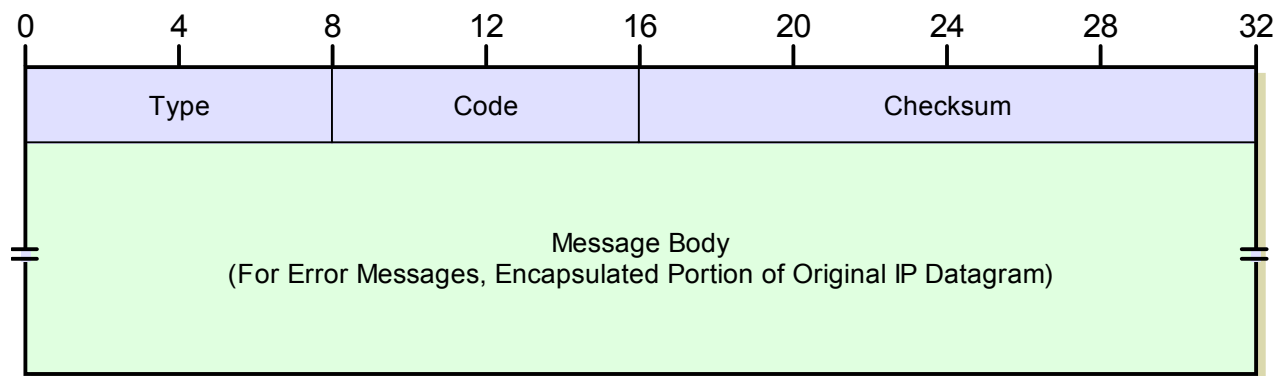

Interestingly, the common message format is basically the same for ICMPv4 and ICMPv6. It is described in [Table 88](#) and [Figure 138](#).

**Table 88: ICMP Common Message Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMP message type. For ICMPv6, values from 0 to 127 are error messages and values 128 to 255 are informational messages. Common values for this field are given in <a href="#">the table in the topic on ICMP message classes and types</a> .
<b>Code</b>	1	<b>Code:</b> Identifies the “subtype” of message within each ICMP message Type value. Thus, up to 256 “subtypes” can be defined for each message type. Values for this field are shown in <a href="#">the individual ICMP message type topics</a> .
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field that is calculated in a manner similar to the <a href="#">IP header checksum in IPv4</a> . It provides error detection coverage for the entire ICMP message. Note that in ICMPv6, a pseudo-header of IPv6 header fields is prepended for checksum calculation; this is similar to <a href="#">the way this is done in TCP</a> .
<b>Message Body / Data</b>	Variable	<b>Message Body:</b> Contains the specific fields used to implement each message type. This is the unique part of the message as I mentioned above.

The message body typically contains one or several fields that carry information of relevance to each specific type of ICMP message. For error messages, we see here one more area of commonality in ICMP messages: all ICMP error messages include a portion of the original IP datagram that led to the ICMP error message. This aids in diagnosing the problem that caused the ICMP message to be generated, by allowing the error to be communicated to higher layers.

**Figure 138: ICMP Common Message Format**

This overall, generic message format is used for both ICMPv4 and ICMPv6 message types.

---

## Original Datagram Inclusion In ICMP Error Messages

The inclusion of original IP datagram information is done differently for the two ICMP versions.

### ICMPv4 Error Messages

Each error message includes the full IP header and the first 8 bytes of the payload. Since the beginning of the payload will contain the encapsulated higher-layer header, this means the ICMP message also carries either the full UDP header, or the first 8 bytes of the TCP header. In both cases, the [source and destination port numbers](#) are part of what is included.

If the original header was a standard IP header with no options, the *Message Body* will therefore have a length of 28 bytes; if options are present, it will be larger.

### ICMPv6 Error Messages

Each error message includes as much of the IPv6 datagram as will fit without causing the size of the ICMPv6 error message (including its IP header encapsulation) to exceed the [minimum IPv6 maximum transmission unit size](#), which is 1280 bytes. This provides additional information for diagnostic purposes compared to ICMPv4, while ensuring that no ICMPv6 error messages will be too large for any physical network segment. The larger size of the included data allows the IPv6 extension headers to be included in the error message, since the error could be in one of those extension headers.

Remember that [in IPv6, routers cannot fragment IP datagrams](#); any datagram that is “oversized” for an underlying physical network is dropped. ICMPv6 is thus designed to ensure that this does not happen by not creating ICMPv6 datagrams over the universal IPv6 MTU size of 1280.

**Key Concept:** Each kind of ICMP message contains data unique to that message type, but all messages are structured according to a common ICMP message format. ICMP error messages always include in their message body field some portion of the original IP datagram that resulted in the error being generated.

---

## ICMP Data Encapsulation

After an ICMP message is formatted, it is [encapsulated in an IP datagram](#) like any other IP message. This is why some people believe ICMP is architecturally a higher layer than IP, though as we discussed earlier it is really more of a special case. You can also see then, that when an ICMP error message is generated, we end up with the original IP header and part or all of the payload, encapsulated in the ICMP message, in turn encapsulated within a new IP header to be sent back as an error report usually to the device that sent the original IP message.

---

## ICMP Message Types and Formats

The Internet Control Message Protocol (ICMP) provides a mechanism for error reporting and the exchange of important information between IP devices. Many different message types exist within ICMP, which have certain common attributes that we saw in [the section discussing ICMP generalities](#). Beyond these commonalities, the details of how ICMP messages are created and used diverge based on the specific message type, so it's time to look at these and see how they work.

In this section I provide specific details on the most commonly-seen ICMP message types, including a description of both their use and their specific message formats. There are 20 different message types currently covered, so they have been divided into four subsections for better organization. These correspond to the four combinations of ICMP version (ICMPv4 and ICMPv6) and message class (error and informational).

**Related Information:** For a cross-reference of message types and corresponding ICMP *Type* field values, [see the general topic on ICMP message classes and types](#). For more information on the “common” ICMP message format fields (*Type*, *Code* and *Checksum*) and incorporation of original IP datagram information in error messages, [see the topic on ICMP Common Message Format and Data Encapsulation](#).

---

---

## **ICMP Version 4 (ICMPv4) Error Message Types and Formats**

ICMP error messages are used by routers and hosts to tell a device that sent a datagram about problems encountered in delivering it. In the original ICMP version 4, five different error messages are defined, which are all described in the original ICMP standard, RFC 792. These are some of the most important ICMP messages, since they provide critical feedback about error conditions and may help a transmitting device take corrective action to ensure reliable and efficient datagram delivery.

In this first of four sections on specific ICMP types, I look at the ICMPv4 error messages. I begin with *Destination Unreachable* messages, which are sent due to datagram delivery failures, and *Source Quench* messages, used to tell a device to slow down the rate at which it sends datagrams. Next I describe *Time Exceeded* messages, sent when a datagram has been traveling the network too long or takes too long to be reassembled from fragments, and *Redirect* messages, which let a router provide feedback about better routes to a host. Finally, I discuss *Parameter Problem* messages, a generic “catch all” type used for problems not covered by other ICMP error messages.

### **ICMPv4 Destination Unreachable Messages**

Since the Internet Protocol is an [unreliable protocol](#), there are no guarantees that a datagram sent by one device to another will ever actually get there. The internetwork of hosts and routers will make a “best effort” to deliver the datagram but it may not get where it needs to for any number of reasons. Of course, devices on an IP network understand that and are designed accordingly. IP software never assumes its datagrams will always be received, and higher layer protocols like [TCP](#) take care of [providing reliability and acknowledgements](#) of received data for applications that need these features.

This setup, with higher layers handling failed deliveries, is sufficient in some cases. For example, suppose device *A* tries to send to device *B*, but a router near *B* is overloaded, so it drops the datagram. In this case the problem is likely intermittent, so *A* can retransmit and eventually reach *B*. But what about a situation where a device is trying to send to an IP address that doesn't exist, or a problem with routing that isn't easily corrected? Having the source just continually retry while it remains “in the dark” about the problem would be inefficient, to say the least.

So in general, while IP is designed to allow IP datagram deliveries to fail, we should take any such failures seriously. What we really need is a feedback mechanism that can tell a source device that something improper is happening, and why. In IPv4, this service is provided through the transmission of *Destination Unreachable* ICMP messages. When a source node receives one of these messages it knows there was a problem sending a datagram, and can then decide what action, if any, it wants to take. Like all ICMP error messages, *Destination Unreachable* messages include a portion of the datagram that could not be delivered, which helps the recipient of the error figure out what the problem is.

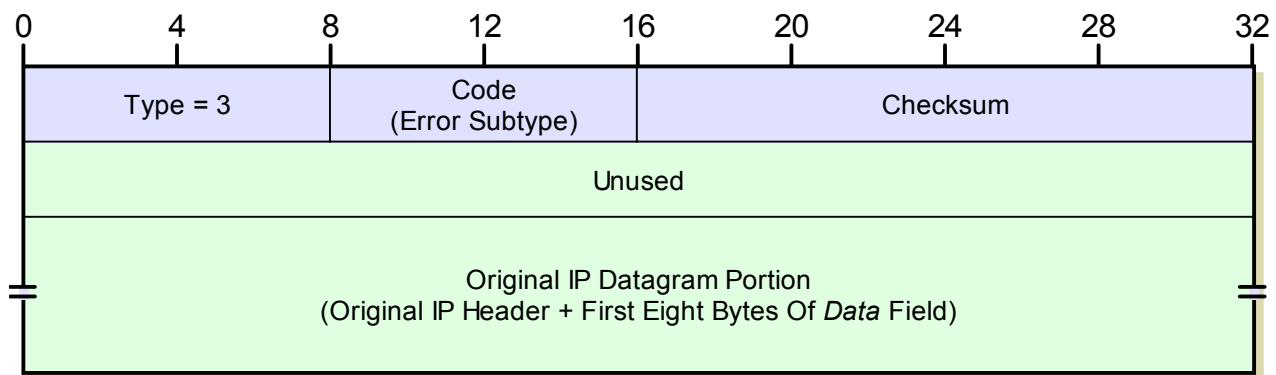

---

## ICMPv4 Destination Unreachable Message Format

Table 89 and Figure 139 show the specific format for ICMPv4 *Destination Unreachable* messages.

**Table 89: ICMPv4 Destination Unreachable Message Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMP message type; for <i>Destination Unreachable</i> messages this is set to 3.
<b>Code</b>	1	<b>Code:</b> Identifies the “subtype” of unreachable error being communicated. See Table 90 for a full list of codes and what they mean.
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .
<b>Unused</b>	4	<b>Unused:</b> 4 bytes that are left blank and not used.
<b>Original Datagram Portion</b>	Variable	<b>Original Datagram Portion:</b> The full IP header and the first 8 bytes of the payload of the datagram that prompted this error message to be sent.

**Figure 139: ICMPv4 Destination Unreachable Message Format**

## ICMPv4 Destination Unreachable Message Subtypes

There are many different reasons why it may not be possible for a datagram to reach its destination. Some of these may be due to erroneous parameters (like the invalid IP address example mentioned above.) A router might have a problem reaching a particular network for whatever reason. There can also be other more “esoteric” reasons as well why a datagram cannot be delivered.

For this reason, the ICMPv4 *Destination Unreachable* message type can really be considered a class of related error messages. The receipt of a *Destination Unreachable* message tells a device that the datagram it sent couldn't be delivered, and the reason for the non-delivery is indicated by the *Code* field in the ICMP header. [Table 90](#) shows the different *Code* values, corresponding message subtypes and a brief explanation of each.

**Table 90: ICMPv4 *Destination Unreachable* Message Subtypes (Page 1 of 2)**

Code Value	Message Subtype	Description
0	<b>Network Unreachable</b>	The datagram could not be delivered to the network specified in the network ID portion of the IP address. Usually means a problem with routing but could also be caused by a bad address.
1	<b>Host Unreachable</b>	The datagram was delivered to the network specified in the network ID portion of the IP address but could not be sent to the specific host indicated in the address. Again, this usually implies a routing issue.
2	<b>Protocol Unreachable</b>	The protocol specified in the Protocol field was invalid for the host to which the datagram was delivered.
3	<b>Port Unreachable</b>	The <a href="#">destination port</a> specified in the UDP or TCP header was invalid.
4	<b>Fragmentation Needed and DF Set</b>	<p>This is one of those “esoteric” codes. ☹ Normally, <a href="#">an IPv4 router will automatically fragment a datagram that it receives if it is too large for the maximum transmission unit (MTU) of the next physical network link</a> the datagram needs to traverse. However, if the <i>DF (Don't Fragment)</i> flag is set in the <a href="#">IP header</a>, this means the sender of the datagram does not <i>want</i> the datagram ever to be fragmented. This puts the router between the proverbial rock and hard place, and it will be forced to drop the datagram and send an error message with this code.</p> <p>This message type is most often used in a “clever” way, by intentionally sending messages of increasing size to discover the maximum transmission size that a link can handle. This process is called <a href="#">MTU path discovery</a>.</p>
5	<b>Source Route Failed</b>	Generated if a source route was specified for the datagram in an option but a router could not forward the datagram to the next step in the route.
6	<b>Destination Network Unknown</b>	Not used; Code 0 is used instead.
7	<b>Destination Host Unknown</b>	The host specified is not known. This is usually generated by a router local to the destination host and usually means a bad address.
8	<b>Source Host Isolated</b>	Obsolete, no longer used.
9	<b>Communication with Destination Network is Administratively Prohibited</b>	The source device is not allowed to send to the network where the destination device is located.
10	<b>Communication with Destination Host is Administratively Prohibited</b>	The source device is allowed to send to the network where the destination device is located, but not that particular device.

---

**Table 90: ICMPv4 *Destination Unreachable* Message Subtypes (Page 2 of 2)**

Code Value	Message Subtype	Description
11	<b><i>Destination Network Unreachable for Type of Service</i></b>	The network specified in the IP address cannot be reached due to inability to provide service specified in the <i>Type Of Service</i> field of the <a href="#">datagram header</a> .
12	<b><i>Destination Host Unreachable for Type of Service</i></b>	The destination host specified in the IP address cannot be reached due to inability to provide service specified in the datagram's <i>Type Of Service</i> field.
13	<b><i>Communication Administratively Prohibited</i></b>	The datagram could not be forwarded due to filtering that blocks the message based on its contents.
14	<b><i>Host Precedence Violation</i></b>	Sent by a first-hop router (the first router to handle a sent datagram) when the <i>Precedence</i> value in the <i>Type Of Service</i> field is not permitted.
15	<b><i>Precedence Cutoff In Effect</i></b>	Sent by a router when receiving a datagram whose <i>Precedence</i> value (priority) is lower than the minimum allowed for the network at that time.

As you can see in that table, not all of these codes are actively used at this time. For example, code 8 is obsolete and code 0 is used instead of 6. Also, some of the higher numbers related to the *Type Of Service* field aren't actively used because *Type Of Service* isn't actively used.

**Key Concept:** ICMPv4 *Destination Unreachable* messages are used to inform a sending device of a failure to deliver an IP datagram. The message's *Code* field provides information about the nature of the delivery problem.

---

### ***Interpretation of Destination Unreachable Messages***

Finally, it's important to remember that just as IP is “best effort”, the reporting of unreachable destinations using ICMP is also “best effort”. For one things, these ICMP messages are themselves carried in IP datagrams. More than that, however, one must remember that there may be problems that prevent a router from detecting failure of delivery of an ICMP message, such as a low-level hardware problem. A router could, theoretically, also be precluded from sending an ICMP message even when failure of delivery *is* detected, for whatever reason.

For this reason, the sending of *Destination Unreachable* messages should be considered **supplemental**. There is no guarantee that every problem sending a datagram will result in a corresponding ICMP message. No device should count on receiving an ICMP *Destination Unreachable* for a failed delivery any more than it counts on the delivery in the first place. This is why the higher-layer mechanisms mentioned at the start of this topic are still important.

---

## **ICMPv4 Source Quench Messages**

When a source device sends out a datagram, it will travel across the internetwork and eventually arrive at its intended destination—hopefully. At that point, it is up to the destination device to process the datagram, by examining it and determining which higher-layer software process to hand the datagram.

If a destination device is receiving datagrams at a relatively slow rate, it may be able to process each datagram “on the fly” as it is received. However, datagram receipt in a typical internetwork can tend to be uneven or “bursty”, with alternating higher and lower rates of traffic. To allow for times when datagrams are arriving faster than they can be processed, each device has a *buffer* where it can temporarily hold datagrams it has received until it has a chance to deal with them.

However, this buffer is itself limited in size. Assuming the device has been properly designed, the buffer may be sufficient to smooth out high-traffic and low-traffic periods most of the time. Certain situations can still arise in which traffic is received so rapidly that the buffer itself fills up entirely. Some examples of scenarios in which this might happen include:

- ☉ A single destination is overwhelmed by datagrams from many sources, such as a popular Web site being swamped by HTTP requests.
- ☉ Device *A* and device *B* are exchanging information but device *A* is a much faster computer than device *B* and can generate outgoing and process incoming datagrams much faster than *B* can.
- ☉ A router receives a large number of datagrams over a high-speed link that it needs to forward over a low-speed link; they start to pile up while waiting to be sent over the slow link.
- ☉ A hardware failure or other situation causes datagrams to sit at a device unprocessed.

A device that continues to receive datagrams when it has no more buffer space is forced to discard them, and is said to be *congested*. A source that has its datagram discarded due to congestion won't have any way of knowing this, since IP itself is unreliable and unacknowledged. Therefore, while it is possible to simply allow higher-layer protocols to detect the dropped datagrams and generate replacements, it makes a lot more sense to have the congested device provide feedback to the sources, telling them that it is overloaded.

In IPv4, a device that is forced to drop datagrams due to congestion provides feedback to the sources that overwhelmed it by sending them ICMPv4 *Source Quench* messages. Just as we use water to quench a fire, a *Source Quench* method is a signal that attempts to quench a source device that is sending too fast. In other words, it's a polite way for one IP device to tell another: “SLOW DOWN!” When a device receives one of these messages it knows it needs to cut down on how fast it is sending datagrams to the device that sent it.

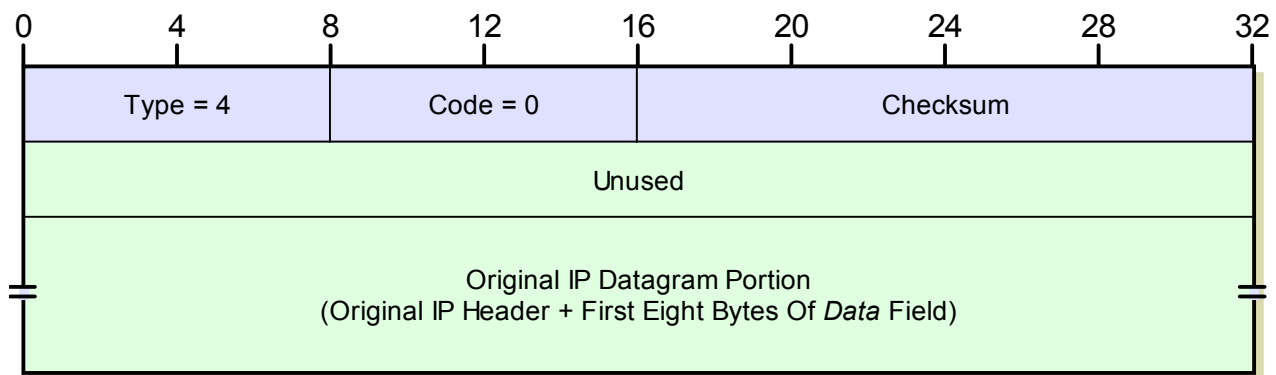

---

## ICMPv4 Source Quench Message Format

The specific format for ICMPv4 *Source Quench* messages can be found in [Table 91](#) and [Figure 140](#).

**Table 91: ICMPv4 Source Quench Message Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMP message type; for <i>Source Quench</i> messages this is set to 4.
<b>Code</b>	1	<b>Code:</b> Identifies the “subtype” of error being communicated. For <i>Source Quench</i> messages this is not used, and the field is set to 0.
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .
<b>Unused</b>	4	<b>Unused:</b> 4 bytes that are left blank and not used.
<b>Original Datagram Portion</b>	Variable	<b>Original Datagram Portion:</b> The full IP header and the first 8 bytes of the payload of the datagram that was dropped due to congestion.

**Figure 140: ICMPv4 Source Quench Message Format**

### Problems With Source Quench Messages

What's interesting about the *Source Quench* format is that it is basically a “null message”. It tells the source that the destination is congested but provides no specific information about that situation, nor does it specify what exactly the destination wants the source to do, other than to cut back on its transmission rate in some way. There is also no method for the destination to signal a source it has “quenched” that it is no longer congested and to resume its prior sending rate. This means the response to a *Source Quench* is left up to the device that receives it. Usually, a device will cut back its transmission rate until it no longer receives the messages any more, and then may try to slowly increase the rate again.

---

In a similar manner, there are no rules about when and how a device generates *Source Quench* messages in the first place. A common convention is that one message is generated for each dropped datagram. However, more intelligent algorithms may be employed, specially on higher-end routers, to predict when the device's buffer will be filled and preemptively quench certain sources that are sending too quickly. Devices may also decide whether to quench all sources when they become busy, or only certain ones. As with other ICMP error messages, a device cannot count on a *Source Quench* being sent when one of its datagrams is discarded by a busy device.

The lack of information communicated in *Source Quench* messages makes them a rather crude tool for managing congestion. In general terms, the process of regulating the sending of messages between two devices is called *flow control*, and is usually a function of the transport layer. The [Transmission Control Protocol \(TCP\)](#) actually has a [flow control mechanism](#) that is far superior to the use of ICMP *Source Quench* messages.

Another issue with *Source Quench* messages is that they can be abused. Transmission of these messages by a malicious user can cause a host to be slowed down when there is no valid reason. This security issue, combined with the superiority of the TCP method for flow control, has caused *Source Quench* messages to largely fall out of favor.

**Key Concept:** ICMPv4 *Source Quench* messages are sent by a device to request that another reduce the rate at which it is sending datagrams. They are a rather crude method of flow control compared to more capable mechanisms such as that provided by TCP.

---

## **ICMPv4 Time Exceeded Messages**

Large IP internetworks can have thousands of interconnected routers that pass datagrams between devices on various networks. In large internetworks, the topology of connections between routes can become complex, which makes routing more difficult. [Routing protocols](#) will normally allow routers to find the best routes between networks, but in some situations an inefficient route might be selected for a datagram.

In the worst case of inefficient routing, a *router loop* may occur. An example of this situation is where Router A thinks datagrams intended for network X should next go to Router B; Router B thinks they should go to Router C; and Router C thinks they need to go to Router A. ([See the ICMPv6 Time Exceeded Message description for an illustration of a router loop.](#))

If a loop like this occurred, datagrams for network X entering this part of the internet would circle forever, chewing up bandwidth and eventually leading to the network being unusable. As insurance against this occurrence, [each IP datagram includes in its header a Time To Live \(TTL\) field](#). This field was originally intended to limit the maximum time (in seconds) that a datagram could be on the internetwork, but now limits the life of a datagram by limiting the number of times the datagram can be passed from one device to the next. The

TTL is set to a value by the source that represents the maximum number of hops it wants for the datagram. Each router decrements the value; if it ever reaches zero the datagram is said to have *expired* and is discarded.

When a datagram is dropped due to expiration of the *TTL* field, the device that dropped the datagram will inform the source of this occurrence by sending it an ICMPv4 *Time Exceeded* message, as shown in Figure 141. Receipt of this message indicates to the original sending device that there is either a routing problem when sending to that particular destination, or that it set the *TTL* field value too low in the first place. As with all ICMP messages, the device receiving it must decide whether and how to respond to receipt of the message. For example, it may first try to re-send the datagram with a higher *TTL* value.

**Figure 141: Expiration of an IP Datagram and *Time Exceeded* Message Generation**

In this example, device A sends an IP datagram to device B that has a *Time To Live (TTL)* field value of only 4 (perhaps not realizing that B is 7 hops away). On the fourth hop the datagram reaches R4, which decrements its *TTL* field to zero and then drops it as expired. R4 then sends an ICMP *Time Exceeded* message back to A.

There is another “time expiration” situation where ICMP *Time Exceeded* messages are used. When an IP message is **broken into fragments**, the destination device is charged with **reassembling them into the original message**. One or more fragments may not make it to the destination, so to prevent the device from waiting forever, it sets a timer when the first fragment arrives. If this timer expires before the others are received, the device gives up on this message. The fragments are discarded, and a *Time Exceeded* message generated.

## ICMPv4 Time Exceeded Message Format

Table 92 and Figure 142 show the specific format for ICMPv4 *Time Exceeded* messages.

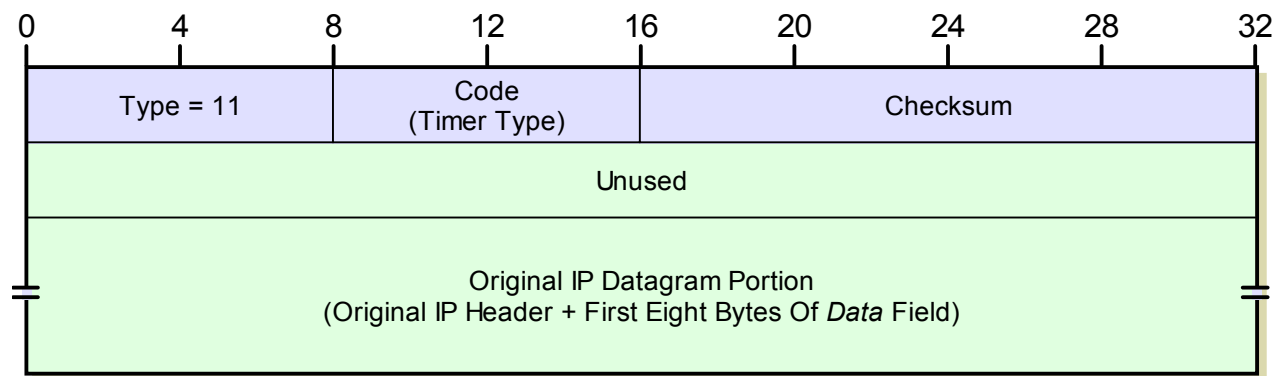

Figure 142: ICMPv4 *Time Exceeded* Message Format

Table 92: ICMPv4 *Time Exceeded* Message Format

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMP message type; for <i>Time Exceeded</i> messages this is set to 11.
<b>Code</b>	1	<b>Code:</b> Identifies the “subtype” of error being communicated. A value of 0 indicates expiration of the IP <i>Time To Live</i> field; a value of 1 indicates that the fragment reassembly time has been exceeded.
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .
<b>Unused</b>	4	<b>Unused:</b> 4 bytes that are left blank and not used.
<b>Original Datagram Portion</b>	Variable	<b>Original Datagram Portion:</b> The full IP header and the first 8 bytes of the payload of the datagram that was dropped due to expiration of the <i>TTL</i> field or reassembly timer.

## Applications of Time Exceeded Messages

As an ICMP error message type, ICMP *Time Exceeded* messages are usually sent in response to the two conditions described above (*TTL* or reassembly timer expiration). Generally, *Time To Live* expiration messages are generated by routers as they try to route a datagram, while reassembly violations are indicated by end hosts. However, there is actually a very clever application of these messages that has nothing to do with reporting errors at all.

**Key Concept:** ICMPv4 *Time Exceeded* messages are sent in two different “time-related” circumstances. The first is if a datagram’s *Time To Live (TTL)* field is reduced to zero, causing it to expire and the datagram to be dropped. The second is when all the pieces of a fragmented message are not received before the expiration of the recipient’s reassembly timer.

---

The TCP/IP *traceroute* (or *tracert*) utility is used to show the sequence of devices over which a datagram is passed on a particular route between a source and destination, as well as the amount of time it takes for a datagram to reach each hop in that route. This utility was originally implemented using *Time Exceeded* messages by sending datagrams with successively higher *TTL* values. First, a “dummy” datagram is sent with a *TTL* value of 1, causing the first hop in the route to discard the datagram and send back an ICMP *Time Exceeded*; the time elapsed for this could be measured. Then, a second datagram is sent with a *TTL* value of 2, causing the second device in the route to report back a *Time Exceeded*, and so on. By continuing to increase the *TTL* value we can get reports back from each hop in the route. [See the topic describing traceroute for more details on its operation.](#)

## **ICMPv4 Redirect Messages**

Every device on an internetwork needs to be able to send to every other device. If hosts were responsible for determining the routes to each possible destination, each host would need to maintain an extensive set of routing information. Since there are so many hosts on an internetwork, this would be a very time-consuming and maintenance-intensive situation.

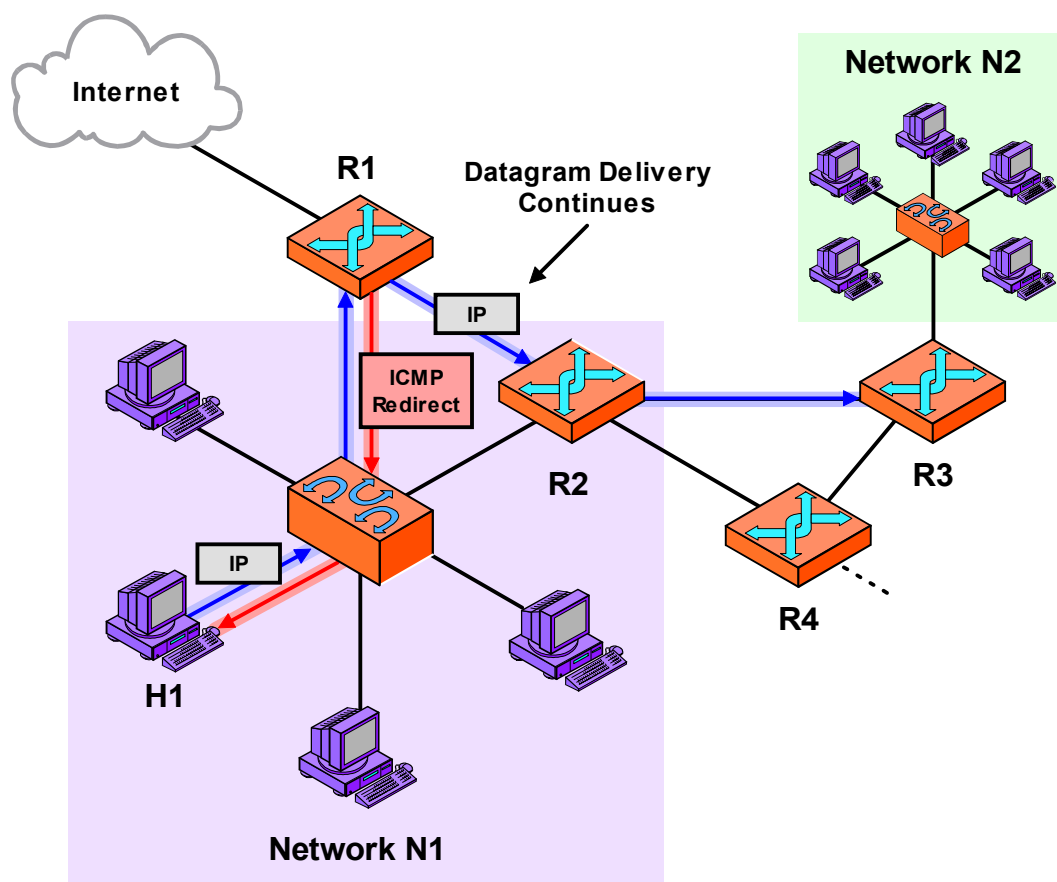

Instead, IP internetworks are designed around a fundamental design decision: routers are responsible for [determining routes and maintaining routing information](#). Hosts only determine when they need a datagram routed, and then hand the datagram off to a local router to be sent where it needs to go. [I discuss this in more detail in my overview of IP routing concepts.](#)

Since most hosts do not maintain routing information, they must rely on routers to know about routes and where to send datagrams intended for different destinations. Typically, a host on an IP network will start out with a routing table that basically tells it to send everything not on the local network to a single *default router*, which will then figure out what to do with it. Obviously if there is only one router on the network, the host will use that as the default router for all non-local traffic. However, if there are two or more routers, sending all datagrams to just one router may not make sense. It is possible that a host could be manually configured to know which router to use for which destinations, but another mechanism in IP can allow a host to learn this automatically.

Consider a network *N1* that contains a number of hosts (*H1*, *H2*, etc...) and two routers, *R1* and *R2*. Host *H1* has been configured to send all datagrams to *R1*, as its default router. Suppose it wants to send a datagram to a device on a different network (*N2*). However, *N2* is most directly connected to *N1* using *R2* and **not** *R1*. The datagram will first be sent to *R1*.

*R1* will look in its routing table and see that datagrams for *N2* need to be sent through *R2*. “But wait,” *R1* says. “*R2* is on the local network, and *H1* is on the local network—so why am I needed as a middleman? *H1* should just send datagrams for *N2* directly to *R2* and leave me out of it.”

In this situation, *R1* will send an ICMPv4 *Redirect* message back to *H1*, telling it that in the future it should send this type of datagram directly to *R2*. This is shown in [Figure 143](#). *R1* will of course also forward the datagram to *R2* for delivery, since there is no reason to drop the datagram. Thus, despite usually being grouped along with true ICMP error messages, *Redirect* messages are really arguably not error messages at all; they represent a situation only where an inefficiency exists, not an outright error. (In fact, in ICMPv6 they have been [reclassified](#).)

**Figure 143: Host Redirection Using an ICMP *Redirect* Message**

In this example *H1* sends to *R1* a datagram destined for network *N2*. However, *R1* notices that *R2* is on the same network and is a more direct route to *N2*. It forwards the datagram on to *R2* but also sends an ICMP *Redirect* message back to *H1* to tell it to use *R2* next time.

---

## ICMPv4 Redirect Message Format

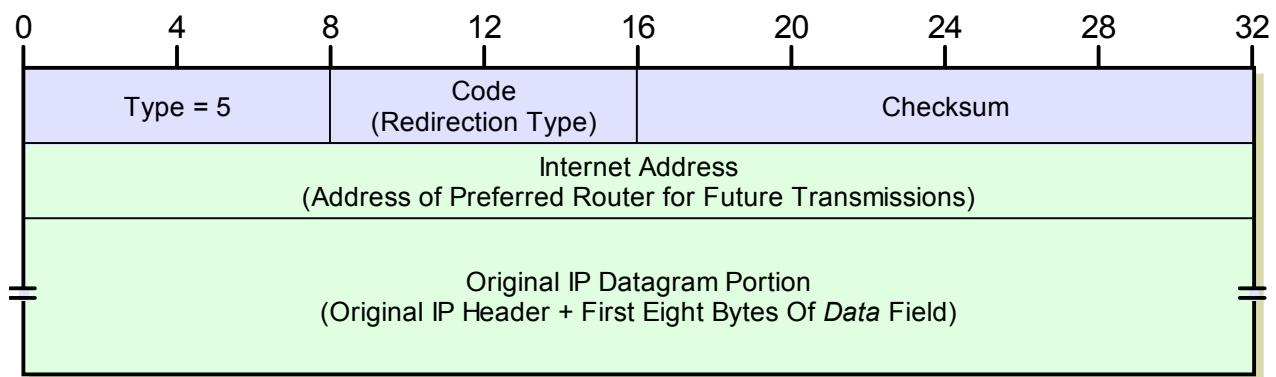

The format for ICMPv4 *Redirect* messages can be found in [Table 93](#) and [Figure 144](#).

**Table 93: ICMPv4 Redirect Message Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMP message type; for <i>Redirect</i> messages this value is 5.
<b>Code</b>	1	<b>Code:</b> Identifies the meaning or “scope” of the <i>Redirect</i> message. See <a href="#">Table 94</a> for an explanation of how this field is used in <i>Redirect</i> messages.
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .
<b>Internet Address</b>	4	<b>Internet Address:</b> The address of the router to which future datagrams sent to the original destination should be sent.
<b>Original Datagram Portion</b>	Variable	<b>Original Datagram Portion:</b> The full IP header and the first 8 bytes of the payload of the datagram that led to the creation of the <i>Redirect</i> .

### Redirect Message Interpretation Codes

When a *Redirect* is received back by a device, it inspects the included portion of the original datagram. Since this contains the original destination address of the redirected target device, this tells the original sender which addresses should be redirected in the future. The *Internet Address* field tells it what router it should use for subsequent datagrams. The *Code* field tells the sender how broadly to interpret the redirection. There are four different *Code* values; see [Table 94](#).

**Figure 144: ICMPv4 Redirect Message Format**

Obviously, routers usually generate *Redirect* messages and send them to hosts; hosts do not normally create them. The specific rules for when *Redirects* are created can be fairly complex, as a number of conditions may exist that preclude these messages from being sent. In particular, special rules exist for when a router may *Redirect* an entire network (or

---

subnet) instead of just a single host. Also, remember that the *Type Of Service* field is optional and often not used, so *Redirects* with *Code* values of 2 or 3 are less common than those with values of 0 and 1.

**Table 94: ICMP *Redirect* Message Interpretation Codes**

Code Value	Message Subtype	Meaning
0	<i>Redirect Datagrams For The Network (Or Subnet)</i>	Redirect all future datagrams sent not only to the device whose address caused this <i>Redirect</i> , but also datagrams sent to all other devices on the network (or subnet) where that device is located. (This code is now obsolete; see the note that follows this table.)
1	<i>Redirect Datagrams For The Host</i>	Redirect all future datagrams only for the address of the specific device to which the original datagram was sent.
2	<i>Redirect Datagrams For The Type Of Service (TOS) and Network (Or Subnet)</i>	As for <i>Code</i> value 0, but only for future datagrams that have the same <i>Type Of Service (TOS)</i> value as the original datagram. (This code is now obsolete; see the note that follows this table.)
3	<i>Redirect Datagrams For The Type Of Service (TOS) and Host</i>	As for <i>Code</i> value 1, but only for future datagrams that have the same <i>Type Of Service (TOS)</i> value as the original datagram.

**Note:** One problem with *Redirects* for whole networks is that the network specification may be ambiguous in an environment where subnetting or classless addressing are used. For this reason, the use of *Code* values 0 and 2 was prohibited by RFC 1812; they are considered obsolete on the modern Internet.

---

### ***Limitations of Redirect Messages***

I must emphasize that ICMP *Redirect* messages are **not** a mechanism by which the general routing process in IP is implemented; they are a support function only. They are a convenient way for hosts to be given information about routes by local routers, but are not used to communicate route information between routers.

This means that a *Redirect* can tell a host to use a more efficient first-hop router, but cannot tell a router to use a more efficient second-hop router. In our example above, suppose that in addition to the connections mentioned, *R2* is connected to *R3* and *R4* as shown in [Figure 143](#). *R2* sends the datagram in question to *R3*, which realizes it needs to send to *R4*, a router already directly connected to *R2*. *R3* **cannot** send a *Redirect* to *R2* telling it to use *R4* next time. The messages are simply not designed for this purpose—remember that ICMP messages always go back to the source of the original datagram, which would not be *R2* in this case. Such inefficiencies must be resolved using [routing protocols](#).

**Key Concept:** ICMPv4 *Redirect* messages are used by a router to inform a host of a preferred router to use for future datagrams sent to a particular host or network. They are not used to alter routes between routers.

## ICMPv4 Parameter Problem Messages

The previous topics in this section describe four specific ICMPv4 message types that allow a device to report various error conditions to the original sender of a datagram. However, other error situations may arise also that don't correspond to any of these four specific message types. Typically, the problem results when a device attempts to process the header fields of an IP datagram and finds something in it that doesn't make sense.

If a device finds a problem with any of the parameters in an IP datagram header that is serious enough that it cannot complete processing the header, it must discard the datagram. Like other cases where a datagram must be tossed out, this is serious enough to warrant communication of the problem back to the device that sent the original datagram. This is accomplished in ICMPv4 using the *Parameter Problem* message type.

This is a “catch all” type of message that can be used to indicate an error in any header field of an IP datagram. The message type does not contain any specific fields or coding to indicate what the problem is. This was done intentionally to keep the *Parameter Problem* message “generic” and ensure that it could indicate any sort of error. Instead of special error codes, most *Parameter Problem* messages tell the original source which parameter caused the problem by including a special pointer that indicates which field in the original datagram header caused the problem.

### ICMPv4 Parameter Problem Message Format

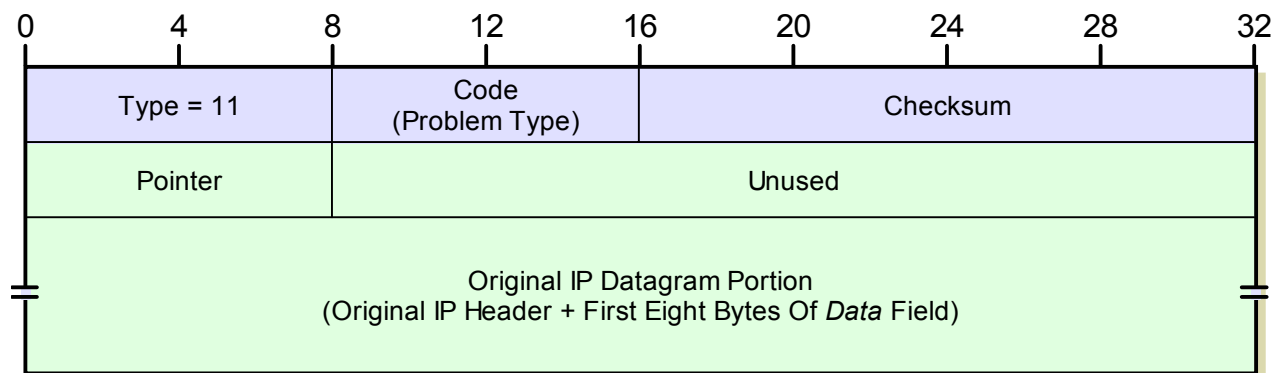

[Table 95](#) and [Figure 145](#) show the format for ICMPv4 *Parameter Problem* messages.

**Table 95: ICMPv4 Parameter Problem Message Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMP message type; for <i>Parameter Problem</i> messages this value is 12.
<b>Code</b>	1	<b>Code:</b> Identifies the “subtype” of problem being communicated. See <a href="#">Table 96</a> for more information on this field for <i>Parameter Problem</i> messages.
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .
<b>Pointer</b>	1	<b>Pointer:</b> An offset that points to the byte location in the datagram that caused the <i>Parameter Problem</i> message to be generated. The device receiving the ICMP message can use this value to get an idea of which field in the original message had the problem.  This field is used only when the Code value is 0.

**Table 95: ICMPv4 *Parameter Problem* Message Format**

Field Name	Size (bytes)	Description
<b>Unused</b>	3	<b>Unused:</b> 3 bytes that are left blank and not used.
<b>Original Datagram Portion</b>	Variable	<b>Original Datagram Portion:</b> The full IP header and the first 8 bytes of the payload of the datagram that prompted this error message to be sent.

**Figure 145: ICMPv4 *Parameter Problem* Message Format**

### ***Parameter Problem Message Interpretation Codes and The Pointer Field***

When a *Parameter Problem* message is generated due to a specific bad field in the original message, the *Pointer* field is used as described above to show the location of the problem. This meaning of the *Parameter Problem* message is the one that was defined in the original ICMP standard, RFC 792, and is associated with *Code* value 0. There are some cases of a parameter problem where a pointer to a specific field in the original message really wouldn't make sense, so other standards have defined two new *Code* field values for *Parameter Problem* messages. [Table 96](#) shows the three *Code* values and provides a brief explanation of each.

**Table 96: ICMPv4 *Parameter Problem* Message Interpretation Codes**

Code Value	Message Subtype	Description
0	<i>Pointer Indicates The Error</i>	This is the normal use of the <i>Parameter Problem</i> message; when this <i>Code</i> value is used, the <i>Pointer</i> field indicates the location of the problem.
1	<i>Missing A Required Option</i>	The IP datagram needed to have an option in it that was missing. Since the option was missing there is no way to point to it, of course. ☺
2	<i>Bad Length</i>	The length of the datagram overall was incorrect, indicating a general problem with the message as a whole. Again, the <i>Pointer</i> field makes no sense here.

**Key Concept:** The ICMPv4 *Parameter Problem* message is a generic “catch all” that can be used to convey an error of any type in an IP datagram. A special *Pointer* field is normally used to indicate to the recipient of the message where the problem was in the original datagram.

---

Note that the *Pointer* field is only 8 bits wide, but since this allows for values up to 256 this is sufficient to allow it to point to any location within the IP header. It is possible for the *Pointer* field to point to a field within an IP option. Both hosts and routers can generate *Parameter Problem* messages.

---

## **ICMP Version 4 (ICMPv4) Informational Message Types and Formats**

The five [ICMP error message types](#) communicate important information about error or problem conditions encountered during the operation of an IP internetwork. In contrast, the other class of ICMP messages contains those messages that are *informational*. They are not sent in response to some issue with a regular IP datagram, but are used on their own to implement various support functions for IP. Informational messages are used for testing and diagnostic purposes, as well as to let devices share critical information they need to function correctly.

In this section I describe nine different ICMP version 4 informational messages. Since many of these messages are used in functional sets, pairs of related messages are described in the same topic. I begin with a discussion of the *Echo (Request)* and *Echo Reply* messages used for network testing, and *Timestamp* and *Timestamp Reply* messages used for clock synchronization. I explain the use and format of *Router Advertisement* and *Router Solicitation* messages, which allow hosts to discover the identity of local routers and learn important information about them. I also describe the *Address Mask Request* and *Address Mask Reply* messages that communicate subnet mask information. I conclude with a look at the *Traceroute* message, which implements a more sophisticated version of the [traceroute utility](#).

**Note:** The original ICMP standard also defined two more informational message types: *Information Request* and *Information Reply*. These were intended to allow devices to determine an IP address and possibly other configuration information. This function was later implemented using protocols such as [RARP](#), [BOOTP](#) and [DHCP](#), and these message types obsoleted. Therefore, they are not discussed in this section. (Well, I guess I *did* just discuss them there... you know what I mean!)

---

### **ICMPv4 Echo (Request) and Echo Reply Messages**

One of the main purposes of ICMP informational messages is to enable testing and diagnostics, to help identify and correct problems on an internetwork. The most basic test that can be conducted between two devices is simply checking if they are capable of sending datagrams to each other. The usual way that this is done is to have one device send a test message to a second device, which receives the message and replies back to tell the first device it received the message.

ICMPv4 includes a pair of messages specifically for connection testing. Suppose Device A wants to see if it can reach Device B. Device A begins the test process by sending an ICMPv4 *Echo* message to B. Device B, when it receives the *Echo*, responds back to Device A with an *Echo Reply* message. When Device A receives this message, it knows that it is able to communicate (both send and receive) successfully with Device B.

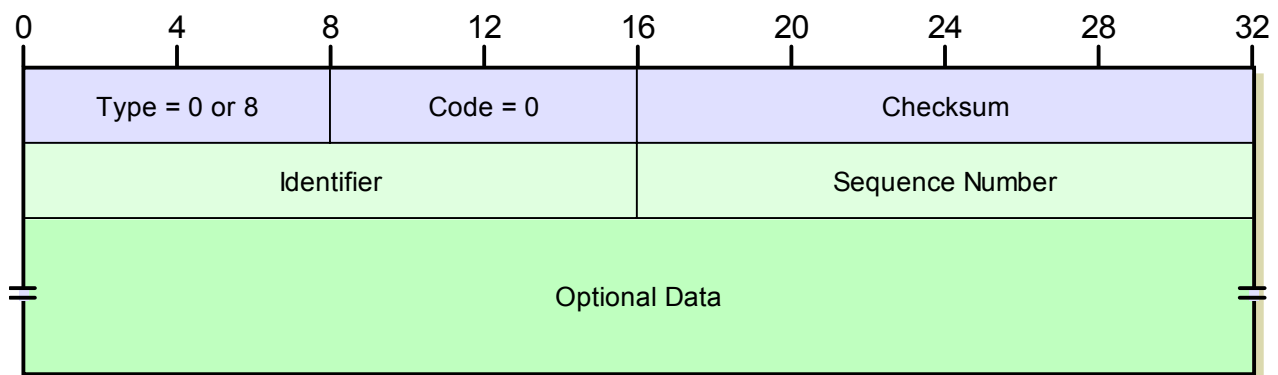

**Note:** The name of the first message in this pair is often given as *Echo Request*. While this does convey the paired nature of the *Echo* and *Echo Reply* messages, the formal name used in the standards is simply an *Echo* message.

### ICMPv4 Echo and Echo Reply Message Format

Table 97 and Figure 146 show the format for both ICMPv4 *Echo* and *Echo Reply* messages.

**Table 97: ICMPv4 Echo and Echo Reply Message Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMP message type. For <i>Echo</i> messages the value is 8; for <i>Echo Reply</i> messages the value is 0.
<b>Code</b>	1	<b>Code:</b> Not used for <i>Echo</i> and <i>Echo Reply</i> messages; set to 0.
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .
<b>Identifier</b>	2	<b>Identifier:</b> An identification field that can be used to help in matching <i>Echo</i> and <i>Echo Reply</i> messages.
<b>Sequence Number</b>	2	<b>Sequence Number:</b> A sequence number to help in matching <i>Echo</i> and <i>Echo Reply</i> messages.
<b>Optional Data</b>	Variable	<b>Optional Data:</b> Additional data to be sent along with the message (not specified.)

**Figure 146: ICMPv4 Echo and Echo Reply Message Format**

It is possible that a source device may want to send more than one *Echo* message to either a single destination or multiple destinations. Conversely, a single destination might receive *Echo* messages from more than one source. It is essential that a device receiving an *Echo Reply* knows which *Echo* prompted it to be sent.

---

Two special fields are used within the format of these messages to allow *Echo* and *Echo Reply* messages to be matched together, and to allow a sequence of messages to be exchanged. The *Identifier* field was envisioned as being used as a higher-level label, like a session identifier, while the *Sequence Number* was seen as something to identify individual test messages within a series. However, the use of these fields is up to the particular implementation. In some cases, the *Identifier* field is filled in with the process number of the application that is using the *Echo* or *Echo Reply* message, to allow several users to use utilities like ping without interference.

### ***Application of Echo and Echo Reply Messages***

The most common way that you may use the *Echo* and *Echo Reply* messages is through the popular utility *ping*, which is used to test host reachability. While the basic test simply consists of sending an *Echo* and waiting for an *Echo Reply*, modern versions of ping are quite sophisticated. They allow the user to specify many parameters, including the number of *Echo* messages sent, how often they are sent, the size of message transmitted and more. They also provide a great deal of information about the connection, including the number of *Echo Reply* messages received, the time elapsed for the pair of messages to be exchanged and a lot more. [See the topic describing ping for a full explanation of the utility.](#)

**Key Concept:** ICMPv4 *Echo (Request)* and *Echo Reply* messages are used to facilitate network reachability testing. A device can test its ability to perform basic communication with another one by sending an *Echo* message and waiting for an *Echo Reply* to be returned by the other device. The *ping* utility, a widely-used diagnostic tool in TCP/IP internetworks, makes use of these messages.

---

### **ICMPv4 Timestamp (Request) and Timestamp Reply Messages**

All of the hosts and routers on an internetwork operate independently of each other. One aspect of this autonomy is that each device maintains a separate system clock. Since even highly-accurate clocks have slight differences in how accurately they keep time, as well as the time they are initialized with, this means that under normal circumstances, no two devices on an internetwork are guaranteed to have exactly the same time.

The creators of TCP/IP recognized that certain applications might not work properly if there was too much differential between the system clocks of a pair of devices. To support this requirement, they created a pair of ICMP messages that allow devices to exchange system time information. The initiating device creates a *Timestamp* message and sends it to the device with which it wishes to synchronize. That device responds with a *Timestamp Reply* message. Timestamp fields in these messages are used to mark the times that these messages are sent and received to allow the devices' clocks to be synchronized.

**Note:** As with [the Echo message](#), the *Timestamp* message is sometimes seen as *Timestamp Request*, though the word “Request” doesn’t appear in its formal name.

### ***ICMPv4 Timestamp and Timestamp Reply Message Format***

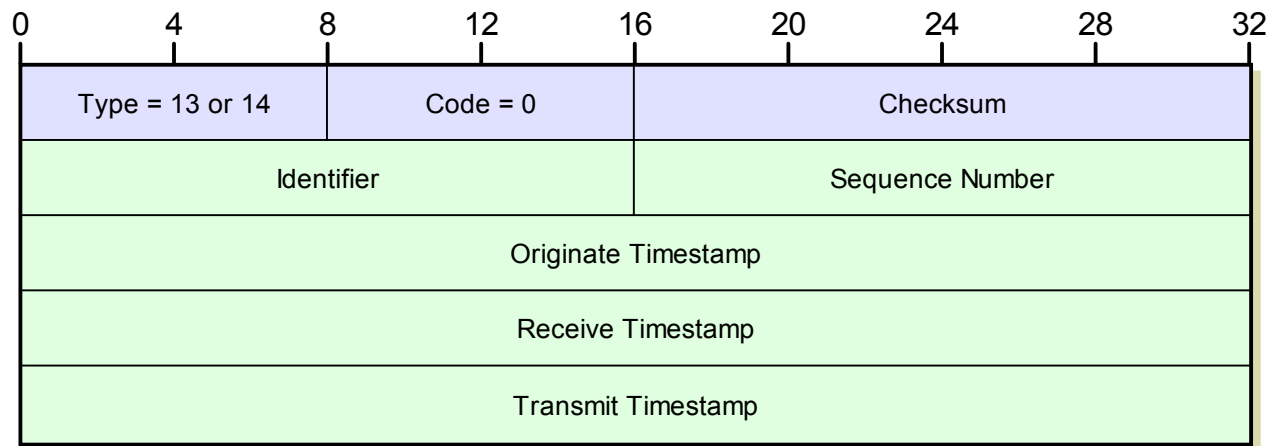

The ICMPv4 *Timestamp* and *Timestamp Reply* messages have the same format. The originating device fills in some of the fields, and the replying device others. The format is as shown in [Table 98](#) and [Figure 147](#).

**Table 98: ICMPv4 *Timestamp* and *Timestamp Reply* Message Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMP message type. For <i>Timestamp</i> messages the value is 13; for <i>Timestamp Reply</i> messages the value is 14.
<b>Code</b>	1	<b>Code:</b> Not used for <i>Timestamp</i> and <i>Timestamp Reply</i> messages; set to 0.
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .
<b>Identifier</b>	2	<b>Identifier:</b> An identification field that can be used to help in matching <i>Timestamp</i> and <i>Timestamp Reply</i> messages.
<b>Sequence Number</b>	2	<b>Sequence Number:</b> A sequence number to help in matching <i>Timestamp</i> and <i>Timestamp Reply</i> messages.
<b>Originate Timestamp</b>	4	<b>Originate Timestamp:</b> A time value filled in by the originating device just before sending the <i>Timestamp</i> message.
<b>Receive Timestamp</b>	4	<b>Receive Timestamp:</b> A time value filled in by the responding device just as it receives the <i>Timestamp</i> message.
<b>Transmit Timestamp</b>	4	<b>Transmit Timestamp:</b> A time value filled in by the responding device just before sending back the <i>Timestamp Reply</i> message.

The *Identifier* and *Sequence Number* fields are used to match *Timestamp* and *Timestamp Reply* messages, exactly as they were used for *Echo* and *Echo Reply* messages. The *Identifier* field is intended as a higher-level label, like a session identifier, while the *Sequence Number* is often used to identify individual messages within a series. However, the use of these fields is up to the particular implementation.

All three timestamps are represented as the number of milliseconds since midnight, *Universal Time* (UT, also called *Greenwich Mean Time* or GMT). The reason there are three timestamps instead of the two you might ordinarily expect, is that a separate timestamp is recorded by the responding device both when it receives the *Timestamp* message and when it generates the *Timestamp Reply*. When the *Reply* is received back by the originating device, it then has the times that both the *Timestamp* and the *Timestamp Reply* were sent.

**Figure 147: ICMPv4 *Timestamp* and *Timestamp Reply* Message Format**

This allows the originating device to differentiate between the time required for transmitting datagrams over the network, and the time for the other device to process the *Timestamp* and turn it into a *Timestamp Reply*.

### ***Issues Using Timestamp and Timestamp Reply Messages***

In practice, even with three timestamp fields, it is difficult to coordinate system clocks over an internetwork—especially a large one like the Internet. The main problem is that the amount of time it takes to send a datagram between any pair of devices varies from one datagram to the next. And again, since IP is unreliable, it's possible the time for a datagram to be received could be infinite—it might be lost or dropped by a router.

This means that a simple exchange of *Timestamp* and *Timestamp Reply* messages is simply not a reliable enough method for ensuring that two devices are synchronized on a typical IP internetwork. For this reason, modern devices often use a more sophisticated method for time synchronization, such as the Network Time Protocol (NTP).

Note that unlike many of the other ICMP message types, support for *Timestamp* and *Timestamp Reply* messages is optional, for both hosts and routers.

### **ICMPv4 Router Advertisement and Router Solicitation Messages**

In [the overview topic describing IP routing fundamentals](#), I discussed a critical aspect of IP internetwork design: the difference between the roles of a router and that of a host with regard to routing. Routers are charged with the job of routing datagrams, and therefore, of knowing routes and exchanging route information. Hosts generally do not know a great deal about routes; they rely on routers to convey datagrams intended for destinations outside the local network.

---

This dependence means that before a host can really participate on an internetwork, it needs to know the identity of at least one router on the local network. One way to ensure that this is the case is to just manually configure each host with the address of a local router as its default router. This method is simple, but has the typical drawbacks associated with manual processes—it is time-consuming to set up, difficult to maintain, and inflexible.

### ***The Router Discovery Process***

It would be better if there were some method whereby a host could automatically discover the identity of local routers, and learn important information about them. In IP, this process is called *router discovery*, and was first defined in RFC 1256, *ICMP Router Discovery Messages*. The messages referenced in the RFC title are the *ICMP Router Advertisement* message and the *Router Solicitation* message, and were added to the ICMP message types defined in earlier standards such as RFC 792.

Routers are responsible for sending *Router Advertisement* messages. These messages tell listening devices that the router exists, and provide important information about the router such as its address (or addresses, if it has more than one) and how long the host should retain information about the router. Routine *Router Advertisement* messages are sent on a regular basis, with the time between messages administrator-configurable (usually between 7 and 10 minutes). Hosts listen for these messages; when an advertisement is received, the host processes it and adds the information about the router to its routing table.

A host that has no manually-configured routing information will have no knowledge of routers when it first powers on. Having it sit for many minutes looking for a routine *Router Advertisement* message is inefficient. Instead of waiting, the host may send a *Router Solicitation* message on its local network(s). This will prompt any router that hears it to immediately send out an extra *Router Advertisement* message directly to that host.

### ***ICMPv4 Router Advertisement Message Format***

The ICMPv4 *Router Advertisement* message format is shown in [Table 99](#) and [Figure 148](#).

**Table 99: ICMPv4 Router Advertisement Message Format (Page 1 of 2)**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMP message type. For <i>Router Advertisement</i> messages the value is 9.
<b>Code</b>	1	<b>Code:</b> Normally set to 0. When a Mobile IP agent is sending a <i>Router Advertisement</i> with an <i>Agent Advertisement</i> extension, it may set the value to 16 if the device is a mobile agent only and doesn't intend to handle normal traffic. <a href="#">See the discussion of Mobile IP agent discovery for details.</a>
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .
<b>Num Addrs</b>	1	<b>Number Of Addresses:</b> The number of addresses associated with this router that are included in this advertisement.

**Table 99: ICMPv4 Router Advertisement Message Format (Page 2 of 2)**

Field Name	Size (bytes)	Description									
<b>Addr Entry Size</b>	1	<b>Address Entry Size:</b> The number of 32-bit words of information included with each address. Since in this message format each router address has a 32-bit address and a 32-bit preference level, this value is fixed at 2.									
<b>Lifetime</b>	2	<b>Lifetime:</b> The number of seconds that a host should consider the information in this message valid.									
<b>Router Address Entries</b>	Value of <i>Num Adrs</i> field * 8	<p><b>Router Address Entries:</b> A number of router address entries equal to the value of the <i>Num Adrs</i> field. Each is 8 bytes and has two subfields:</p> <table> <tr> <th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr> <tr> <td><b>Router Address</b></td><td>4</td><td><b>Router Address:</b> A valid address for an interface to the router sending this message.</td></tr> <tr> <td><b>Preference Level</b></td><td>4</td><td><b>Preference Level:</b> The preference level of this address. When more than one address is included in an advertisement, this field indicates which address the router would prefer that hosts use. Higher values mean greater preference.</td></tr> </table>	Subfield Name	Size (bytes)	Description	<b>Router Address</b>	4	<b>Router Address:</b> A valid address for an interface to the router sending this message.	<b>Preference Level</b>	4	<b>Preference Level:</b> The preference level of this address. When more than one address is included in an advertisement, this field indicates which address the router would prefer that hosts use. Higher values mean greater preference.
Subfield Name	Size (bytes)	Description									
<b>Router Address</b>	4	<b>Router Address:</b> A valid address for an interface to the router sending this message.									
<b>Preference Level</b>	4	<b>Preference Level:</b> The preference level of this address. When more than one address is included in an advertisement, this field indicates which address the router would prefer that hosts use. Higher values mean greater preference.									

**Figure 148: ICMPv4 Router Advertisement Message Format**

---

## ICMPv4 Router Solicitation Message Format

ICMPv4 *Router Solicitation* messages are much simpler, because they only need to convey a single piece of information: “if you are a router and can hear this, please send a *Router Advertisement* to me”. The format is therefore just the trivial set of fields shown in [Table 100](#) and [Figure 149](#).

**Table 100: ICMPv4 Router Solicitation Message Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMP message type. For Router Solicitation messages the value is 10.
<b>Code</b>	1	<b>Code:</b> Not used; value set to 0.
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .
<b>Reserved</b>	4	<b>Reserved:</b> 4 reserved bytes sent as 0.

**Figure 149: ICMPv4 Router Solicitation Message Format**

## Addressing and Use of Router Advertisement and Router Solicitation Messages

If possible, both *Router Advertisement* and *Router Solicitation* messages are sent out multicast for efficiency. *Router Advertisements* use the “all devices” multicast address (224.0.0.1), since they are intended for hosts to hear, while *Router Solicitation* messages use the “all routers” multicast address (224.0.0.2). If the local network does not support multicast, messages are instead sent out broadcast (to address 255.255.255.255).

It is important to remember that just like [ICMP Redirect messages](#), *Router Advertisement* messages are not a generalized method for exchanging routing information. They are a support mechanism only, used to inform hosts about the existence of routers. Detailed information about routes is communicated between routers using [routing protocols](#), like [RIP](#) and [OSPF](#).

I should also mention that while I suggested router discovery was the alternative to manual configuration of a host's default router, there are other alternatives as well. For example, a host configuration protocol like [DHCP](#) can allow a host to learn the address of a default router on the local network.

---

Finally, note that when [Mobile IP](#) is implemented, *Router Advertisement* messages are used as the basis for Mobile-IP-aware routers to send *Agent Advertisements*. One or more special *extensions* are added to the regular *Router Advertisement* format to create an *Agent Advertisement*. This is discussed extensively in [the topic on Mobile IP agent discovery](#).

**Key Concept:** ICMP *Router Advertisement* messages are sent regularly by IP routers to inform hosts of their presence and characteristics, so hosts know to use them for delivery of datagrams to distant hosts. A host that is new to a network and wants to find out immediately what routers are present may send a *Router Solicitation*, which will prompt listening routers to send out *Router Advertisements*.

---

## **ICMPv4 Address Mask Request and Reply Messages**

When the Internet Protocol was first developed, IP addresses were based on a simple two-level structure, with a *network identifier* and *host identifier*. To provide more flexibility, a technique called *subnetting* was soon developed that expands the addressing scheme into a three-level structure, with each address containing a network identifier, subnet identifier and host identifier. The *subnet mask* is a 32-bit number that tells devices (and users) which bits are part of the subnet identifier, as opposed to the host identifier. All of this is described in considerable detail in [the section on IP addressing](#).

To function properly in a subnetting environment, each host must know the [subnet mask](#) that corresponds to each address it is assigned—without the mask it cannot properly interpret IP addresses. Just like [determining the identity of a local router](#), a host can be informed of the local network's subnet mask either manually or automatically. The manual method is to simply to have the subnet mask manually assigned to each host. The automatic method makes use of a pair of ICMP messages for subnet mask determination, which were defined in RFC 950, the same standard that defined [subnetting](#) itself.

To use this method, a host sends an *Address Mask Request* message on the local network, usually to get a response from a router. If it knows the address of a local router it may send the request directly (unicast), but otherwise will broadcast it to any listening router. A local router (or other device) will hopefully receive this message and respond back with an *Address Mask Reply* containing the subnet mask for the local network. This process is somewhat similar to the mechanism used by a host to solicit a router to respond with a *Router Advertisement*, except that routers do not routinely send subnet mask information; it must be requested.

---

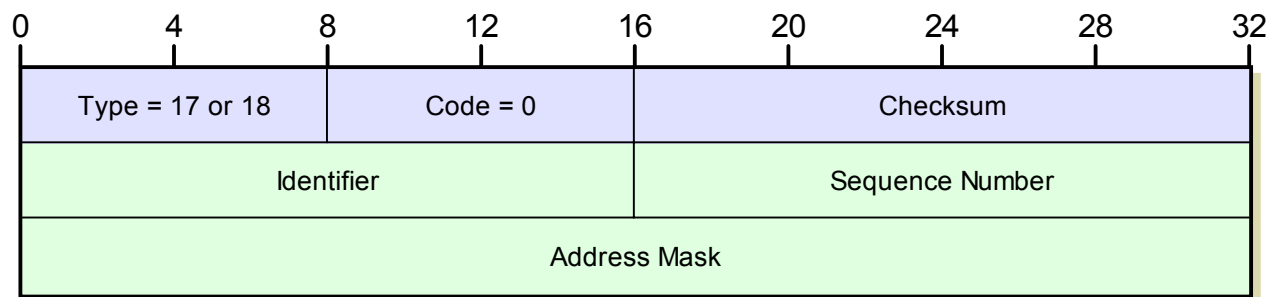

## ICMPv4 Address Mask Request and Address Mask Reply Message Format

The *Address Mask Request* and *Address Mask Reply*, like some other request/reply pairs, have the same basic format—the host creates the request with all fields filled in except the subnet mask value itself, and the router supplies the mask and sends the reply back to the host. The format is described in [Table 101](#) and [Figure 150](#).

**Table 101: ICMPv4 Address Mask Request and Address Mask Reply Message Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMP message type. For <i>Address Mask Request</i> messages the value is 17; for <i>Address Mask Reply</i> messages, it is 18.
<b>Code</b>	1	<b>Code:</b> Not used for either message type; set to 0.
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .
<b>Identifier</b>	2	<b>Identifier:</b> An identification field that can be used to help in matching <i>Address Mask Request</i> and <i>Address Mask Reply</i> messages.
<b>Sequence Number</b>	2	<b>Sequence Number:</b> A sequence number to help in matching <i>Address Mask Request</i> and <i>Address Mask Reply</i> messages.
<b>Address Mask</b>	4	<b>Address Mask:</b> The subnet mask for the local network, filled in by the router in the <i>Address Mask Reply</i> message.

The *Identifier* and *Sequence Number* fields can be used to match up requests and replies, as they are for *Echo* and *Echo Reply* messages. However, a host won't normally send multiple requests for subnet masks the way it might send *Echo* messages for testing. For this reason, the *Identifier* and *Sequence Number* fields may be ignored by some implementations.

**Figure 150: ICMPv4 Address Mask Request and Address Mask Reply Message Format**

---

## ***Use of Address Mask Request and Address Mask Reply Messages***

The use of *Address Mask Request* and *Address Mask Reply* messages is optional, just as the router discovery described in the previous topic is. Other methods besides these messages or manual configuration may be used to tell a host what subnet mask to use. Again, a common alternative to ICMP for this is a host configuration protocol like the TCP/IP [Dynamic Host Configuration Protocol \(DHCP\)](#). Routers do have to be able to respond to *Address Mask Requests* for hosts that choose to send them.

## **ICMPv4 Traceroute Messages**

The *Echo* and *Echo Reply* messages we explored [earlier in this section](#) are used for the most basic type of test that can be conducted between two devices: checking if they can communicate. A more sophisticated test can also be performed, to see not just if the devices are able to talk, but discover the exact sequence of routers used to move datagrams between them. In TCP/IP this diagnostic is performed using the [traceroute \(or tracert\) utility](#).

The first implementation of *traceroute* used a clever application of [Time Exceeded error messages](#). By sending a test message to a destination first with a *Time To Live* value of 1, then 2, then 3 and so on, each router in the path between the source and destination would successively discard the test messages and send back a *Time Exceeded* message, displaying the sequence of routers between the two hosts. This bit of “trickery” works well enough in general terms, but is suboptimal in a couple of respects. For example, it requires the source device to send one test message for each router in the path, instead of just a single test message. It also doesn't take into account the possibility that the path between two devices may change during the test.

Recognizing these limitations, a new experimental standard was developed in 1993 that defined a more efficient way to conduct a *traceroute*: RFC 1393, [Traceroute Using an IP Option](#). As the title suggests, this method of doing a *traceroute* works by having the source device send a single datagram to the destination, containing a special *Traceroute* IP option. Each router that sees that option as the test message is conducted along the route, responds back to the original source with an ICMP *Traceroute* message, also defined in RFC 1393.

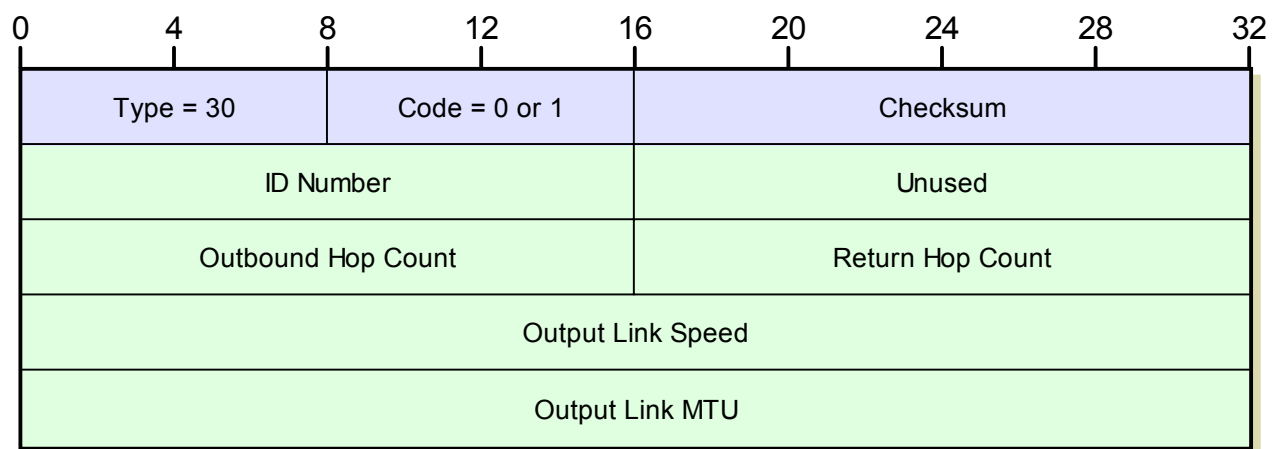

---

## ICMPv4 Traceroute Message Format

Since the *Traceroute* message was specifically designed for the *traceroute* utility, it was possible to incorporate into it extra information of use to a host tracing a route. The message format is as shown in [Table 102](#) and [Figure 151](#).

**Table 102: ICMPv4 Traceroute Message Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMP message type, in this case 30.
<b>Code</b>	1	<b>Code:</b> Set to the value 0 if the datagram the source device sent was successfully sent to the next router, or 1 to indicate that the datagram was dropped (meaning the traceroute failed).
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .
<b>ID Number</b>	2	<b>ID Number:</b> An identification field used to match up this <i>Traceroute</i> message to the original message sent by the source (the one containing the <i>Traceroute</i> IP option).
<b>Unused</b>	2	<b>Unused:</b> Not used, set to 0.
<b>Outbound Hop Count</b>	2	<b>Outbound Hop Count:</b> The number of routers the original message has already passed through.
<b>Return Hop Count</b>	2	<b>Return Hop Count:</b> The number of routers the return message has passed through.
<b>Output Link Speed</b>	4	<b>Output Link Speed:</b> The speed of the link over which the <i>Traceroute</i> message is being sent, in bytes per second.
<b>Output Link MTU</b>	4	<b>Output Link MTU:</b> The <a href="#">Maximum Transmission Unit (MTU)</a> of the link over which the <i>Traceroute</i> message is being sent, in bytes.

**Figure 151: ICMPv4 Traceroute Message Format**

---

## Why Traceroute Messages Are Not Widely Used

Note that while this method of implementing *traceroute* indeed has advantages over the older *Time Exceeded* method, it has one critical flaw as well: it requires changes to both hosts and routers to support the new IP option and the *Traceroute* ICMP message. People aren't big on change, especially when it comes to the basic operation of IP. For this reason, RFC 1393 never moved beyond “experimental” status, and most IP devices still use the older method of implementing *traceroute*. It is possible that you may encounter ICMP *Traceroute* messages, however, so it's good to know they exist.

**Key Concept:** ICMP *Traceroute* messages were designed to provide a more capable way of implementing the traceroute (tracert) utility. However, most TCP/IP implementations still use ICMP *Time Exceeded* messages for this task.

---

---

## **ICMP Version 6 (ICMPv6) Error Message Types and Formats**

The original ICMP defines for version 4 of the Internet Protocol (IPv4) a number of error messages to allow communication of problems on an internetwork. When IP version 6 (IPv6) was developed, the differences between IPv4 and IPv6 were significant enough that a new version of ICMP was also required: the *Internet Control Message Protocol (ICMPv6) for the Internet Protocol Version 6 (IPv6)*, currently specified in RFC 2463. Like ICMPv4, ICMPv6 defines several error messages that let a source be informed when something goes wrong.

In this section I describe the four ICMPv6 error messages defined in RFC 2463. I first discuss ICMPv6 *Destination Unreachable* messages, used to tell a device a datagram it sent could not be delivered for a variety of reasons. I describe *Packet Too Big* error messages, which are sent when a datagram can't be sent due to being too large for an underlying network it needs to traverse. I explain the use of *Time Exceeded* messages, which indicate that too much time was taken to accomplish a transmission. I conclude with a look at messages, which provide a generalized way of reporting errors not described by any of the preceding ICMPv6 error message types.

**Note:** Three of the four ICMPv6 error messages (all except *Packet Too Big*) are equivalent to the [ICMPv4 error messages](#) that have the same names. However, to allow this section to stand on its own, I describe each one fully, in addition to pointing out any significant differences between the ICMPv4 and ICMPv6 version of the message.

---

### **ICMPv6 Destination Unreachable Messages**

Version 6 of the Internet Protocol (IPv6) includes some important enhancements over the older version 4, but the basic operation of the two protocols is still fundamentally the same. Like IPv4, IPv6 is an unreliable network protocol that makes a “best effort” to deliver datagrams, but offers no guarantees that they will always get there. Just as was the case in IPv4, devices on an IPv6 network must not assume that datagrams sent to a destination will always be received.

When a datagram cannot be delivered, recovery from this condition normally falls to higher-layer protocols like TCP, which will detect the miscommunication and re-send the lost datagrams. In some situations, such as a datagram dropped due to congestion of a router, this is sufficient, but in other cases a datagram may not be delivered due to an inherent problem with how it is being sent. For example, the source may have specified an invalid destination address, which means even if resent many times, the datagram will never get to its intended recipient.

In general, having the source just re-send undelivered datagrams while having no idea why they were lost is inefficient. It is better to have a feedback mechanism that can tell a source device about undeliverable datagrams and provide some information about why the

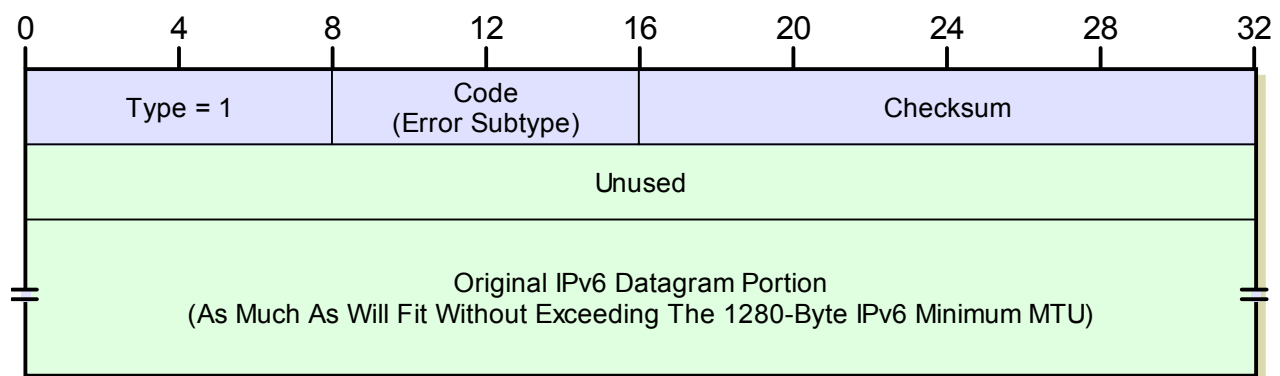

datagram delivery failed. As in ICMPv4, in ICMPv6 this is done with *Destination Unreachable* messages. Each message includes a code that indicates the basic nature of the problem that caused the datagram not to be delivered, and includes all or part of the datagram that was undelivered, to help the source device diagnose the problem.

### ICMPv6 Destination Unreachable Message Format

Table 103 and Figure 152 illustrate the specific format for ICMPv6 *Destination Unreachable* messages:

**Table 103: ICMPv6 Destination Unreachable Message Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMPv6 message type; for <i>Destination Unreachable</i> messages this is set to 1.
<b>Code</b>	1	<b>Code:</b> Identifies the “subtype” of unreachable error being communicated. See Table 104 for a full list of codes and what they mean.
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in the topic on the ICMP common message format.
<b>Unused</b>	4	<b>Unused:</b> 4 bytes that are left blank and not used.
<b>Original Datagram Portion</b>	Variable	<b>Original Datagram Portion:</b> As much of the IPv6 datagram as will fit without causing the size of the ICMPv6 error message (including its own IP header) to exceed the minimum IPv6 maximum transmission unit (MTU) of 1280 bytes.

**Figure 152: ICMPv6 Destination Unreachable Message Format**

### ICMPv6 Destination Unreachable Message Subtypes

There are a number of different reasons why a destination may be unreachable. To provide additional information about the nature of the problem to the device that originally tried to send the datagram, a value is placed in the message's *Code* field. One interesting difference between ICMPv4 and ICMPv6 *Destination Unreachable* messages is that there

---

are many fewer *Code* values for ICMPv6. The ICMPv6 *Code* values were “streamlined”, mainly because several of the ICMPv4 codes were related to relatively obscure features that aren’t applicable to ICMPv6.

Table 104 shows the different *Code* values, corresponding message subtypes and a brief explanation of each:

**Table 104: ICMPv6 *Destination Unreachable* Message Subtypes**

Code Value	Message Subtype	Description
0	<i>No Route To Destination</i>	The datagram was not delivered because it could not be routed to the destination. Since this means the datagram could not be sent to the destination device’s local network, this is basically equivalent to the “Network Unreachable” message subtype in ICMPv4.
1	<i>Communication With Destination Administratively Prohibited</i>	The datagram could not be forwarded due to filtering that blocks the message based on its contents. Equivalent to the message subtype with the same name (and <i>Code</i> value 13) in ICMPv4.
3	<i>Address Unreachable</i>	There was a problem attempting to deliver the datagram to the host specified in the destination address. This code is equivalent to the ICMPv4 “Host Unreachable” code and usually means the destination address was bad or there was a problem with resolving it into a layer two address.
4	<i>Port Unreachable</i>	The destination port specified in the UDP or TCP header was invalid or does not exist on the destination host.

Note that *Code* value 2 is not used. Also, *Destination Unreachable* messages are only sent when there is a fundamental problem with delivering a particular datagram; they are not sent when a datagram is dropped simply due to congestion of a router.

### ***Processing of Destination Unreachable Messages***

It is up to the recipient of an ICMPv6 *Destination Unreachable* message to decide what to do with it. However, just as the original datagram may not reach its destination, the same is true of the *Destination Unreachable* message itself. Therefore, a device cannot rely on the receipt of one of these error messages to inform it of every delivery problem. This is especially true given that it is possible some unreachable destination problems may not be detectable.

**Key Concept:** ICMPv6 *Destination Unreachable* messages are used in the same manner as the ICMPv4 message of that name: to inform a sending device of a failure to deliver an IP datagram. The message’s *Code* field provides information about the nature of the delivery problem (though the *Code* values are different than they are in ICMPv4.)

---

---

## ICMPv6 Packet Too Big Messages

One of the most interesting changes made to the operation of the Internet Protocol in version 6 is related to the process of datagram fragmentation and reassembly. In IPv4, a host can send a datagram of any size allowed by the IP specification out onto the inter-network. If a router needs to send the datagram over a physical link that has a maximum transmission unit (MTU) size that is too small for the size of the datagram, it will automatically *fragment* the datagram and send the fragments individually so they will fit. The destination device will receive the fragments and reassemble them. I explain the basics behind this in [the section on IPv4 datagram size, MTU, fragmentation and reassembly](#).

**Note:** Recall that “packet” is a synonym for “datagram”. I generally use the latter term, but this message has “packet” in the name and it’s not like I was just going to change it!

---

Even though it is convenient for hosts to be able to rely on routers to automatically fragment messages as needed, it is inefficient for routers to spend time doing this. For this reason, in IPv6 the decision was made to not allow routers to fragment datagrams. This puts the responsibility on each host to ensure that datagrams they send out are small enough to fit over every physical network between itself and any destination. This is done either by using the IPv6 default minimum MTU of 1280, which every physical link must support, or a special *Path MTU Discovery* process for determining the minimum MTU between a pair of devices. Again, the full details are in [the discussion of IPv6 datagram size, MTU, fragmentation and reassembly](#).

If an IPv6 router is not allowed to fragment an IPv6 datagram that is too large to fit on the next physical link over which it must be forwarded, what should the router do with it? The datagram can't be forwarded, so the router has no choice but to discard it. When this happens, the router is required to report this occurrence back to the device that initially sent the datagram, using an ICMPv6 *Packet Too Big* message. The source device will know that it needs to fragment the datagram in order to have it successfully reach its destination.

### ICMPv6 Packet Too Big Message Format

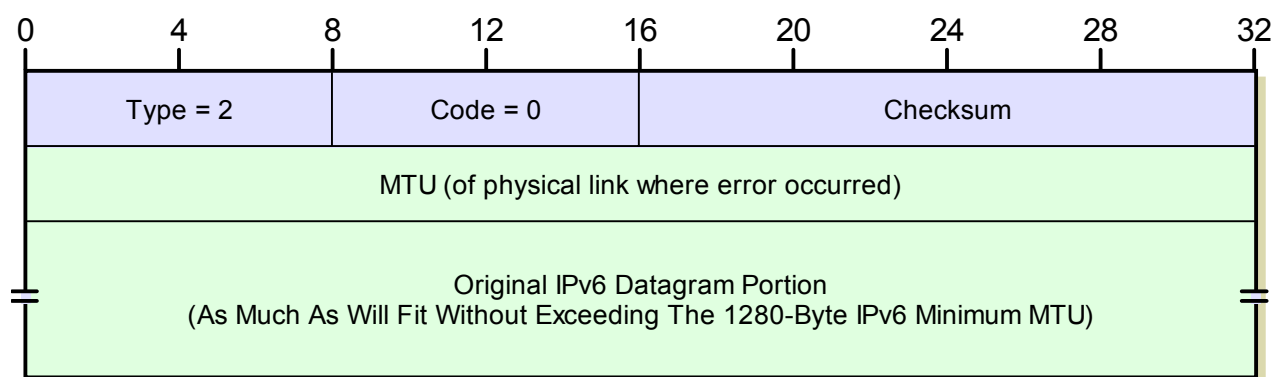

[Table 105](#) and [Figure 153](#) show the format for ICMPv6 *Packet Too Big* messages:

**Table 105: ICMPv6 Packet Too Big Message Format (Page 1 of 2)**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMPv6 message type; for <i>Packet Too Big</i> messages this is set to 2.
<b>Code</b>	1	<b>Code:</b> Not used for this message type; set to 0.
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .

**Table 105: ICMPv6 *Packet Too Big* Message Format (Page 2 of 2)**

Field Name	Size (bytes)	Description
<b>MTU</b>	4	<b>MTU:</b> The maximum transmission unit (MTU) size, in bytes, of the physical link over which the router wanted to send the datagram, but was not able to do so due to the datagram's size. Including this value in the <i>Packet Too Big</i> message tells the source device the size it needs to use for its next transmission to this destination to avoid this problem in the future (at least for this particular link.)
<b>Original Datagram Portion</b>	Variable	<b>Original Datagram Portion:</b> As much of the IPv6 datagram as will fit without causing the size of the ICMPv6 message (including its own IP header) to exceed the minimum IPv6 MTU of 1280 bytes.

**Figure 153: ICMPv6 *Packet Too Big* Message Format**

**Key Concept:** In IPv6, routers are not allowed to fragment datagrams that are too large to send over a physical link to which they are connected. An oversized datagram is dropped, and an ICMPv6 *Packet Too Big* message sent back to the datagram's originator to inform it of this occurrence.

### ***Applications of Packet Too Big Messages***

While *Packet Too Big* is obviously an error message, it also has another use: the implementation of *Path MTU Discovery*. This process, described in RFC 1981, defines a method for a device to determine the minimum MTU for a path to a destination. To perform path MTU discovery, the source device sends a series of test messages, decreasing the size of the datagram until it no longer receives *Packet Too Big* messages back in response to its tests. [See the topic on IPv6 MTU and fragmentation issues for a bit more detail on this.](#)

**Note:** The *Packet Too Big* message is new to ICMPv6. However, its use is somewhat similar to the use of the *Fragmentation Needed and DF Set* version of the [ICMP4 Destination Unreachable](#) message type, which is used as part of IPv4's path MTU discovery feature.

---

Incidentally, *Packet Too Big* is an exception to [the rule that ICMP messages are sent only in response to unicast datagrams](#); it may be sent in reply to an oversized multicast datagram. If this occurs, it is important to realize that some of the intended targets of the multicast may still have received it, if the path the multicast took to them did not go through the link with the small MTU that caused the error.

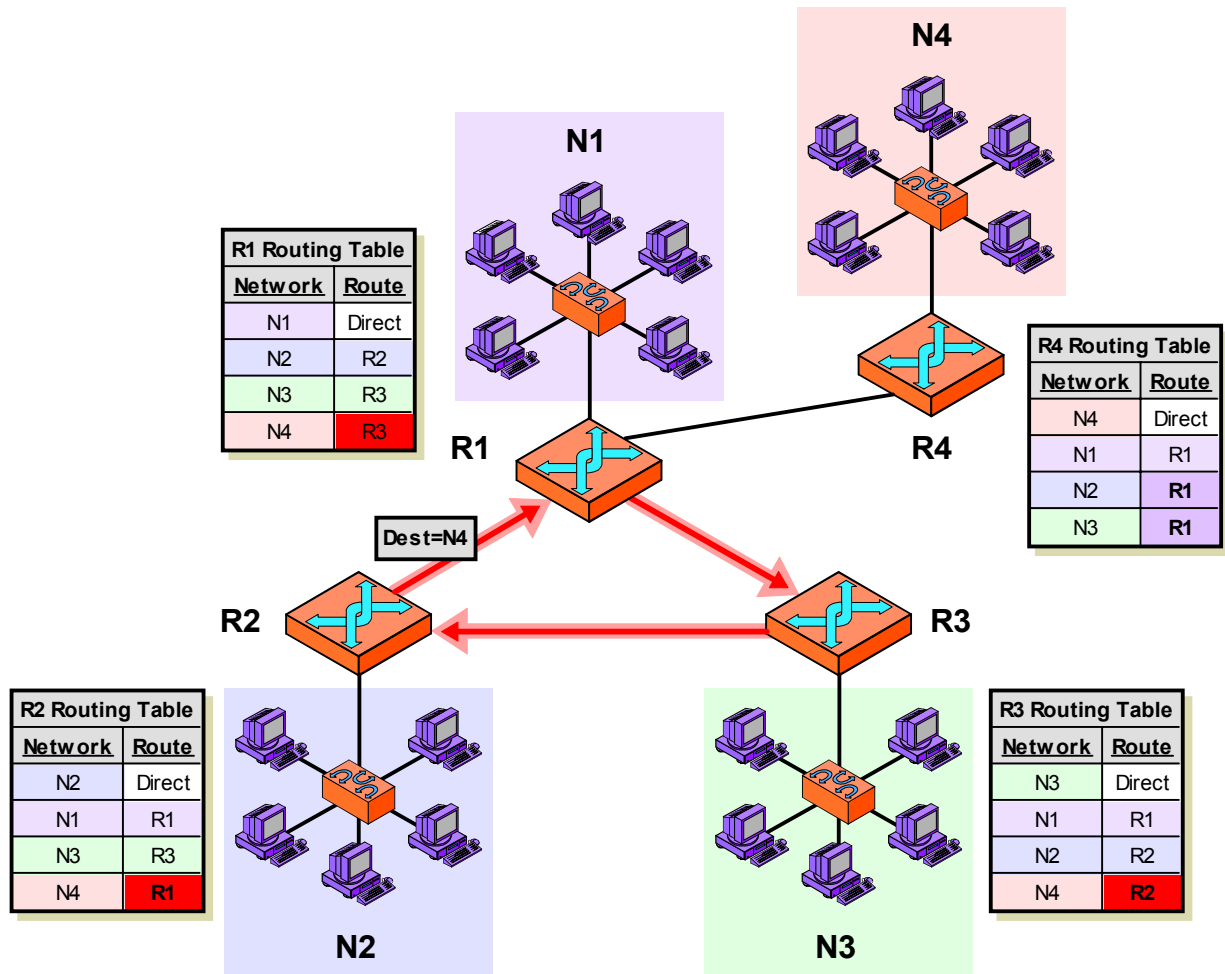

## **ICMPv6 Time Exceeded Messages**

The engineers who first designed the Internet Protocol recognized that due to the nature of how routing works on an internetwork, there was always a danger that a datagram might get “lost in the system” and spend too much time being passed from one router to another. They included in IPv4 datagrams a field called *Time To Live*, which was intended to be set to a time value by the device sending the datagram, and used as a timer to cause the discard of the datagram if it took too long to get it to its destination.

Eventually, the meaning of this field changed so it was used not as a time in seconds but a number of hops through which the datagram was allowed to be sent. In IPv6, the new meaning of this field was formalized when it was renamed *Hop Limit*. Regardless of name, the field still has the same basic purpose: it restricts how long a datagram can exist on an internetwork by limiting the number of times routers can forward it. This is particularly designed to provide protection against *router loops* that may occur in large or improperly-configured internetworks. An example of this situation is where Router *A* thinks datagrams intended for network *X* should next go to Router *B*; *B* thinks they should go to Router *C*; and *C* thinks they need to go to *A*. Without a *Hop Limit*, such datagrams would circle forever, clogging networks and never accomplishing anything useful, as shown in [Figure 154](#).

Each time a router passes an IPv6 datagram, it decreases the *Hop Limit* field. If the value ever reaches zero, the datagram *expires* and is discarded. When this happens, the router that dropped the datagram sends an ICMPv6 *Time Exceeded* message back to the datagram's originator to inform it that the datagram was dropped. This is basically the same as the ICMPv4 Time Exceeded message. As in the ICMPv4 case, the device receiving the message must decide whether and how to respond to receipt of the message. For example, since the error can be caused by a device using a *Hop Limit* that was too low, the device may try to re-send the datagram with a higher value before concluding that there is a routing problem and giving up. ([See the topic covering the ICMPv4 Time Exceeded message for an illustration of how TTL expiration works.](#))

Just as with the ICMPv4 equivalent, there is also another “time expiration” situation that ICMPv6 *Time Exceeded* messages are used for. When an IP message is broken into fragments that are sent independently, the destination device is charged with reassembling

**Figure 154: An Example of A Router Loop**

This diagram shows a simple internetwork consisting of four networks, each of which is served by a router. It is an adaptation of [Figure 93](#), but in this case the routing tables have been set up incorrectly. *R1* thinks that it needs to route any traffic intended for network *N4* to *R3*; *R3* thinks it goes to *R2*; and *R2* thinks it goes back to *R1*. This means that when any device tries to send to *N4*, the datagram will circle this “triangle” until its *Hop Limit* is reached, at which point an ICMPv6 *Time Exceeded* message will be generated.

the fragments into the original message. One or more fragments may not make it to the destination, however. To prevent the device from waiting forever, it sets a timer when the first fragment arrives. If this timer expires before all of the other fragments are also received, the device gives up on this message. The fragments are tossed out, and a *Time Exceeded* message is also generated.

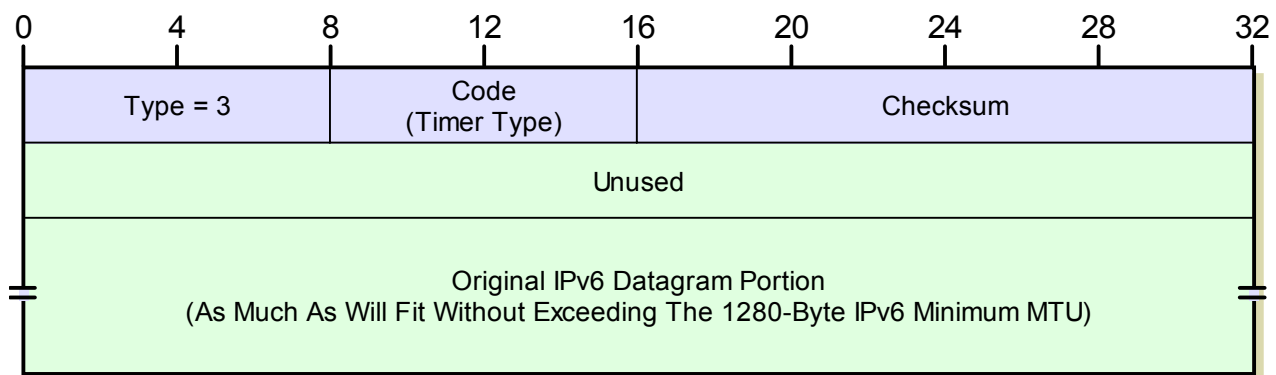

---

## ICMPv6 Time Exceeded Message Format

The format for ICMPv6 *Time Exceeded* messages can be found in [Table 106](#) and [Figure 155](#).

**Table 106: ICMPv6 *Time Exceeded* Message Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMPv6 message type; for <i>Time Exceeded</i> messages this is set to 3.
<b>Code</b>	1	<b>Code:</b> Identifies the “subtype” of time error being communicated. A value of 0 indicates expiration of the <i>Hop Limit</i> field; a value of 1 indicates that the fragment reassembly time has been exceeded.
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .
<b>Unused</b>	4	<b>Unused:</b> 4 bytes left blank and not used.
<b>Original Datagram Portion</b>	Variable	<b>Original Datagram Portion:</b> As much of the IPv6 datagram as will fit without causing the size of the ICMPv6 error message (including its own IP header) to exceed the minimum IPv6 maximum transmission unit (MTU) of 1280 bytes.

**Figure 155: ICMPv6 *Time Exceeded* Message Format**

**Key Concept:** Like their ICMPv4 namesakes, ICMPv6 *Time Exceeded* messages are sent in two different “time-related” circumstances. The first is if a datagram’s *Hop Limit* field is reduced to zero, causing it to expire and the datagram to be dropped. The second is when all the pieces of a fragmented message are not received before the recipient’s reassembly timer expires.

---

---

## ***Applications of Time Exceeded Messages***

In IPv4, ICMP *Time Exceeded* messages are used both as an error message and in a clever application to implement the TCP/IP *traceroute* command. This is done by first sending a “dummy” datagram with a *Time To Live* value of 1, causing the first hop in the route to discard the datagram and send back an ICMP *Time Exceeded*. Then, a second datagram is sent to the same destination with a *TTL* value of 2, causing the second device in the route to report back a *Time Exceeded*, and so on.

There is of course an IPv6 version of *traceroute*, sometimes called *traceroute6*. Due to IPv6 and its protocols and applications still being in development, I have not been able to confirm definitively that *traceroute6* is implemented using ICMPv6 *Time Exceeded* messages in the manner described above, but I believe this is the case (and it certainly would make sense.) [See the topic discussing traceroute for further information.](#)

## **ICMPv6 Parameter Problem Messages**

The ICMPv6 *Destination Unreachable*, *Packet Too Big* and *Time Exceeded* messages described in the previous topics in this section are used to indicate specific error conditions to the original sender of a datagram. Recognizing that a router or host may encounter some other problem in processing a datagram that is not covered by any of these message types, ICMPv6 includes a generic error message type, just as ICMPv4 did. This is called the ICMPv6 *Parameter Problem* message.

As the name suggests, a *Parameter Problem* message indicates that a device found a problem with a parameter (another name for a datagram field) while attempting to work its way through the header (or headers) in an IPv6 datagram. This message is only generated when the error encountered is serious enough that the device could not make sense of the datagram and had to discard it. That is, if an error is found that a device is able to recover from and not drop the datagram, no *Parameter Problem* message is created.

As was the case for [the ICMPv4 version of this message](#), the ICMPv6 message was designed to be generic, so it can indicate an error in basically any field in the original datagram. A special *Pointer* field is used that points to the place in that datagram where the error was encountered. By looking at the structure of the original message (which as you may recall is included, up to a certain size, in the ICMP message format) the original device can tell which field contained the problem. The *Code* value is also used to communicate additional general information about the nature of the problem.

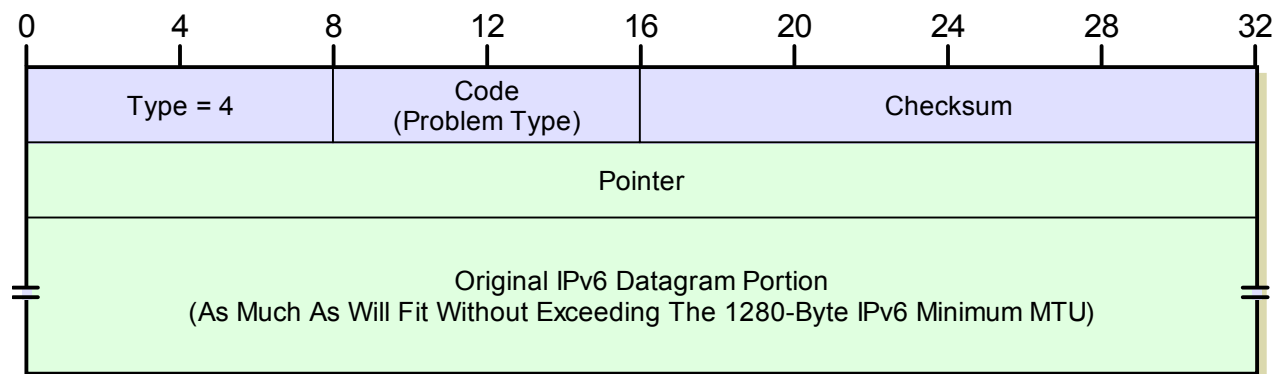

---

## ICMPv6 Parameter Problem Message Format

Table 107 and Figure 156 show the format for ICMPv4 *Parameter Problem* messages:

**Table 107: ICMPv6 *Parameter Problem* Message Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMPv6 message type; for <i>Parameter Problem</i> messages this is set to 4.
<b>Code</b>	1	<b>Code:</b> Identifies the general class of the parameter problem. See <a href="#">Table 108</a> for more information.
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .
<b>Pointer</b>	4	<b>Pointer:</b> An offset that points to the byte location in the original datagram that caused the <i>Parameter Problem</i> message to be generated. The device receiving the ICMP message can use this value to get an idea of which field in the original message had the problem.
<b>Original Datagram Portion</b>	Variable	<b>Original Datagram Portion:</b> As much of the IPv6 datagram as will fit without causing the size of the ICMPv6 error message (including its own IP header) to exceed the minimum IPv6 maximum transmission unit (MTU) of 1280 bytes.

**Figure 156: ICMPv6 *Parameter Problem* Message Format**

### ***Parameter Problem Message Interpretation Codes and The Pointer Field***

The *Pointer* field, which was only 8 bits wide in ICMPv4, has been widened to 32 bits in ICMPv6, to provide more flexibility in isolating the error. The *Code* value is also used somewhat differently in ICMPv6 than it was in the ICMPv4 version of this message type. In ICMPv4, the *Pointer* was used only when the *Code* field was 0, and other code values indicated other problem categories for which the *Pointer* field did not make sense. In ICMPv6, the *Pointer* field is used with all *Code types*, to indicate the general nature of what the problem is. This means the *Pointer* field tells the recipient of the *Parameter Problem*

---

where in the message the problem happened, and the *Code* field tells it what the nature of the problem is. The following table shows the three *Code* values and provides a brief explanation of each:

**Table 108: ICMPv6 *Parameter Problem* Message Interpretation Codes**

Code Value	Message Subtype	Description
0	Erroneous Header Field Encountered	The <i>Pointer</i> field points to a header that contains an error or otherwise could not be processed.
1	Unrecognized Next Header Type Encountered	Recall that in IPv6 <a href="#">a datagram can have multiple headers</a> , each of which contains a <i>Next Header</i> field that points to the next header in the datagram. This code indicates that the <i>Pointer</i> field points to a <i>Next Header</i> field containing an unrecognized value.
2	Unrecognized IPv6 Option Encountered	The <i>Pointer</i> field points to an <a href="#">IPv6 option</a> that was not recognized by the processing device.

**Key Concept:** The ICMPv6 *Parameter Problem* message is a generic error message that can be used to convey an error of any type in an IP datagram. The *Pointer* field is used to indicate to the recipient of the message where the problem was in the original datagram.

---

---

## **ICMP Version 6 (ICMPv6) Informational Message Types and Formats**

In the previous section we explored a number of ICMPv6 error messages, which are sent back to the originator of an IPv6 datagram when an error is detected in it that makes it impossible to be delivered. Just as was the case with the original version of ICMP (ICMPv4), ICMPv6 also defines another class of message: *informational* messages. These ICMPv6 messages are used not to report errors, but to allow the sharing of information required to implement various test, diagnostic and support functions critical to the operation of IPv6.

In this section I describe eight different ICMPv6 informational messages in five topics (six of these messages are used in matching pairs, and the pairs are described together). I begin by describing ICMPv6 *Echo Request* and *Echo Reply* messages, used for network connectivity testing. I explain the format of *Router Advertisement* and *Router Solicitation* messages, used to let hosts discover local routers and learn necessary parameters from them. I then describe ICMPv6 *Neighbor Advertisement* and *Neighbor Solicitation* messages, used for various communications between hosts on a local network, including IPv6 address resolution. I discuss IPv6 *Redirect* messages, which let routers inform hosts of better first-hop routers, and IPv6 *Router Renumbering* messages.

Several of the ICMPv6 informational messages include additional information that is either optional, recommended or mandatory, depending on the circumstances under which the message is generated. Some of these are shared between message types, so they are described in a separate topic at the end of the section.

In IPv4, the use of many of the ICMP informational messages was described in a variety of different standards. In IPv6, many of the functions using informational messages have been gathered together and formalized in the IPv6 *Neighbor Discovery (ND)* Protocol. The solicitation and advertisement of local routers and neighboring hosts, as well as communication of redirection information are both examples of activities for which ND is responsible. In fact, five of the ICMP messages described in this section are actually defined in the Neighbor Discovery standard, RFC 2461.

ND and ICMPv6 are obviously closely related, given that ND describes the use of several of the ICMP messages: *Router Advertisement*, *Router Solicitation*, *Neighbor Advertisement*, *Neighbor Solicitation* and *Redirect*. Thus, just as ICMPv4 is an important “assistant” to IPv4, both ICMPv6 and ND are important helpers for IPv6. In this Guide, I provide most of the description of how these messages are used in [the detailed section on ND](#). In this section, I provide only a brief summary of their use, while focusing primarily on message format and the meaning of each of the fields in that format.

**Note:** In ICMPv6, the *Redirect* message is informational, and no longer considered an error message [as it was in ICMPv4](#).

---

---

## ICMPv6 Echo Request and Echo Reply Messages

IP is a relatively simple protocol that does not itself include any method for performing tests between devices to help in diagnosing internetwork problems. This means that this job, like other support tasks, falls to ICMP. The simplest test performed when there is a problem using TCP/IP is usually a check that a pair of devices is able to send datagrams to each other. This is most often done by an initiating device sending a test message to a second device, which receives it and replies back to tell the first device it received the message.

Like ICMPv4, ICMPv6 includes a pair of messages specifically for connection testing. To use them, Device A begins the test process by sending an ICMPv4 *Echo Request* message to Device B. Device B responds back to Device A with an *Echo Reply* message. When Device A receives this message, it knows that it is able to communicate (both send and receive) successfully with Device B.

**Note:** As a side note, in ICMPv4, the first message type was named just *Echo* but was often called *Echo Request* instead. In ICMPv6 they finally just added the “Request” to the message name and were done with it. A modest but useful improvement from a clarity standpoint.

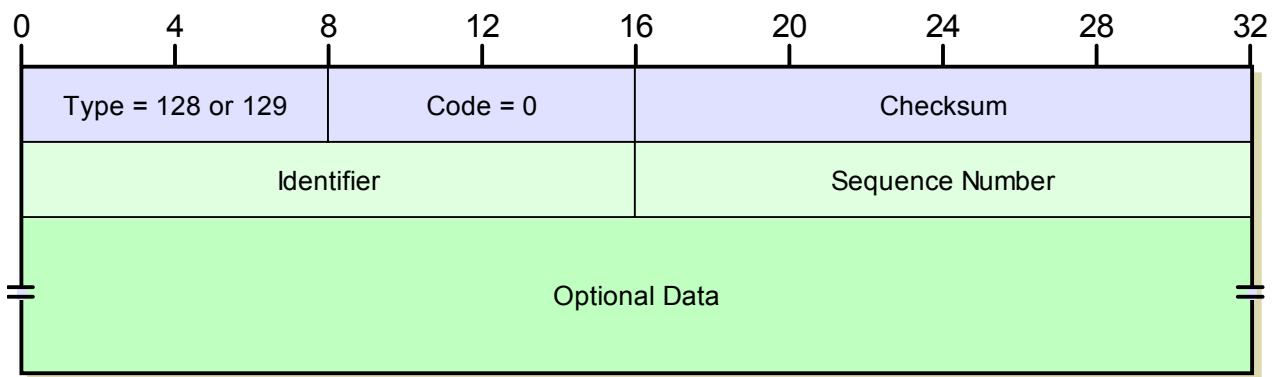

---

### ICMPv6 Echo and Echo Reply Message Format

The format for ICMPv6 *Echo Request* and *Echo Reply* messages is very similar to that of the ICMPv4 version, as shown in [Table 109](#) and [Figure 157](#).

**Table 109: ICMPv6 Echo Request and Echo Reply Message Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMPv6 message type; for <i>Echo Request</i> messages the value is 128, and for <i>Echo Reply</i> messages 129. (Recall that in ICMPv6, informational messages always have a <i>Type</i> value of 128 or higher.)
<b>Code</b>	1	<b>Code:</b> Not used; set to 0.
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .
<b>Identifier</b>	2	<b>Identifier:</b> An optional identification field that can be used to help in matching <i>Echo Request</i> and <i>Echo Reply</i> messages.
<b>Sequence Number</b>	2	<b>Sequence Number:</b> A sequence number to help in matching <i>Echo Request</i> and <i>Echo Reply</i> messages.
<b>Optional Data</b>	Variable	<b>Optional Data:</b> Additional optional data to be sent along with the message. If this is sent in the <i>Echo Request</i> it is copied into the <i>Echo Reply</i> to be sent back to the source.

**Figure 157: ICMPv6 Echo Request and Echo Reply Message Format**

As with ICMPv4, it is often necessary to match an *Echo Reply* message with the *Echo Request* message that led to it being generated. Two special fields are used within the format of these messages to allow *Echo Request* and *Echo Reply* messages to be matched together, and to allow a sequence of messages to be exchanged. The *Identifier* field is provided so a particular test session can be identified, and the *Sequence Number* field allows a series of tests in a session to be numbered. The use of both fields is optional.

### **Application of Echo and Echo Reply Messages**

ICMPv6 *Echo Request* and *Echo Reply* messages are used via the IPv6 version of the IP *ping* utility, commonly called *ping6*. Like its IPv4 predecessor this utility allows an administrator to configure a number of test options to perform either a simple or rigorous test of the connection between a pair of devices. See the topic describing *ping* for a full explanation.

**Key Concept:** ICMPv6 *Echo Request* and *Echo Reply* messages are used to facilitate network reachability testing. A device tests its ability to communicate with another by sending it an *Echo Request* message and waiting for an *Echo Reply* in response. The *ping* utility, a widely-used diagnostic tool in TCP/IP internetworks, makes use of these messages.

### **ICMPv6 Router Advertisement and Router Solicitation Messages**

At the highest level, we can separate IP devices into two groups: hosts and routers. Both participate in the use of the internetwork, but they have different roles. An important IP principle related to this division is that routers take care of routing—moving data between networks—while hosts generally don't need to worry about this job. Hosts rely on the routers on their local networks to facilitate communication to all other hosts except those on the local network.

---

The implications of this are clear: a host cannot really use an internetwork until it knows the identity of at least one local router, and the method by which that router is to be used. In IPv4, a technique known as *router discovery* was invented, which provides a means by which a host can locate a router and learn important parameters related to the operation of the local network.

Router discovery in IPv6 works in a very similar manner, by having routers send *Router Advertisement* messages both on a regular basis and in response to hosts prompting for them using *Router Solicitation* messages. The router discovery function has been incorporated into the *Neighbor Discovery (ND)* protocol, where it is part of a larger class of tools that I call [host-router discovery functions](#).

### **ICMPv6 Router Advertisement Message Format**

The formats of the ICMPv6 *Router Advertisement* and *Router Solicitation* messages are fairly similar to [their counterparts in ICMPv4](#). The main differences are in the parameters that are communicated. Since routers are responsible for a few more functions in IPv6 than they are in IPv4, the *Router Advertisement* message in ICMPv6 has a few more fields than the older version.

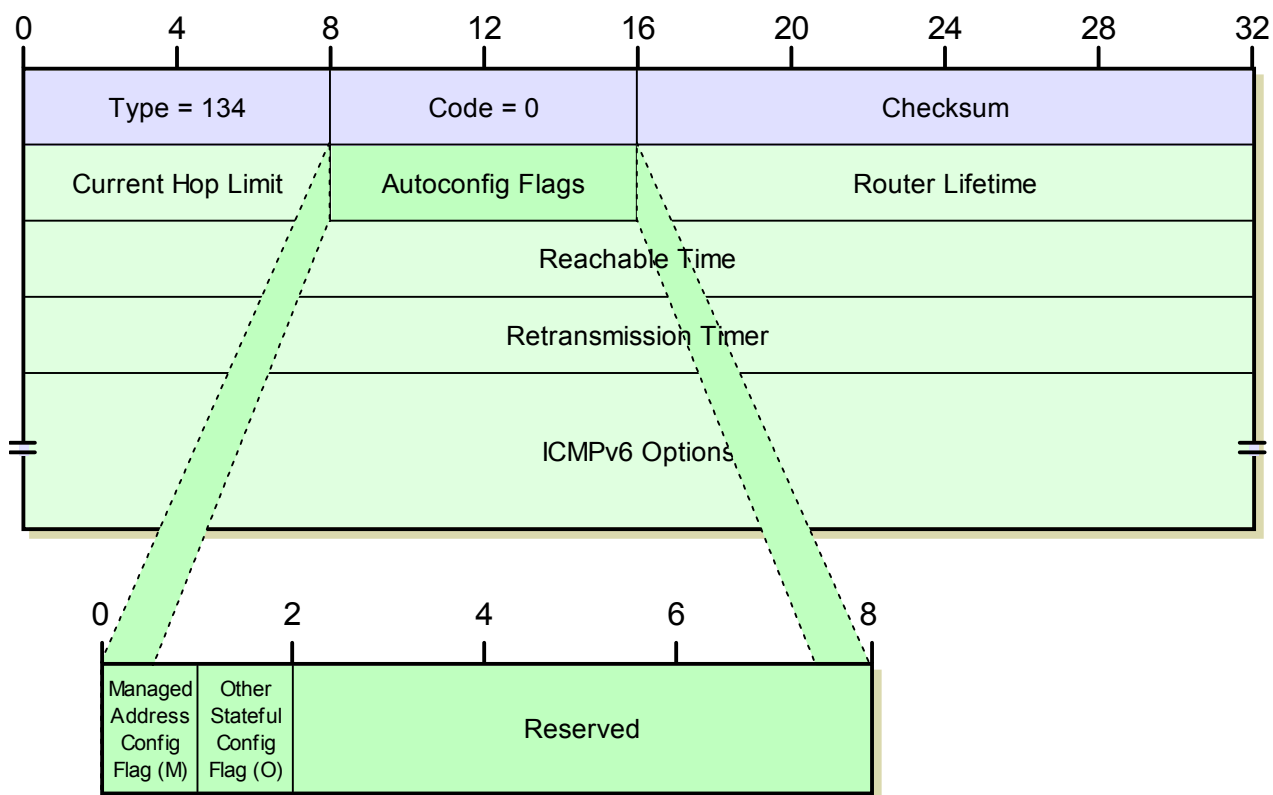

The format of an ICMPv6 *Router Advertisement* message is described in [Table 110](#) and shown in [Figure 158](#).

**Table 110: ICMPv6 Router Advertisement Message Format (Page 1 of 2)**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMPv6 message type; for <i>Router Advertisement</i> messages the value is 134.
<b>Code</b>	1	<b>Code:</b> Not used; set to 0.
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .
<b>Cur Hop Limit</b>	1	<b>Current Hop Limit:</b> This is a default value the router is telling hosts on the local network they should put in the <i>Hop Limit</i> field of datagrams they send. If 0, the router is not recommending a <i>Hop Limit</i> value in this <i>Router Advertisement</i> .

**Table 110: ICMPv6 Router Advertisement Message Format (Page 2 of 2)**

Field Name	Size (bytes)	Description												
<b>Autoconfig Flags</b>	1	<p><b>Autoconfiguration Flags:</b> Two flags that let the router tell the host how autoconfiguration is performed on the local network. <a href="#">See the topic on IPv6 autoconfiguration for more details:</a></p> <table> <tr> <th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr> <tr> <td><b>M</b></td><td>1/8 (1 bit)</td><td><b>Managed Address Configuration Flag:</b> When set, this flag tells hosts to use an administered or “stateful” method for address autoconfiguration, such as <a href="#">DHCP</a>.</td></tr> <tr> <td><b>O</b></td><td>1/8 (1 bit)</td><td><b>Other Stateful Configuration Flag:</b> When set, tells hosts to use an administered or “stateful” autoconfiguration method for information other than addresses.</td></tr> <tr> <td><b>Reserved</b></td><td>6/8 (6 bits)</td><td><b>Reserved:</b> Reserved for future use; sent as zeroes.</td></tr> </table>	Subfield Name	Size (bytes)	Description	<b>M</b>	1/8 (1 bit)	<b>Managed Address Configuration Flag:</b> When set, this flag tells hosts to use an administered or “stateful” method for address autoconfiguration, such as <a href="#">DHCP</a> .	<b>O</b>	1/8 (1 bit)	<b>Other Stateful Configuration Flag:</b> When set, tells hosts to use an administered or “stateful” autoconfiguration method for information other than addresses.	<b>Reserved</b>	6/8 (6 bits)	<b>Reserved:</b> Reserved for future use; sent as zeroes.
Subfield Name	Size (bytes)	Description												
<b>M</b>	1/8 (1 bit)	<b>Managed Address Configuration Flag:</b> When set, this flag tells hosts to use an administered or “stateful” method for address autoconfiguration, such as <a href="#">DHCP</a> .												
<b>O</b>	1/8 (1 bit)	<b>Other Stateful Configuration Flag:</b> When set, tells hosts to use an administered or “stateful” autoconfiguration method for information other than addresses.												
<b>Reserved</b>	6/8 (6 bits)	<b>Reserved:</b> Reserved for future use; sent as zeroes.												
<b>Router Lifetime</b>	2	<p><b>Router Lifetime:</b> Tells the host receiving this message how long, in seconds, this router should be used as a default router. If 0, tells the host this router should not be used as a default router.</p> <p>Note that this is an expiration interval only for the status of the router as a default, not for other information in the <i>Router Advertisement</i> message.</p>												
<b>Reachable Time</b>	4	<p><b>Reachable Time:</b> Tells hosts how long, in milliseconds, they should consider a neighbor to be reachable after they have received reachability confirmation. <a href="#">See the Neighbor Discovery topic discussing neighbor unreachability detection for more.</a></p>												
<b>Retrans Timer</b>	4	<p><b>Retransmission Timer:</b> The amount of time, in milliseconds, that a host should wait before retransmitting <a href="#">Neighbor Solicitation</a> messages.</p>												
<b>Options</b>	Variable	<p><b>Options:</b> <i>Router Advertisement</i> messages may contain three possible options (<a href="#">see the topic on ICMPv6 options for details</a>):</p> <ul style="list-style-type: none"> <li>➊ <b>Source Link-Layer Address:</b> Included when the router sending the <i>Advertisement</i> knows its link-layer (layer two) address.</li> <li>➋ <b>MTU:</b> Used to tell local hosts the <a href="#">MTU</a> of the local network when this information may not be known by hosts on the network.</li> <li>➌ <b>Prefix Information:</b> Tells local hosts what prefix or prefixes to use for the local network. (Recall that the <a href="#">“prefix” indicates which bits of an IPv6 address are the network identifier</a> compared to the host identifier; it is thus analogous to an IPv4 subnet mask).</li> </ul>												

**Figure 158: ICMPv6 Router Advertisement Message Format**

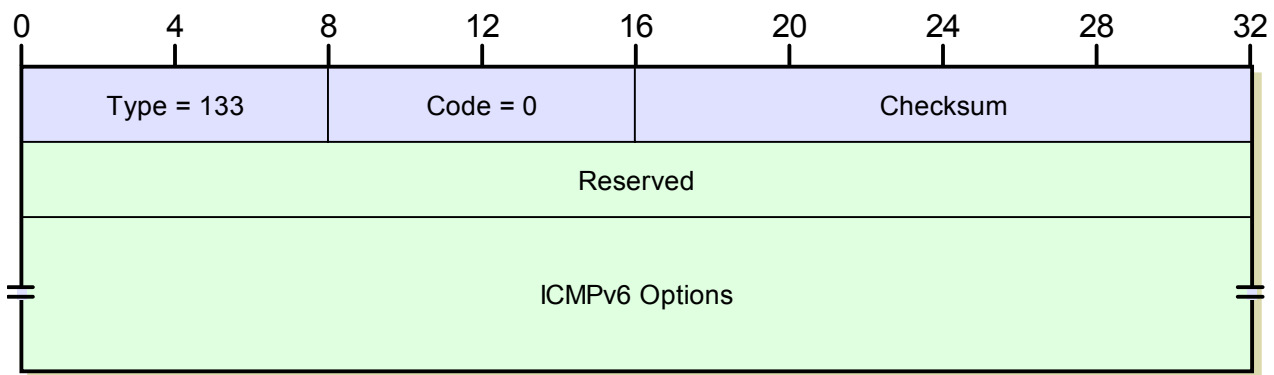

### ICMPv6 Router Solicitation Message Format

The format of an ICMPv6 *Router Solicitation* message is as shown [Table 111](#) and [Figure 159](#).

**Table 111: ICMPv6 Router Solicitation Message Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMPv6 message type; for <i>Router Solicitation</i> messages the value is 133.
<b>Code</b>	1	<b>Code:</b> Not used; set to 0.
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .
<b>Reserved</b>	4	<b>Reserved:</b> 4 reserved bytes set to 0.
<b>Options</b>	Variable	<b>Options:</b> If the device sending the <i>Router Solicitation</i> knows its layer two address, it should be included in a <i>Source Link-Layer Address</i> option. <a href="#">Option formats are described in a separate topic</a> .

**Figure 159: ICMPv6 Router Solicitation Message Format**

### **Addressing of Router Advertisement and Router Solicitation Messages**

*Router Solicitation* messages are normally sent to the IPv6 “all routers” multicast address; this is the most efficient method since routers are required to subscribe to this multicast address while hosts will ignore it. A routine (unsolicited) *Router Advertisement* is sent to all devices using the “all nodes” multicast address for the local network. A *Router Advertisement* that is sent in response to a *Router Solicitation* goes unicast back to the device that sent the solicitation.

**Key Concept:** ICMPv6 *Router Advertisement* messages are sent regularly by IPv6 routers to inform hosts of their presence and characteristics, and to provide hosts with parameters they need to function properly on the local network. A host that wants to find out immediately what routers are present may send a *Router Solicitation*, which will prompt listening routers to send out *Router Advertisements*.

### **ICMPv6 Neighbor Advertisement and Neighbor Solicitation Messages**

The previous topic described the *Router Advertisement* and *Router Solicitation* messages, which are used to facilitate host-router discovery functions as part of the IPv6 Neighbor Discovery (ND) protocol. The other main group of tasks for which ND is responsible relates to the exchange of information between neighboring hosts on the same network. I call these *host-host communication* or *host-host discovery* functions.

Arguably, the most important additions to the Neighbor Discovery protocol are the functions that formalize the exchange of parameters, and the methods for determining the existence of neighboring hosts. These tasks include the new method of address resolution in IPv6, as well the processes of next-hop determination and neighbor unreachability detection. They require the use of two ICMPv6 messages: the *Neighbor Solicitation* message and the *Neighbor Advertisement* message.

The *Neighbor Solicitation* message allows a device to check that a neighbor exists and is reachable, and to initiate address resolution. The *Neighbor Advertisement* message confirms the existence of a host or router, and also provides layer-two address information when needed. As you can see, these two messages are comparable to the *Router Advertisement* and *Router Solicitation* messages, but are used differently and include different parameters.

### ICMPv6 Neighbor Advertisement Message Format

The format for the *Neighbor Advertisement* message is described in [Table 112](#) and [Figure 160](#).

**Table 112: ICMPv6 Neighbor Advertisement Message Format (Page 1 of 2)**

Field Name	Size (bytes)	Description															
Type	1	Type: Identifies the ICMPv6 message type; for Neighbor Advertisement messages the value is 136.															
Code	1	Code: Not used; set to 0.															
Checksum	2	Checksum: 16-bit checksum field for the ICMP header, as described in the topic on the ICMP common message format.															
Flags	4	Flags: Three flags that convey information about the message (and lots of empty space for future use):															
		<table><tr><th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr><tr><td>R</td><td>1/8 (1 bit)</td><td>Router Flag: Set when a router sends a Neighbor Advertisement, and cleared when a host sends one. This identifies the type of device that sent the datagram, and is also used as part of Neighbor Unreachability Detection to detect when a device changes from acting as a router to functioning as a regular host.</td></tr><tr><td>S</td><td>1/8 (1 bit)</td><td>Solicited Flag: When set, indicates that this message was sent in response to a Neighbor Solicitation message. Cleared for unsolicited Neighbor Advertisements.</td></tr><tr><td>O</td><td>1/8 (1 bit)</td><td>Override Flag: When set, tells the recipient that the information in this message should override any existing cached entry for the link-layer address of this device. This bit is normally set in unsolicited Neighbor Advertisements since these are sent when a host needs to force a change of information in the caches of its neighbors.</td></tr><tr><td>Reserved</td><td>3 5/8 (29 bits)</td><td>Reserved: A big whopping set of reserved bits. ☺</td></tr></table>	Subfield Name	Size (bytes)	Description	R	1/8 (1 bit)	Router Flag: Set when a router sends a Neighbor Advertisement, and cleared when a host sends one. This identifies the type of device that sent the datagram, and is also used as part of Neighbor Unreachability Detection to detect when a device changes from acting as a router to functioning as a regular host.	S	1/8 (1 bit)	Solicited Flag: When set, indicates that this message was sent in response to a Neighbor Solicitation message. Cleared for unsolicited Neighbor Advertisements.	O	1/8 (1 bit)	Override Flag: When set, tells the recipient that the information in this message should override any existing cached entry for the link-layer address of this device. This bit is normally set in unsolicited Neighbor Advertisements since these are sent when a host needs to force a change of information in the caches of its neighbors.	Reserved	3 5/8 (29 bits)	Reserved: A big whopping set of reserved bits. ☺
		Subfield Name	Size (bytes)	Description													
		R	1/8 (1 bit)	Router Flag: Set when a router sends a Neighbor Advertisement, and cleared when a host sends one. This identifies the type of device that sent the datagram, and is also used as part of Neighbor Unreachability Detection to detect when a device changes from acting as a router to functioning as a regular host.													
		S	1/8 (1 bit)	Solicited Flag: When set, indicates that this message was sent in response to a Neighbor Solicitation message. Cleared for unsolicited Neighbor Advertisements.													
		O	1/8 (1 bit)	Override Flag: When set, tells the recipient that the information in this message should override any existing cached entry for the link-layer address of this device. This bit is normally set in unsolicited Neighbor Advertisements since these are sent when a host needs to force a change of information in the caches of its neighbors.													
Reserved	3 5/8 (29 bits)	Reserved: A big whopping set of reserved bits. ☺															

**Table 112: ICMPv6 *Neighbor Advertisement* Message Format (Page 2 of 2)**

Field Name	Size (bytes)	Description
<b>Target Address</b>	16	<p><b>Target Address:</b> If the <i>Neighbor Advertisement</i> is being sent in response to a <i>Neighbor Solicitation</i>, this is the same value as in the <i>Target Address</i> field of the <i>Solicitation</i>. This field will commonly contain the IPv6 address of the device sending the <i>Neighbor Advertisement</i>, but not in all cases. For example, if a device responds as a proxy for the target of the <i>Neighbor Solicitation</i>, the <i>Target Address</i> field contains the address of the target, not the device sending the response. <a href="#">See the topic on address resolution proxying for details.</a></p> <p>If the <i>Neighbor Advertisement</i> is being sent unsolicited, then this is the IPv6 address of the device sending it.</p>
<b>Options</b>	Variable	<p><b>Options:</b> When sent in response to a multicast <i>Neighbor Solicitation</i>, a <i>Neighbor Advertisement</i> message must contain a <i>Target Link-Layer Address</i> option, which carries the link-layer address of the device sending the message. This is a good example of an “option” that’s not really “optional”. ☺</p> <p>When the <i>Neighbor Advertisement</i> is sent in response to a unicast <i>Neighbor Solicitation</i>, this option is technically not required (since the sender of the <i>Solicitation</i> must already have the target’s link-layer address to have sent it unicast.) Despite this, it is still normally included, to ensure that the link-layer address of the target is refreshed in the cache of the device that sent the <i>Neighbor Solicitation</i>.</p>

**Figure 160: ICMPv6 Neighbor Advertisement Message Format**

### ICMPv4 Neighbor Solicitation Message Format

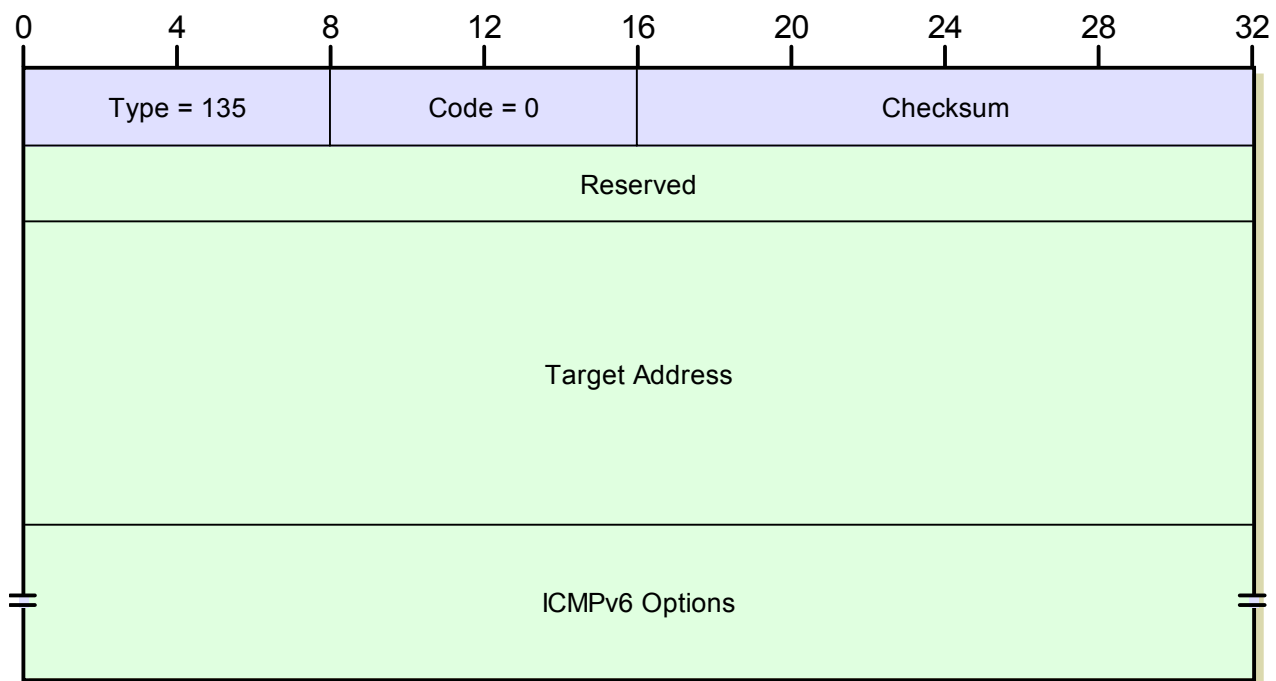

The *Neighbor Solicitation* message format is much simpler, as depicted in [Table 113](#) and [Figure 161](#).

**Table 113: ICMPv6 Neighbor Solicitation Message Format (Page 1 of 2)**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMPv6 message type; for <i>Neighbor Solicitation</i> messages the value is 135.
<b>Code</b>	1	<b>Code:</b> Not used; set to 0.
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .
<b>Reserved</b>	4	<b>Reserved:</b> 4 reserved bytes set to 0.

**Table 113: ICMPv6 *Neighbor Solicitation* Message Format (Page 2 of 2)**

Field Name	Size (bytes)	Description
<b>Target Address</b>	16	<b>Target Address:</b> The IPv6 address of the target of the solicitation. For IPv6 address resolution, this is the actual unicast IP address of the device whose layer two (link-layer) address we are trying to resolve.
<b>Options</b>	Variable	<b>Options:</b> If the device sending the <i>Neighbor Solicitation</i> knows both its own IP address and layer two address, it should include the layer two address in a <i>Source Link-Layer Address</i> option. The inclusion of this option will allow the destination of the <i>Neighbor Solicitation</i> to enter the layer two and layer three addresses of the source of this message into its own address cache. <a href="#">See the discussion of IPv6 address resolution.</a>

**Figure 161: ICMPv6 *Neighbor Solicitation* Message Format**

**Key Concept:** ICMPv6 *Neighbor Advertisement* and *Neighbor Solicitation* messages are similar in many ways to the Router Advertisement and Router Solicitation messages. However, rather than being used to communicate parameters from routers to hosts, they are used for various types of communication between hosts on a physical network, such as address resolution, next-hop determination and neighbor unreachability detection.

---

## Addressing of Neighbor Advertisement and Neighbor Solicitation Messages

*Neighbor Solicitation* messages are sent either unicast to the address of the target device, or to the solicited-node multicast address of the target. This latter address is a special type used to allow a device to send a multicast that will be heard by the target whose address it is trying to resolve, but won't be heard by most other devices; [it is explained in the topic on IPv6 address resolution](#).

When a *Neighbor Advertisement* message is generated in response to a *Neighbor Solicitation*, it is sent unicast back to the device that sent the *Solicitation*, unless that message was sent from [the unspecified address](#), in which case it is multicast to the “all nodes” multicast address. If the *Neighbor Advertisement* message is sent unsolicited (for example, by a device that wishes to inform others of a change in link-layer address), it is sent to the “all nodes” multicast address.

## ICMPv6 Redirect Messages

Because of the different roles of routers and hosts in an IPv6 internetwork, hosts don't need to know very much about routes. They send datagrams intended for destinations on the local network directly, while those for other networks they dump to their local routers and let them “do the driving”, so to speak.

If a local network has only a single router, then it will send all such non-local traffic to that router. If it has more than one local router, the host then must decide which router to use for which traffic. In general terms, a host will not know the most efficient choice of router for every type of datagram it may need to send. In fact, many nodes start out with a limited routing table that says to send **everything** to a single default router, even if there are several routers on the network.

When a router receives datagrams destined for certain networks, it may realize that it would be more efficient if such traffic was sent by a host to a different router on the local network. If so, it will invoke the *Redirect* function by sending an ICMPv6 *Redirect* message to the device that sent the original datagram. This is the last of the functions that in IPv6 are performed by the Neighbor Discovery protocol, and is explained in [a topic on the Redirect function in that section](#). *Redirect* messages are always sent unicast to the address of the device that originally sent the datagram that led to the *Redirect* being created.

## ICMPv6 Redirect Message Format

The format of ICMPv6 *Redirect* messages is shown in [Table 114](#) and [Figure 162](#).

**Table 114: ICMPv6 Redirect Message Format (Page 1 of 2)**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMPv6 message type; for <i>Redirect</i> messages the value is 137.
<b>Code</b>	1	<b>Code:</b> Not used; set to 0.

Table 114: ICMPv6 *Redirect* Message Format (Page 2 of 2)

Field Name	Size (bytes)	Description
<b>Checksum</b>	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .
<b>Reserved</b>	4	<b>Reserved:</b> 4 bytes sent as zeroes.
<b>Target Address</b>	16	<b>Target Address:</b> The address of the router that the router creating the <i>Redirect</i> is telling the recipient of the <i>Redirect</i> to use as a first hop for future transmissions to the destination. Phew. Example time: if router <i>R2</i> generated a <i>Redirect</i> telling host <i>A</i> that in the future transmissions to host <i>B</i> should be sent first to router <i>R1</i> , then <i>R1</i> 's IPv6 address would be in this field.
<b>Destination Address</b>	16	<b>Destination Address:</b> The address of the device whose future transmissions are being redirected; this is the destination of the datagram that originally led to the <i>Redirect</i> being generated. Repeating the example above: if router <i>R2</i> generated a <i>Redirect</i> telling host <i>A</i> that in the future transmissions to host <i>B</i> should be sent first to router <i>R1</i> , then host <i>B</i> 's IPv6 address would be in this field.
<b>Options</b>	Variable	<b>Options:</b> Redirect messages normally include two <a href="#">ICMPv6 option fields</a> : <ul style="list-style-type: none"> <li>• <b>Target Link-Layer Address:</b> The layer-two address of the <i>Target Address</i>, if known. This saves the recipient of the <i>Redirect</i> message from needing to perform an address resolution on the target.</li> <li>• <b>Redirected Header:</b> As much of the IPv6 datagram that spawned this <i>Redirect</i> as will fit without causing the size of the ICMPv6 error message (including its own IP header) to exceed the minimum IPv6 maximum transmission unit (MTU) of 1280 bytes.</li> </ul>

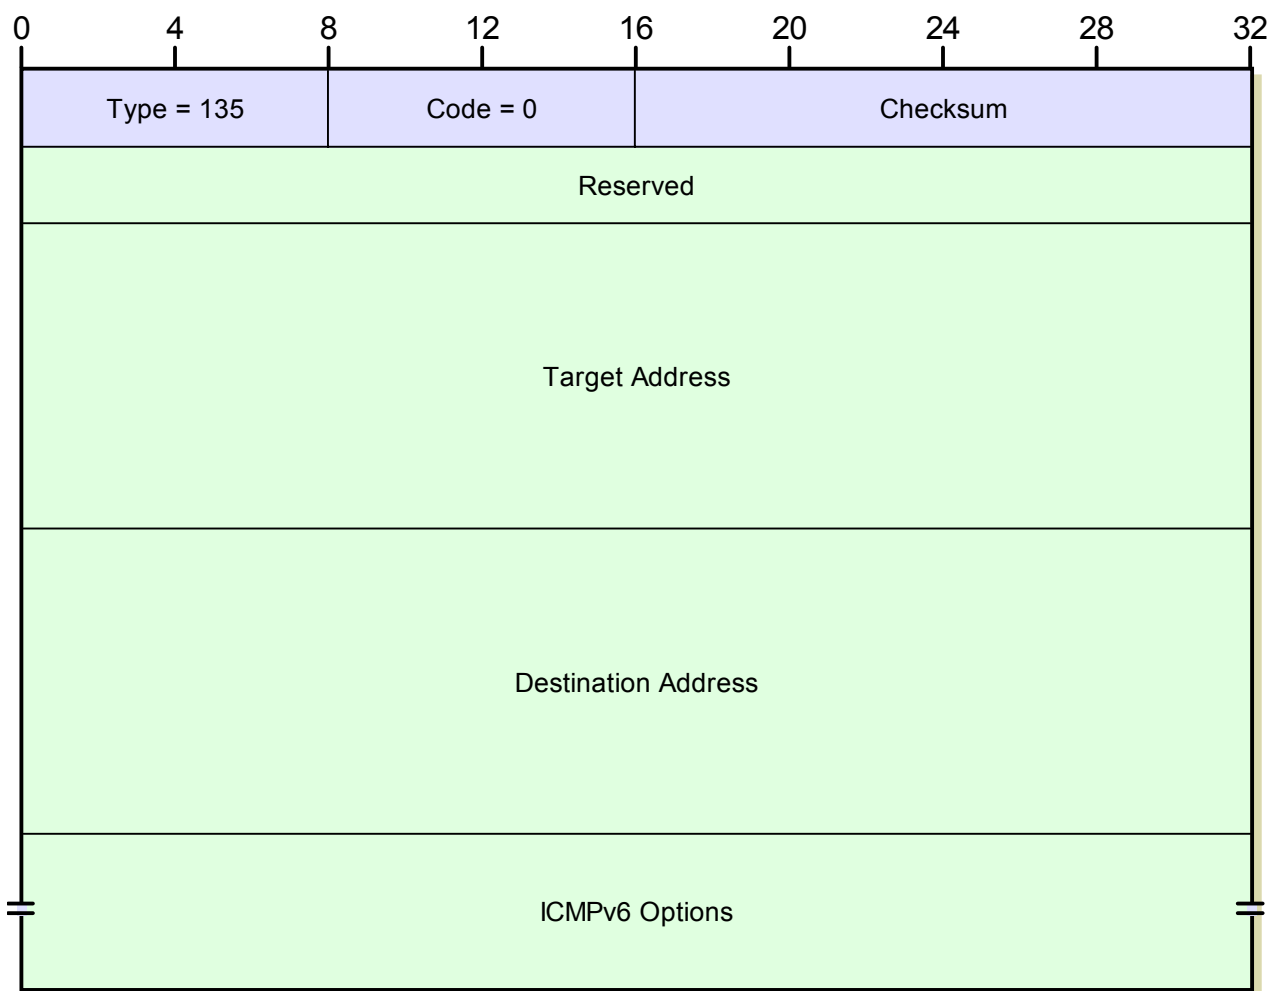

**Note:** As an aside, the *Redirect* message has always been somewhat of an oddball. In ICMPv4, [it is considered an error message](#), but this makes it different from other error messages. For one thing, it's not really an error, since it doesn't represent a failure to deliver, only an inefficiency in doing so. For this reason, in ICMPv6 it was “moved” to the set of informational message types. Here too it doesn't really fit in with the others, since it is sent in reaction to a regular IP message, and it also includes a copy of (part of) the datagram that spawned it, like error messages do.

**Key Concept:** ICMPv6 *Redirect* messages are used by a router to inform a host of a better router to use for future datagrams sent to a particular host or network. They are not used to alter routes between routers, however.

**Figure 162: ICMPv6 *Redirect* Message Format**

## **ICMPv6 Router Renumbering Messages**

One of the more interesting decisions made in IPv6 was the selection of a [very large 128-bit address size](#). This provides an address space far larger than what humans are ever likely to need—and probably larger than was needed for IPv6, strictly speaking. What this wealth of bits provides is the flexibility to assign meaning to different bits in the address structure. This in turn serves as the basis for important features such as the [autoconfiguration and automated renumbering of IPv6 addresses](#).

The renumbering feature in IPv6 is of particular interest to network administrators, since it has the potential to make large network migrations and merges much simpler. In August 2000, the IETF published RFC 2894, *Router Renumbering for IPv6*, which describes a similar technique to allow routers in an autonomous system to be renumbered, by giving them new prefixes (network identifiers).

Router renumbering is actually a fairly simple process—especially if we avoid the gory details, which is exactly what I intend to do. A network administrator uses a device on the internetwork to generate one or more *Router Renumbering Command* messages. These messages provide a list of prefixes of routers that are to be renumbered. Each router processes these messages to see if the addresses on any of their interfaces match the specified prefixes. If so, they change the matched prefixes to the new ones specified in the message. Additional information is also included in the *Router Renumbering Command* as appropriate to control how and when the renumbering is done.

If the *Command* message requests it, each router processing the message will respond with a *Router Renumbering Result* message. This message serves as feedback to let the originator of the *Command* know whether the renumbering was successful, and what changes, if any, were made.

The router renumbering standard also defines a few important management features. Many of these reflect the great power of something that can mass-renumber routers—and hence, the potential for such power to be abused. It is possible to send commands in a “test mode”, where they are processed but the renumbering not actually executed. Messages include a sequence number to guard against replay attacks, and a special *Sequence Number Reset* message can be used to reset the sequence number information routers have previously stored. For added security, the standard specifies that messages be authenticated and identity-checked.

### ICMPv6 Router Renumbering Message Format

The format of *Router Renumbering* messages is in [Table 115](#) and [Figure 163](#).

**Table 115: ICMPv6 Router Renumbering Message Format (Page 1 of 3)**

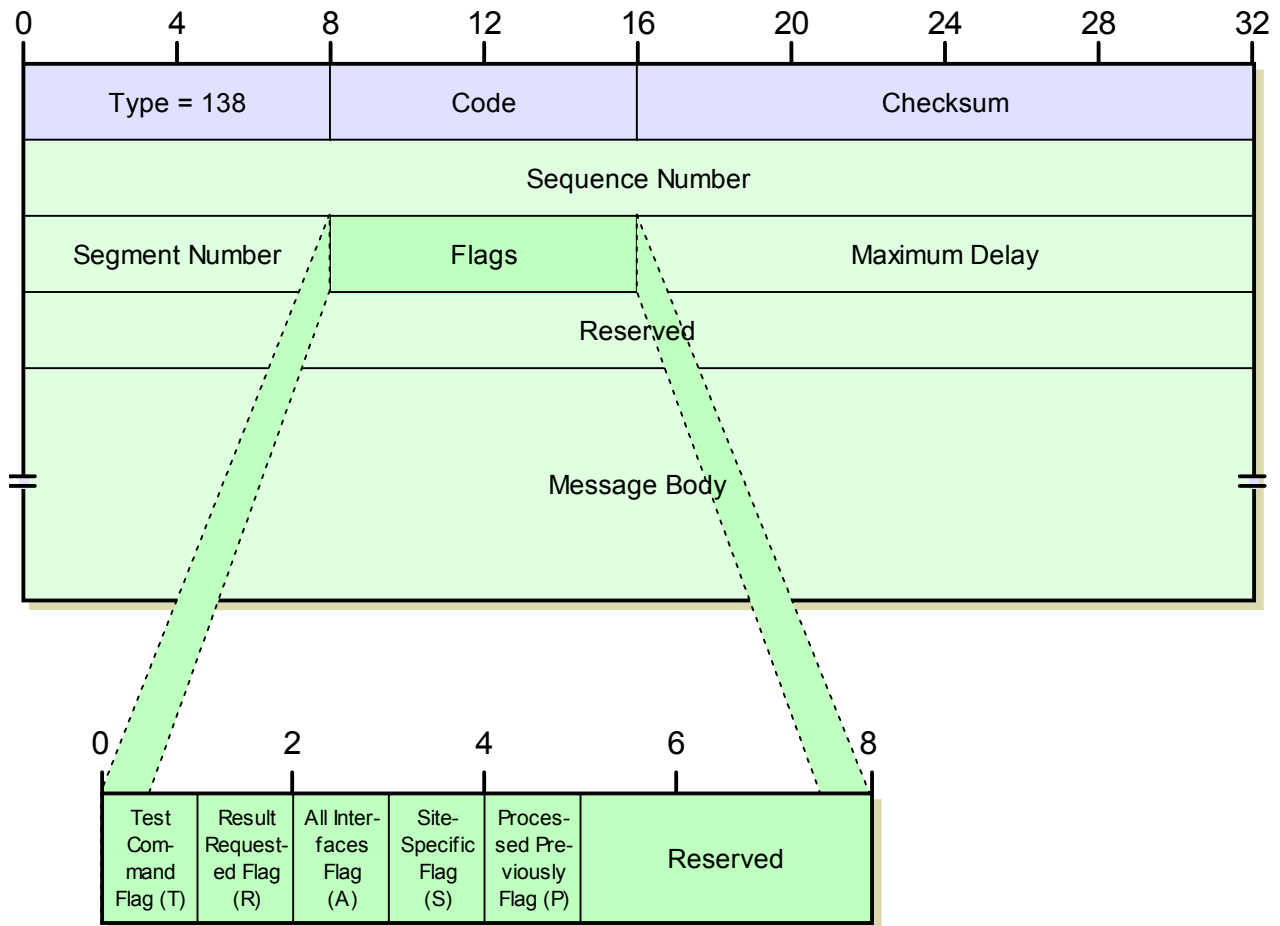

Field Name	Size (bytes)	Description								
Type	1	<b>Type:</b> Identifies the ICMPv6 message type; for <i>Router Renumbering</i> messages the value is 138.								
Code	1	<b>Code:</b> Indicates the subtype of <i>Router Renumbering</i> message: <table><tr><th>Value (Decimal)</th><th>Message Subtype</th></tr><tr><td>0</td><td><i>Router Renumbering Command</i></td></tr><tr><td>1</td><td><i>Router Renumbering Result</i></td></tr><tr><td>255</td><td><i>Sequence Number Reset</i></td></tr></table>	Value (Decimal)	Message Subtype	0	<i>Router Renumbering Command</i>	1	<i>Router Renumbering Result</i>	255	<i>Sequence Number Reset</i>
Value (Decimal)	Message Subtype									
0	<i>Router Renumbering Command</i>									
1	<i>Router Renumbering Result</i>									
255	<i>Sequence Number Reset</i>									
Checksum	2	<b>Checksum:</b> 16-bit checksum field for the ICMP header, as described in <a href="#">the topic on the ICMP common message format</a> .								
Sequence Number	4	<b>Sequence Number:</b> A 32-bit sequence number used to guard against “replay” attacks by allowing a recipient to detect stale, duplicate or “out of order” commands.								

Table 115: ICMPv6 Router Renumbering Message Format (Page 2 of 3)

Field Name	Size (bytes)	Description																					
<b>Segment Number</b>	1	<b>Segment Number:</b> Differentiates between valid <i>Router Renumbering</i> messages within the same <i>Sequence Number</i> .																					
<b>Flags</b>	1	<p><b>Flags:</b> Five flags used to control the renumbering process. The first four flags (<i>T</i>, <i>R</i>, <i>A</i> and <i>S</i>) control the operation of <i>Command</i> messages and in a <i>Result</i> message are just copied verbatim from the <i>Command</i> that led to the <i>Result</i> being created. The <i>P</i> flag is only used in <i>Result</i> messages (0 in <i>Command</i> messages):</p> <table> <tr> <th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr> <tr> <td><i>T</i></td><td>1/8 (1 bit)</td><td><b>Test Command Flag:</b> When set to 1, flags this <i>Command</i> as being a test message. This tells the recipient to only “simulate” processing of the renumber and not actually do it.</td></tr> <tr> <td><i>R</i></td><td>1/8 (1 bit)</td><td><b>Result Requested Flag:</b> When set to 1, requests that a <i>Result</i> message be sent after processing the <i>Command</i>, when 0, says not to send one.</td></tr> <tr> <td><i>A</i></td><td>1/8 (1 bit)</td><td><b>All Interfaces Flag:</b> When this flag is clear (0), the <i>Command</i> is not applied to any router interfaces that have been administratively shut down. When 1, it is applied to all interfaces.</td></tr> <tr> <td><i>S</i></td><td>1/8 (1 bit)</td><td><b>Site-Specific Flag:</b> This flag has meaning only when a router treats its interfaces as belonging to different sites. If so, a value of 1 tells it to apply the <i>Command</i> only to interfaces on the same site as the interface for which the <i>Command</i> was received. A value of 0 applies it to all interfaces regardless of site.</td></tr> <tr> <td><i>P</i></td><td>1/8 (1 bit)</td><td><b>Processed Previously Flag:</b> This flag is normally 0, meaning the <i>Command</i> was not previously seen and the <i>Result</i> message contains the report of processing it. When 1, indicates that the recipient of the <i>Command</i> believes it has seen it before and is not processing it. (Test commands are not included in the assessment of whether a <i>Command</i> has been seen before.)</td></tr> <tr> <td><b>Reserved</b></td><td>3/8 (3 bits)</td><td><b>Reserved:</b> Three bits reserved for future flags.</td></tr> </table>	Subfield Name	Size (bytes)	Description	<i>T</i>	1/8 (1 bit)	<b>Test Command Flag:</b> When set to 1, flags this <i>Command</i> as being a test message. This tells the recipient to only “simulate” processing of the renumber and not actually do it.	<i>R</i>	1/8 (1 bit)	<b>Result Requested Flag:</b> When set to 1, requests that a <i>Result</i> message be sent after processing the <i>Command</i> , when 0, says not to send one.	<i>A</i>	1/8 (1 bit)	<b>All Interfaces Flag:</b> When this flag is clear (0), the <i>Command</i> is not applied to any router interfaces that have been administratively shut down. A value of 0 applies it to all interfaces regardless of site.																					
<i>P</i>	1/8 (1 bit)	<b>Processed Previously Flag:</b> This flag is normally 0, meaning the <i>Command</i> was not previously seen and the <i>Result</i> message contains the report of processing it. When 1, indicates that the recipient of the <i>Command</i> believes it has seen it before and is not processing it. (Test commands are not included in the assessment of whether a <i>Command</i> has been seen before.)																					
<b>Reserved</b>	3/8 (3 bits)	<b>Reserved:</b> Three bits reserved for future flags.																					
<b>Max Delay</b>	2	<b>Maximum Delay:</b> Tells a router receiving a message the maximum amount of time (in milliseconds) it is allowed to delay before sending a reply.																					

**Table 115: ICMPv6 Router Renumbering Message Format (Page 3 of 3)**

Field Name	Size (bytes)	Description
Reserved	4	<b>Reserved:</b> 4 reserved bytes.
Message Body	Variable	<p><b>Message Body:</b> For a <i>Router Renumbering Command</i>, the message body contains two sets of information. The first is a <i>Match-Prefix Part</i> for the prefix being renumbered. The second is one or more <i>Use-Prefix Parts</i> that describe the new prefix for each match. A router receiving a <i>Command</i> checks its own interface addresses and if they match the <i>Match-Prefix-Part</i>, they use <i>Use-Prefix Parts</i> data to accomplish the renumbering.</p> <p>For a <i>Router Renumbering Result</i>, the message body contains zero or more <i>Match Results</i> entries that describe each prefix that a router matched from a <i>Router Renumbering Command</i>. Each entry provides information regarding whether renumbering was successful or not for a prefix.</p>

**Figure 163: ICMPv6 Router Renumbering Message Format**

---

## Addressing of Router Renumbering Messages

Since these messages are intended for all routers on a site, they are normally sent to the “all routers” multicast address, using either [link-local](#) or [site-local scope](#). They may also be sent to local unicast addresses.

### ICMPv6 Informational Message Options

Each of the five ICMPv6 informational messages types defined and used by the [Neighbor Discovery \(ND\) protocol](#) has an [Options](#) field into which one or more options may be inserted. This probably isn't the best name for these sets of data, since they are only optional in certain cases. In fact, in some cases the “option” is actually the entire point of the message. For example, a *Neighbor Advertisement* message containing a link-layer address for address resolution carries it in an “option”, but the message wouldn't be of much use without it.

Each option has its own structure of subfields based on the classical “type, length and value” triplet used in many message formats. The *Type* subfield indicates the option type and the *Length* field indicates its length so the device processing the option can determine where it ends. The “value” is not a single field, but rather one or more that contain the actual information for which the option is being used.

Some options are used for only one kind of ICMPv6 message, while others are used for more than one variety. So, they are best thought of as “modular components” used in different types of messages as needed. I describe the format of each of these five options below.

#### **Source Link-Layer Address Option Format**

This option carries the link-layer address of a device sending an ICMPv6 message, as shown in [Table 116](#) and [Figure 164](#). Used in *Router Advertisement*, *Router Solicitation* and *Neighbor Solicitation* messages:

**Table 116: ICMPv6 Source Link-Layer Address Option Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMPv6 option type. For the <i>Source Link-Layer Address</i> option, the value is 1.
<b>Length</b>	1	<b>Length:</b> The length of the entire option (including the <i>Type</i> and <i>Length</i> fields), expressed in units of 8 octets (64 bits).
<b>Source Link-Layer Address</b>	Variable	<b>Source Link-Layer Address:</b> The link-layer (layer two) address of the device sending the ICMPv6 message.

**Figure 164: ICMPv6 Source Link-Layer Address Option Format**

### **Target Link-Layer Address Option Format**

The counterpart of *Source Link-Layer Address*, this option carries the link-layer address corresponding to the *Target Address* field in *Neighbor Advertisement* and *Redirect* messages; see [Table 117](#) and [Figure 165](#).

**Table 117: ICMPv6 Target Link-Layer Address Option Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMPv6 option type. For the <i>Target Link-Layer Address</i> option, the value is 2.
<b>Length</b>	1	<b>Length:</b> The length of the entire option (including the <i>Type</i> and <i>Length</i> fields), expressed in units of 8 octets (64 bits).
<b>Target Link-Layer Address</b>	Variable	<b>Target Link-Layer Address:</b> The link-layer (layer two) address of the target device.

**Figure 165: ICMPv6 Target Link-Layer Address Option Format**

---

## Prefix Information Option Format

This option provides a prefix and related information in *Router Advertisement* messages. This is the longest and most complex of the options, as you can see in [Table 118](#) and [Figure 166](#).

**Table 118: ICMPv6 Prefix Information Option Format (Page 1 of 2)**

Field Name	Size (bytes)	Description												
<b>Type</b>	1	<b>Type:</b> Identifies the ICMPv6 option type. For the <i>Prefix Information</i> option, the value is 3.												
<b>Length</b>	1	<b>Length:</b> The length of the entire option (including the <i>Type</i> and <i>Length</i> fields), expressed in units of 8 octets (64 bits). The <i>Prefix Information</i> option is fixed in size at 32 bytes, so the value of the <i>Length</i> field is 4.												
<b>Prefix Length</b>	1	<b>Prefix Length:</b> The number of bits in the <i>Prefix</i> field (below) that are considered part of the network identifier (the remainder are used for the host identifier and ignored). <a href="#">See this overview discussion of IPv6 address notation for details on prefix lengths.</a>												
<b>Flags</b>	1	<b>Flags:</b> A pair of flags that convey information about the prefix: <table><tr><th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr><tr><td><b>L</b></td><td>1/8 (1 bit)</td><td><b>On-Link Flag:</b> When set to 1, tells the recipient of the option that this prefix can be used for on-link determination. This means the prefix can be used for deciding whether or not an address is “on-link” (on the recipient’s local network). When 0, the sender is making no statement regarding whether the prefix can be used for this or not.</td></tr><tr><td><b>A</b></td><td>1/8 (1 bit)</td><td><b>Autonomous Address-Configuration Flag:</b> When set to 1, specifies that this prefix can be used for <a href="#">IPv6 address autoconfiguration</a>.</td></tr><tr><td><b>Reserved</b></td><td>6/8 (6 bits)</td><td><b>Reserved:</b> 6 “leftover” bits reserved and sent as zeroes.</td></tr></table>	Subfield Name	Size (bytes)	Description	<b>L</b>	1/8 (1 bit)	<b>On-Link Flag:</b> When set to 1, tells the recipient of the option that this prefix can be used for on-link determination. This means the prefix can be used for deciding whether or not an address is “on-link” (on the recipient’s local network). When 0, the sender is making no statement regarding whether the prefix can be used for this or not.	<b>A</b>	1/8 (1 bit)	<b>Autonomous Address-Configuration Flag:</b> When set to 1, specifies that this prefix can be used for <a href="#">IPv6 address autoconfiguration</a> .	<b>Reserved</b>	6/8 (6 bits)	<b>Reserved:</b> 6 “leftover” bits reserved and sent as zeroes.
Subfield Name	Size (bytes)	Description												
<b>L</b>	1/8 (1 bit)	<b>On-Link Flag:</b> When set to 1, tells the recipient of the option that this prefix can be used for on-link determination. This means the prefix can be used for deciding whether or not an address is “on-link” (on the recipient’s local network). When 0, the sender is making no statement regarding whether the prefix can be used for this or not.												
<b>A</b>	1/8 (1 bit)	<b>Autonomous Address-Configuration Flag:</b> When set to 1, specifies that this prefix can be used for <a href="#">IPv6 address autoconfiguration</a> .												
<b>Reserved</b>	6/8 (6 bits)	<b>Reserved:</b> 6 “leftover” bits reserved and sent as zeroes.												
<b>Valid Lifetime</b>	4	<b>Valid Lifetime:</b> The amount of time, in seconds, that the recipient of the message containing this option should consider the prefix valid for purposes of on-link determination (see description of the “L” flag just above). A value of all 1s means “infinity” (“forever”).												
<b>Preferred Lifetime</b>	4	<b>Preferred Lifetime:</b> When the recipient of this prefix uses it to automatically generate addresses using address autoconfiguration, specifies the amount of time, in seconds, that such addresses remain “preferred” (meaning, valid and freely usable). A value of all 1s means “infinity” (“forever”).												

Table 118: ICMPv6 *Prefix Information* Option Format (Page 2 of 2)

Field Name	Size (bytes)	Description
<b>Reserved</b>	4	<b>Reserved:</b> 4 unused bytes sent as zeroes.
<b>Prefix</b>	16	<b>Prefix:</b> The prefix being communicated from the router to the host in the <i>Router Advertisement</i> message. The <i>Prefix Length</i> field indicates how many of the 128 bits in this field are significant (part of the network ID). Only these bits are placed in the <i>Prefix</i> field, the remaining bits are cleared to zero.

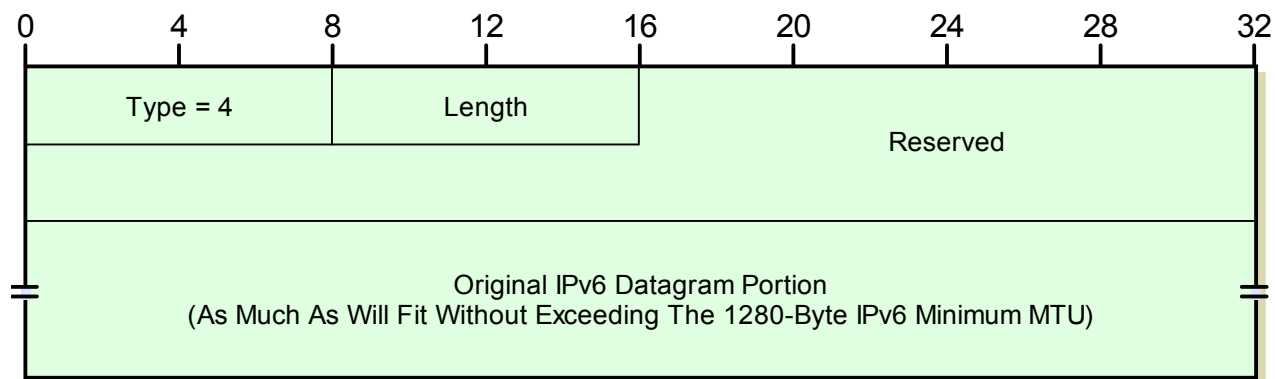

Figure 166: ICMPv6 *Prefix Information* Option Format

## Redirected Header Option Format

In a *Redirect* message, provides a copy of the original message (or a portion of it) that led to the *Redirect* being generated. This option can be found in [Table 119](#) and [Figure 167](#).

**Table 119: ICMPv6 Redirected Header Option Format**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMPv6 option type. For the <i>Redirected Header</i> option, the value is 4.
<b>Length</b>	1	<b>Length:</b> The length of the entire option (including the <i>Type</i> and <i>Length</i> fields), expressed in units of 8 octets (64 bits).
<b>Reserved</b>	6	<b>Reserved:</b> 6 reserved bytes sent as zeroes.
<b>IP Header + Data</b>	Variable	<b>IP Header + Data:</b> As much of the original IPv6 datagram as will fit without causing the size of the ICMPv6 error message (including its own IP header) to exceed the minimum IPv6 maximum transmission unit (MTU) of 1280 bytes.

**Figure 167: ICMPv6 Redirected Header Option Format**

## MTU Option Format

The *MTU* option lets a router convey a recommended [MTU value](#) in *Router Advertisement* messages. Its format is described in [Table 120](#) and [Figure 168](#).

**Table 120: ICMPv6 MTU Option Format (Page 1 of 2)**

Field Name	Size (bytes)	Description
<b>Type</b>	1	<b>Type:</b> Identifies the ICMPv6 option type. For the <i>MTU</i> option, the value is 5.
<b>Length</b>	1	<b>Length:</b> The length of the entire option (including the <i>Type</i> and <i>Length</i> fields), expressed in units of 8 octets (64 bits). The <i>MTU</i> option is fixed in length at 8 bytes so the value of this field is 1.

Table 120: ICMPv6 *MTU* Option Format (*Page 2 of 2*)

Field Name	Size (bytes)	Description
<b>Reserved</b>	2	<b>Reserved:</b> 2 reserved bytes sent as zeroes.
<b>MTU</b>	4	<b>MTU:</b> The <a href="#">maximum transmission unit (MTU) value</a> , in bytes, that the router is recommending for use on the local link.

Figure 168: ICMPv6 *MTU* Option Format

---

## **TCP/IP IPv6 Neighbor Discovery Protocol (ND)**

The new [Internet Protocol version 6 \(IPv6\)](#) represents an evolution of the venerable Internet Protocol. It maintains the same basic operational principles of IPv4, but makes some important modifications, particularly in the area of addressing. In fact, some of the more significant changes in IPv6 are actually not in the IP protocol itself, but in the protocols that support IP. One of the most interesting of these was the creation of an entirely new support protocol for IPv6. It combines several tasks previously performed by other protocols in IPv4, adds some new functions, and makes numerous improvements to the whole package. This new standard is called the IPv6 *Neighbor Discovery (ND)* protocol.

In this section I describe the new Neighbor Discovery protocol used in IPv6. I begin with an overview of the protocol, discussing its history, the motivation for its creation and the standards that define it. I then describe its operation in general terms, listing the fundamental functions that ND performs, the three groups these functions fit into, and the ICMPv6 message types used to carry them out. I describe the key differences between ND and the way that its functions were carried out in IPv4. I then provide more information on the three functional groups in ND: those that involve discovery of important internetwork information from routers, those that are related to address resolution and neighbor communication between hosts, and finally, router redirection.

**Background Information:** This section assumes basic comprehension of [IP version 6](#), which in turn requires understanding [IPv4](#). ND uses ICMP version 6 (ICMPv6) messages, so reference is made to [the ICMP section](#). Finally, since ICMP performs some functions done by the Address Resolution Protocol (ARP) in IPv4, you may need to refer to [the ARP discussion](#) if unfamiliar with its operation.

---

### **IPv6 ND Overview. History. Motivation and Standards**

[The purpose of network layer protocols like the Internet Protocol](#) is to provide a means of connecting together individual local networks to create a much larger internetwork. To higher protocol layers and to users, this internetwork behaves in most respects as if it were a single large network, because the lower layers hide the details that “glue” together the individual networks. Any device can send information to any other, regardless of where it is located, and “like magic”, it will work. At least, most of the time.

The existence of an internetwork means that devices can treat all other devices as peers, at least from the perspective of higher protocol layers and applications. From the standpoint of lower layers, however, there is a very important difference between devices that are on a host's local network and those that are elsewhere. In a general sense, most devices have a more important relationship with the devices that are on its local network than those that are far away. Some of the most obvious tasks that a device must perform specifically with other devices on its local network include:

- 
- ☉ **Direct Datagram Delivery:** [Devices deliver data directly to other devices on their local network](#), while data going to distant devices must be *indirectly* delivered (routed).
  - ☉ **Layer Two Addressing:** To facilitate direct delivery, devices need to know the layer two addresses of the other devices on the local network; they don't need to know them for non-local devices.
  - ☉ **Router Identification:** To delivery indirectly, a device needs to find a router on its local network that it can talk to.
  - ☉ **Router Communication:** The local router must communicate information to each of the local hosts using it so they know how best to use it.
  - ☉ **Configuration:** Hosts will usually look to information provided by local devices to let them perform configuration tasks such as determining their own IP address.

To support these and other requirements, several special protocols and functions were developed along with the original Internet Protocol (version 4). The IP addressing scheme lets devices differentiate local addresses from distant ones. The [Address Resolution Protocol \(ARP\)](#) lets devices determine layer two addresses from layer three addresses. The [Internet Control Message Protocol \(ICMP\)](#) provides a messaging system to support various communication requirements between local devices, including the ability of a host to find a local router and the router to provide information to local hosts.

These features all work properly in IPv4, but they were developed sort of in an ad hoc manner. They are defined not in a single place, but rather in a variety of different Internet standards. There were also some limitations with the way these “local device” functions were implemented.

### ***Formalizing Local Network Functions: The Concept of Neighbors***

IP version 6 represents the biggest change in decades to not just the Internet Protocol itself, but the entire TCP/IP suite. It thus provided an ideal opportunity to formalize and integrate the many disparate functions and tasks related to communication between local devices. The result was the creation of a new protocol: *Neighbor Discovery for IP Version 6*, also commonly called the *IPv6 Neighbor Discovery* protocol. Since this protocol is new in version 6, there is no IPv4 version of it, so the name is usually just seen as the *Neighbor Discovery (ND)* protocol with no further qualifications; its use with IPv6 is implied.

The term *neighbor* is one that has been used for years in various networking standards and technologies to refer to devices that are local to each other. In the context of our current discussion, two devices are *neighbors* if they are on the same local network, meaning that they can send information to each other directly; the term can refer to either a regular host or a router. I think this is a good analogy to the way humans refer to those who live or work nearby. Just as most of us have a special relationship with people who are our neighbors and communicate more with them than with those who are far away, so do IP devices.

Since a neighbor is a local device, the name of the Neighbor Discovery protocol would seem to indicate that ND is all about how neighbors discover each other's existence. In the context of this protocol, however, the term *discovery* has a much more generic meaning: it refers to discovering not just who are neighbors are but also important information about

---

them. In addition to letting devices identify their neighbors, ND facilitates all the tasks in the bullet list above, including such functions as address resolution, parameter communication, autoconfiguration and much more as we will see in the next few topics.

### ***Neighbor Discovery Standards***

The Neighbor Discovery protocol was originally defined in RFC 1970, published in August 1996, and revised in the current defining standard, RFC 2461, published December 1998. Most of the functions of the ND protocol are implemented using a set of five [special ICMPv6 control messages](#). Thus, to some extent, the operation of ND is partially described by the ICMPv6 standard, RFC 2463. Where ICMPv4 can be considered IPv4's "administrative assistant", IPv6 really has two such assistants working closely together: ICMPv6 and the IPv6 ND protocol. I discuss more of the differences between the ways IPv4 and IPv6 implement ND's functions later in this section.

**Key Concept:** The new *IPv6 Neighbor Discovery* protocol formalizes for IPv6 a number of functions related to communication between devices on a local network that are performed in IPv4 by protocols such as ARP and ICMP. ND is considered another "helper" protocol for IPv6, and is closely related to ICMPv6.

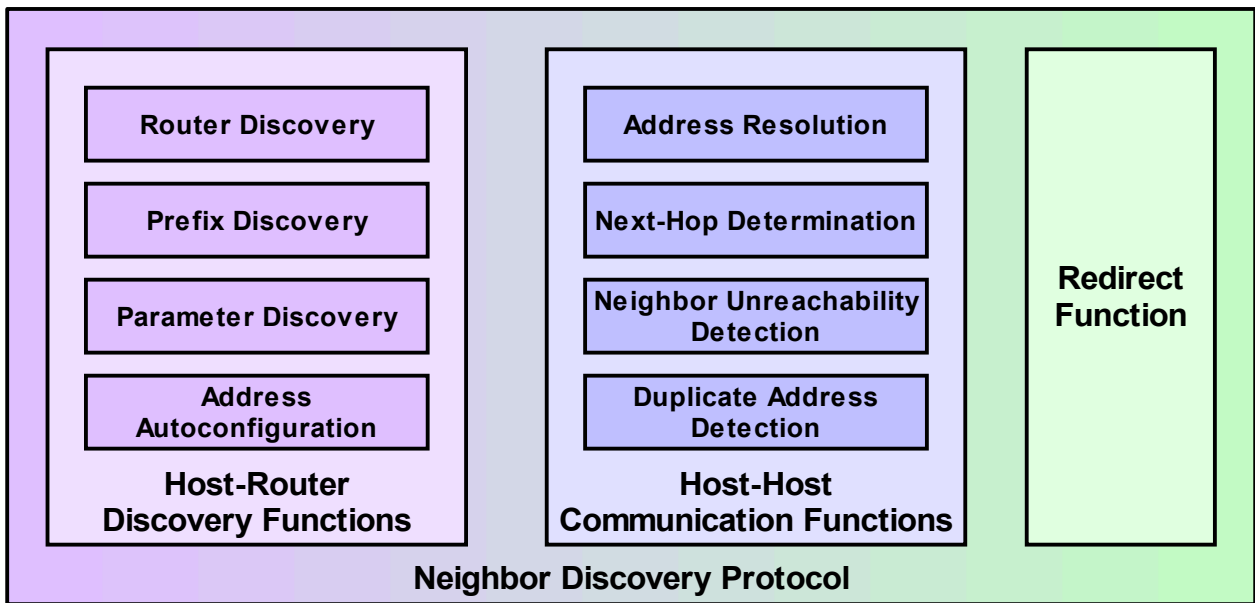

---

### **IPv6 ND General Operational Overview: ND Functions, Functional Groups and Message Types**

As I mentioned in [the preceding overview](#), the name of the Neighbor Discovery (ND) protocol really does not do it justice. The protocol facilitates not merely the discovery of neighboring devices, but a substantial number of functions related to local network connectivity, datagram routing and configuration. Both regular hosts and routers in an IPv6 environment count on the ND protocol to facilitate important exchanges of information that are necessary for proper internetwork operation.

The Neighbor Discovery protocol has a number of similarities to the [Internet Control Message Protocol](#). An important one is that like ICMP, ND is a **messaging** protocol. It doesn't implement a single specific function but rather a group of activities that are performed through the exchange of messages. This means we can't explain the operation of ND through a specific description of "what ND does", but rather must define its operation by means of a list of messages ND provides and specific ways that they are used.

Any local network on an internet will have both regular hosts and routers, and the term *neighbor* can refer to either. Of course, hosts and routers play different roles on a network, and as a result *neighbor discovery* is very different for each. The ND standard describes nine specific functions performed by the protocol. To better understand these functions and how they are related, we can divide them into three functional groups based on communication type and the kinds of devices involved (see [Figure 169](#)).

**Figure 169: Neighbor Discovery Protocol (ND) Functional Groups and Functions**

### ***Host-Router Discovery Functions***

One of the two main groups of functions in ND are those that facilitate the discovery of local routers and the exchange of information between them and hosts. This includes four specific functions:

- 🕒 **Router Discovery:** This is the core function of this group: the method by which hosts locate routers on their local network.
- 🕒 **Prefix Discovery:** Closely related to the process of router discovery is prefix discovery. Recall that [the term “prefix” refers to the network portion of an IP address](#). Hosts use this function to determine what network they are on, which in turn tells them how to differentiate between local and distant destinations and whether to attempt direct or indirect delivery of datagrams.
- 🕒 **Parameter Discovery:** Also closely related to router discovery, this is the method by which a host learns important parameters about the local network and/or routers, such as the [maximum transmission unit](#) of the local link.
- 🕒 **Address Autoconfiguration:** Hosts in IPv6 are designed to be able to [automatically configure themselves](#), but this requires information that is normally provided by a router.

### ***Host-Host Communication Functions***

The other main group of functions is that associated with information determination and communication directly between nodes, usually hosts. Some of these functions can be performed between hosts and routers, but this group is not specifically related to router discovery; it includes:

- 
- 🕒 **Address Resolution:** The process by which a device determines the layer two address of another device on the local network from that device's layer three (IP) address. This is the job performed by [ARP](#) in IP version 4.
  - 🕒 **Next-Hop Determination:** The method for looking at an IP datagram's destination address and determining where it should next be sent.
  - 🕒 **Neighbor Unreachability Detection:** The process of determining whether or not a neighbor device can be directly contacted.
  - 🕒 **Duplicate Address Detection:** Determining if an address that a device wishes to use already exists on the network.

### ***Redirect Function***

The last functional group contains just one function: *Redirect*. The technique whereby a router informs a host of a better next-hop node to use for a particular destination.

**Key Concept:** The *Neighbor Discovery* protocol encompasses nine individual functions, many of which are related to each other. They are organized into three functional groups: host-router discovery functions, host-host communications functions, and the redirect function.

---

### ***Relationships Between Functions***

The division of ND's overall functionality into nine tasks in three groups is somewhat arbitrary, but provides a good frame of reference for understanding what the protocol does. Obviously some of the functions in different groups are related; next-hop determination uses information obtained as part of parameter discovery. The redirect function is also a form of router-host communication but is distinct from router discovery.

### ***ICMPv6 Messages Used By the Neighbor Discovery Protocol***

Just as ND is similar to ICMP in its operation, the two protocols are related in another way: the method that messaging is done. ND actually implements its functions using ICMPv6 messages. A set of five message types is described in the ND standard:

- 🕒 **Router Advertisement Messages:** Sent regularly by routers to tell hosts that they exist and provide important prefix and parameter information to them.
- 🕒 **Router Solicitation Messages:** Sent by hosts to request that any local routers send a *Router Advertisement* message so they don't have to wait for the next regular advertisement message.
- 🕒 **Neighbor Advertisement Messages:** Sent by hosts to indicate the existence of the host and provide information about it.
- 🕒 **Neighbor Solicitation Messages:** Sent to verify the existence of another host and to ask it to transmit a *Neighbor Advertisement*.

- 
- ☉ **Redirect Messages:** Sent by a router to tell a host of a better method to route data to a particular destination.

More details on how these message types are used can be found in the topics later in this section that describe the three functional groups above in more detail. The structures of each of the five ICMPv6 message types used by ND can be found in the section on [ICMPv6 informational message types and formats](#).

## **IPv6 ND Functions Compared to Equivalent IPv4 Functions**

The IPv6 Neighbor Discovery protocol has the distinction of being the only truly *new* protocol created as part of the core of [Internet Protocol version 6](#); there is no “NDv4” at all. Of course, most of the services that ND provides to IPv6 were also required in version 4 of the Internet Protocol. They were just provided in a rather diverse set of protocols and standards that the ND protocol has formalized, integrated and improved.

What this means is that while ND is new, the jobs it does are equivalent to the tasks performed by several other protocols in IPv4. Specifically, the bulk of ND functions correspond to the following set of standards, features and message types in IPv4:

- ☉ **ICMPv4 Router Discovery:** Most of the functions associated with identifying and obtaining information from routers in ND are based on the use of ICMPv4 *Router Advertisement* and *Router Solicitation* messages as defined in RFC 1256.
- ☉ **Address Resolution Protocol:** ND provides enhanced address resolution capabilities that are similar to the functions provided in IPv4 by [ARP](#).
- ☉ **ICMPv4 Redirect:** ND's redirect function and *Redirect* messages are based on similar functionality defined in IPv4 and ICMPv4.

Of course, there are other aspects of ND that only somewhat correlate to how things work in IPv4. There are also improvements or new functionality compared to how these IPv4 functions work. Some of these are in fact due to differences in how IPv6 itself operates compared to IPv4. For example, prefix discovery in ND is sort of related to the *Address Mask Request* and *Address Mask Reply* messaging in ICMPv4.

Overall, ND represents a substantial improvement compared to the way its job was done in IP version 4. Like IPv6 itself, ND is generally better suited to the needs of modern networks than the older protocols. Some of the more important specific improvements made in ND compared to how its job was done in IPv4 include the following:

- ☉ **Formalizing Of Router Discovery:** In IPv4 the process of router discovery and solicitation was arguably an “afterthought”; ND formalizes this process and makes it part of the core of the TCP/IP protocol suite.
- ☉ **Formalizing Of Address Resolution:** In a similar manner, address resolution is handled in a superior way in ND. ND functions at layer three and is tightly tied to IP just like ICMP is. There is no more need for an “ambiguously-layered” protocol like ARP, whose implementation is very dependent on the underlying physical and data link layers.

- 
- ☉ **Ability To Perform Functions Securely:** ND operates at the network layer, so it can make use of the authentication and encryption capabilities of [IPSec](#) for tasks such as address resolution or router discovery.
  - ☉ **Autoconfiguration:** In combination with features built into IPv6, ND allows many devices to automatically configure themselves even without the need for something like a DHCP server (though [DHCPv6](#) does also exist.)
  - ☉ **Dynamic Router Selection:** Devices use ND to detect if neighbors are reachable or not. If a device is using a router that stops being reachable it will detect this and automatically switch to another one.
  - ☉ **Multicast-Based Address Resolution:** Address resolution is performed using special [multicast addresses](#) instead of broadcasts, reducing unnecessary disruption of “innocent bystanders” when resolution messages must be sent.
  - ☉ **Better Redirection:** Improvements have been made to the method that redirects are generated and used.

## **IPv6 ND Host-Router Discovery Functions: Router Discovery, Prefix Discovery, Parameter Discovery and Address Autoconfiguration**

Internetworks are created by connecting together individual networks. The devices that are responsible for this connection of networks are routers, which send data from one network to the next. A host must rely on a router to forward transmissions to all devices other than those on the local network. For this reason, before a host can properly use an internetwork, it needs to find a local router and learn important information about both the router and the network itself. Enabling this information exchange is one of the most important jobs of the IPv6 Neighbor Discovery protocol.

The general term used to describe most of the ND communication between hosts and routers on a local network is *discovery*. [As we discussed earlier in this section](#), the term encompasses not merely discovery of the router but also communication of important parameters. Most of this communication flows from the routers to the hosts, since routers really control the way that each network is used. They provide information to hosts so the hosts know how best to operate.

The various discovery features related to host-router communication are all facilitated by the same exchange of two different ICMPv6 message types. *Router Advertisement* messages are sent only by routers, and contain information about the router and also the network on which it is located. *Router Solicitation* messages are optional, and sent by hosts when they want to find a local router. The format of each of these messages is described in [the section on ICMPv6 informational messages](#).

### ***Host-Router Discovery Functions Performed By Routers***

The mechanisms for using these messages is not really that complicated. The best way to see how the discovery process works overall is to look at the specific tasks performed both by routers and hosts in ND. Let's start with those performed by routers:

- 
- 🕒 **Routine Advertisement:** The main job that routers do in ND is the regular transmission of *Router Advertisement* messages. Each router maintains a timer that controls how often an advertisement is sent out. Advertisements are also sent when any sort of special situation arises. For example, a message will be sent if key information about the router changes, such as its address on the local network.

*Router Advertisement* messages include key information about both the router and the network. [See the relevant topic in the ICMPv6 section for a full description of the Router Advertisement message format.](#)

- 🕒 **Parameter Maintenance:** Routers are responsible for maintaining key parameters about the local network so they can be sent in advertisements. These include the default *Hop Limit* that should be used by hosts on the network, a default [MTU](#) value for the network, and information such as network prefixes that are used for both first-hop routing by hosts and autoconfiguration.

Again, some more details on these can be found in [the topic that discusses Router Advertisement fields.](#)

- 🕒 **Solicitation Processing:** Routers listen for *Router Solicitation* messages and when one is received, will immediately send a *Router Advertisement* to the requesting host.

### ***Host-Router Discovery Functions Performed By Hosts***

For their part, hosts are responsible for three main functions.

- 🕒 **Advertisement Processing:** Hosts listen for advertisements on their local network and process them. They then set appropriate parameters based on the information in these messages. This includes maintaining various data structures such as lists of prefixes and routers, which are updated regularly as new advertisement information comes in.
- 🕒 **Solicitation Generation:** Under certain conditions a host will generate a *Router Solicitation* and send it out on the local network. This very simple message just requests that any local routers that hear it immediately send a *Router Advertisement* message back to the device that made the request. This is most often done when a host is first turned on, so it doesn't have to sit “in limbo” waiting for the next routine advertisement.
- 🕒 **Autoconfiguration:** When required, and if the network supports the function, the host will use information from the local router to allow it to [automatically configure itself](#) with an IP address and other parameters.

**Key Concept:** One of the two main functional groups of the Neighbor Discovery protocol is the set of host-router discovery functions. They allow hosts on a local network to discover the identity of a local router and learn important parameters about how the network is to be used. Host-router discovery operations are performed using ICMPv6 *Router Advertisement* and *Router Solicitation* messages.

---

**Note:** Both *Router Advertisement* and *Router Solicitation* messages may include an optional layer two address of the device sending the message. This is used to update address resolution caches to save time when address resolution is needed later on.

---

## **IPv6 ND Host-Host Communication Functions: Address Resolution, Next-Hop Determination, Neighbor Unreachability Detection and Duplicate Address Detection**

The delivery of datagrams in IP can be divided into two methods: *direct* and *indirect*. Indirect datagram delivery requires that routers provide help to hosts, which leads to the host-router discovery functions we examined in [the previous topic](#). Direct delivery of datagrams is performed from one host to another on the same network. This doesn't require the use of routers, but necessitates other functions IPv6 ND protocol functions that involve Next-Hop Determination communication directly between local hosts.

### ***Next-Hop Determination***

The first task that any host must perform when it wants to send a datagram is *Next-Hop Determination*. This is the process by which a device looks at the destination address in a datagram and decides whether direct or indirect delivery are required. In early IPv4 this was done [by looking at the class of the address, and later on, by using the subnet mask](#). In IPv6, the prefix information obtained from local routers is compared to the destination of the datagram to determine if the destination device is local or distant. If it is local, the next hop is the same as the destination address; if it is non-local, the next hop is chosen from the device's list of local routers (which are determined either by manual configuration or using the host-router discovery features of ND.)

For efficiency purposes, hosts do not perform this next-hop determination for each and every datagram. They maintain a *destination cache* that contains information about what the next hop should be for recent devices to which datagrams have been sent. Each time a next hop determination is performed for a particular destination, information from that determination is entered into the cache, so it can be used the next time datagrams are sent to that device.

### ***Address Resolution***

If a host determines that the destination of a datagram is in fact local, it will then need to send the datagram to that device. The actual transmission will occur using whatever physical layer and data link layer technology has been used to implement the local network. This requires that we know the layer two address of the destination, even though we only generally have the layer three address from the datagram. Getting from the layer three address to the layer two address is known as [the address resolution problem](#).

---

In IPv6, the ND protocol is responsible for address resolution. When a host wants to get the layer two address of a datagram destination it sends a *Neighbor Solicitation* ICMPv6 message containing the IP address of the device whose layer two address it wishes to determine. That device responds back with a *Neighbor Advertisement* message that contains its layer two address. Instead of using a broadcast that would disrupt each device on the local network, the solicitation is sent using a special multicast to the destination device's *solicited-node address*. [A more complete description of address resolution in IPv6 can be found in the general section on address resolution.](#)

Note also that even though this discussion does concentrate on communication between hosts, address resolution may also be done when a host needs to send a datagram to a local router and has no entry for it in its destination cache. In the context of address resolution, a destination device is “just a neighbor”. Whether it is a host or a router only matters in terms of what happens after the datagram has been sent and received. In other words, these “host-to-host” functions are so named only because they are not specific to the communication between hosts and routers like the tasks in the preceding topic.

### ***Updating Neighbors Using Neighbor Advertisement Messages***

Devices do not routinely send *Neighbor Advertisements* the way routers send *Router Advertisements*. There really isn't any need for this: neighbors don't change much over time, and resolution will occur naturally over time as devices send datagrams to each other. In addition, having advertisements sent regularly by so many devices on a network would be wasteful.

A host may, however, send an unsolicited *Neighbor Advertisement* under certain conditions where it feels it is necessary to immediately provide updated information to other neighbors on the local network. A good example of this is a hardware failure—in particular, the failure of a network interface card. When the card is replaced, the device's layer two (MAC) address will change. Assuming this can be detected by the device's IP layer, it can send out an unsolicited *Neighbor Advertisement* message to tell other devices to update their resolution caches with the new MAC address.

### ***Neighbor Unreachability Detection and the Neighbor Cache***

*Neighbor Solicitation* and *Neighbor Advertisement* messages are most often associated with address resolution, but also have other purposes. One of these is *Neighbor Unreachability Detection*. Each device maintains information about each of its neighbors and updates it dynamically as network conditions change. The information is kept for both host and router devices that are neighbors on the local network.

Knowing that a device has become unreachable is important because a host can adapt its behavior accordingly. In the case of an unreachable host, a device may wait a certain period of time before trying to send datagrams to an unreachable host instead of flooding the network with repeated attempts to send to the host. An unreachable router, on the other hand, is a signal that the device needs to find a new router to use, if an alternate is available.

---

Each host maintains a *neighbor cache* that contains information about neighboring devices. Each time a host receives a datagram from a neighbor, it knows the neighbor is reachable at that particular moment, so the device makes an entry in the cache for the neighbor to indicate this. Of course, receiving a datagram from a neighbor now only means the neighbor is reachable now; the more time that elapses since the last datagram was received, the greater the chance that something has happened to make the neighbor no longer reachable.

For this reason, neighbor reachability information must be considered temporary. Each time a neighbor is entered into the cache as reachable, a timer is started. When the timer expires, the reachability information for that neighbor is considered *stale*, and reachability is no longer assumed for that neighbor. When a new datagram is received from the neighbor in question the timer is reset and the cache is again set to indicate that the device is reachable. The amount of time a host should consider a neighbor reachable before expiring it is communicated by a local router using a field in a [Router Advertisement message](#).

A host can also dynamically seek out a neighbor if it needs to know its reachability status. It sends a *Neighbor Solicitation* to the device and waits for a *Neighbor Advertisement* in response. It then updates the cache accordingly.

### ***Duplicate Address Detection***

The last use of the two messages we have been discussing here is for *Duplicate Address Detection*. When a host uses the [IPv6 autoconfiguration facility](#), one of the steps in the process is to ensure that the address it is trying to use doesn't already exist on the network. This is done by sending a *Neighbor Solicitation* message to the address the device wishes to use. If a *Neighbor Advertisement* is received in reply the address is already in use.

**Key Concept:** The second of the two main functional groups of the Neighbor Discovery protocol is the set of host-host communication functions. Two ICMPv6 messages are defined, *Neighbor Advertisement* and *Neighbor Solicitation*, which enable a variety of types of essential communication between adjacent hosts on a local network. These include address resolution, determining the next hop to which a datagram should be sent, and also the assessment of a neighboring device's reachability.

---

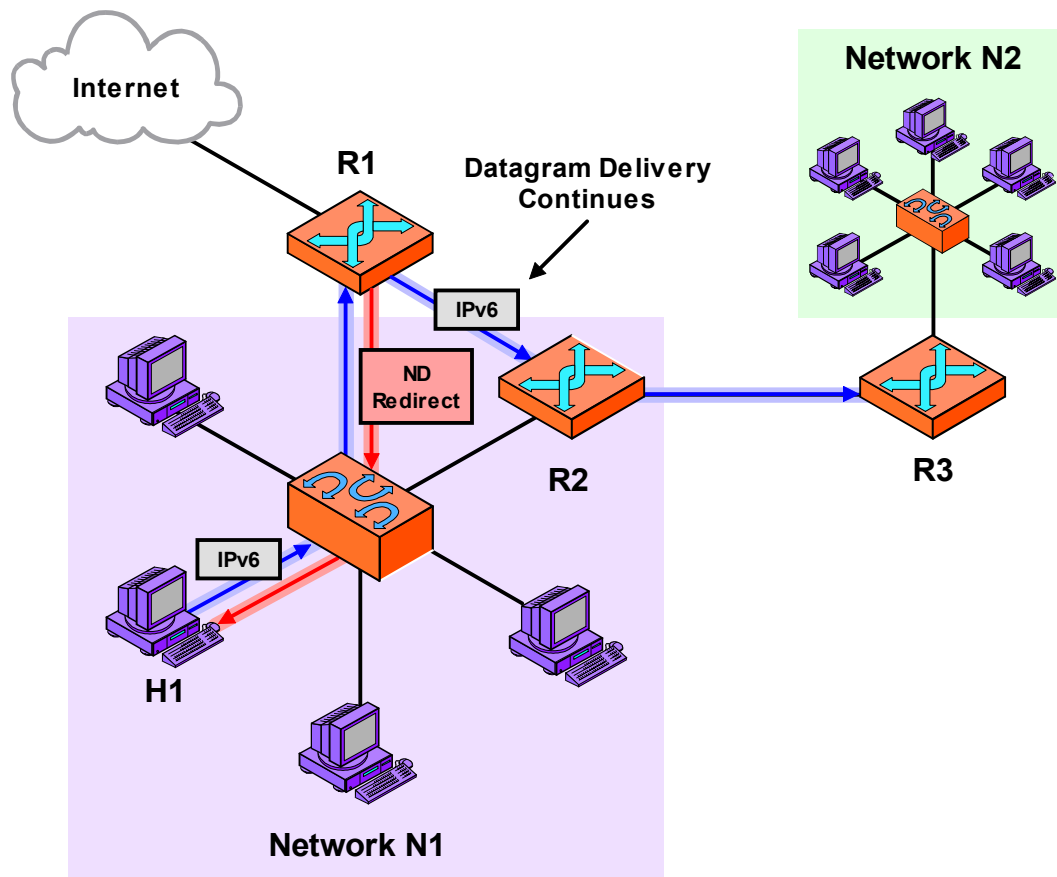

## **IPv6 ND Redirect Function**

The last of the major responsibilities of the IPv6 Neighbor Discovery protocol is the *redirect function*. This is used by a router to inform a host of a better route to use for datagrams sent to a particular destination. An argument could be made that the redirect function should be part of the host-router group since it represents a form of communication between routers and regular hosts. However, it is somewhat different from the other “discovery” functions and so the standard treats it separately.

Routers are responsible for detecting situations where a host on the local network has made an inefficient first-hop routing decision, and then attempting to correct it. For example, consider a network that has two routers on it, *R1* and *R2*. A host *H1* wants to send a datagram to device *X2* on another network that is connected to *H1*'s network through router *R2*. If *H1* sends the datagram to *R1*, *R1* will of course know it has to go through *R2* and will send it there. Seeing that *R2* was also on the local network, *R1* therefore knows that *H1* made a poor initial routing decision: the datagram should have been sent to *R2* directly, not *R1*. If this sounds very similar to ICMPv4 redirect feature, [that's because it is](#).

In response, *R1* will create a special *Redirect* ICMPv6 message. This message will tell *H1* that for any subsequent datagrams to be sent to *X2* should be first sent to *R2* instead of *R1*. It is also possible that a router may determine other situations where the first hop from a particular host should be different and will advise the host using a *Redirect* message. This is illustrated in [Figure 170](#).

**Figure 170: ND Host Redirection Using an ICMPv6 *Redirect* Message**

*H1* sends to *R1* an IPv6 datagram destined for a device on network *N2*. However, *R1* notices that *R2* is on the same network as the source device and is a more direct route to *N2*. It forwards the datagram on to *R2* but also sends an ICMPv6 *Redirect* message back to *H1* to tell it to use *R2* next time.

---

Only routers send *Redirect* messages, not hosts. Hosts are responsible for looking for these *Redirect* messages and processing them. A host receiving such a message will look in it to see which destination's datagram led to the redirect, and which new first hop the router is saying the host should use in the future for that destination. In this case, *H1* will see that *R1* is saying any further datagrams to *X2* should be sent to *R2* instead of *R1*. *H1* will update its destination cache for *X2* accordingly.

**Key Concept:** The Neighbor Discovery protocol redirect function allows a router to tell a host to use a different router for future transmissions to a particular destination. It is similar to the IPv4 redirect feature and is implemented using ICMPv6 *Redirect* messages.

---

When a router sends a *Redirect*, it may also include in the message the data link layer address of the destination to which it is redirecting. This address is used by the host to update its address resolution cache, if necessary. This may save bandwidth in the future by eliminating an address resolution cycle, when the redirected host tries to send to the new, redirected location. In our example, *R1* may include *R2*'s own layer two address in the redirect. This can be used by *H1* the next time it has a datagram for *X2*.

IPv6 also supports authentication of *Redirect* messages, to prevent unauthorized devices from causing havoc by sending inappropriate *Redirects*. A host may be configured to discard *Redirects* that are not properly authenticated.

---

## TCP/IP Routing Protocols (Gateway Protocols)

Routing is not just one of the most important activities that takes place at the network layer: it is the function that really **defines** [layer three of the OSI Reference Model](#). Routing is what enables small local networks to be linked together to form potentially huge internetworks that can span cities, countries or even the entire globe. It is the job done by special devices called *routers*, which forward datagrams from network to network, allowing any device to send to any other even if the source has no idea where the destination is.

Routing is a complicated subject. The short summary of the process is that routers decide how to forward a datagram based on its destination address, which is compared to information the router keeps in special [routing tables](#). These tables contain entries for each of the networks the router knows about, telling the router which adjacent router the datagram should be sent to in order for it to reach its eventual destination.

As you can imagine, routing tables are critically important to the routing process. It is possible for these tables to be manually maintained by network administrators, but this is tedious, time-consuming and doesn't allow routers to deal with changes or problems in the internetwork. Instead, most modern routers are designed with functionality that lets them share route information with other routers, so they can keep their routing tables up to date automatically. This information exchange is accomplished through the use of *routing protocols*.

In this section I provide a description of the most common routing (or gateway) protocols used in TCP/IP. I begin with an overview of various concepts that are important to know in order to understand how routing protocols work. I then describe the TCP/IP routing protocols themselves in two subsections. The first covers interior routing protocols, which are used between routers in an autonomous system, and the second looks at exterior routing protocols, used between autonomous systems.

If you don't understand what an autonomous system is or the difference between an interior and exterior protocol, then you know why I included an overview topic on concepts first. In fact, it is really much easier to understand routing protocols once you have a good background on the entire process of routing.

You may notice that in the title of this section I refer to both *routing protocols* and *gateway protocols*. These terms are interchangeable, and in fact, the word *gateway* appears in the name of several of the protocols. This is an artifact of the historical use of the term *gateway* in early TCP/IP standards to refer to the devices we now call routers. Today, the term *gateway* normally refers not to a router, but to a different type of network interconnection device, so this can be particularly confusing. The term "routing protocol" is now preferred, and is the one I use.

**Note:** Some of the protocols in this section are generic enough that they could be applied to support the routing of any network layer protocol. They are most often associated with IP, however, as TCP/IP is by far the most popular internetworking protocol suite, and that is my assumption in describing them. Also, this section focuses primarily on the routing protocols used in Internet Protocol version 4. There is limited discussion of IPv6 versions of the protocols at this time.

---

**Note:** Strictly speaking, an argument could be made that some routing protocols don't belong in layer three. For example, many of them send messages using TCP or UDP at layer four. Despite this, routing is inherently a layer three activity and for this reason, it is traditional to consider routing protocols part of layer three.

---

**Note:** Like all topics related to routing, routing protocols are generally quite complex. I cover the major ones here in more detail than most general networking references, but even so, you should recognize that I am only scratching the surface, especially of the more complicated ones like OSPF. You can check out the referenced Internet standards (RFCs) for more details if you desire. I should also point out that there are still more routing protocols in use on IP networks that I do not cover here, such as IS-IS (which is actually an OSI protocol and not formally part of TCP/IP).

---

---

## Overview Of Key Routing Protocol Concepts: Architectures, Protocol Types, Algorithms and Metrics

Routing protocols play an important part in the overall process of routing in an internetwork. It is therefore easiest to understand them in the scope of an overall discussion of routing. It's difficult to describe the individual TCP/IP routing protocols without some background information on how routing protocols work. For this reason, I feel it is worth taking a brief look at key routing protocol concepts here, so that you will have more luck making sense of the rest of the routing protocol topics in this section.

### ***Routing Protocol Architectures***

Let's start with a look at routing protocol architectures. In this context, the word *architecture* refers to the way that an internetwork is structured. Once we have a number of networks and routers we wish to connect together, there are any number of ways that we can do this. The architecture we choose is based on the way that routers are linked up, and this has an impact on the way that routing is done, and how routing protocols operate.

#### **Core Architecture**

TCP/IP and the Internet were developed simultaneously, so TCP/IP routing protocols evolved as the Internet itself did. Early architecture of the Internet consisted of a small number of *core* routers that contained comprehensive information about the internetwork. When the Internet was very small, it was expanded by adding more routers to this core. However, each time the core was expanded, the amount of routing information that needed to be maintained grew.

Eventually, the core became too large, so a two-level hierarchy was formed to allow further expansion. *Non-core* routers were located on the periphery of the core and contained only partial routing information; they relied on the core routers for transmissions that went across the internetwork. A special routing protocol called the *Gateway-to-Gateway Protocol (GGP)* was used within the core of the internetwork, while another protocol called the *Exterior Gateway Protocol (EGP)* was used between non-core and core routers. The non-core routers were sometimes single, stand-alone routers that connected a single network to the core, or they could be sets of routers for an organization.

This architecture served for a while, but itself did not **scale** very well as the Internet grew. The problem was mainly due to the fact that there was only a single level to the architecture: every router in the core had to communicate with every other. Even with peripheral routers being kept outside the core, the amount of traffic in the core kept growing.

#### **Autonomous System (AS) Architecture**

To resolve the limitations of the early core system, a new architecture was created that moved away from the centralized concept of a core towards an architecture that was better suited to a larger and growing internetwork. This decentralized architecture treats the

---

Internet as a set of independent groups, which each group called an *autonomous system* (AS). An AS consists of a set of routers and networks controlled by a particular organization or administrative entity, which uses a single consistent policy for internal routing.

The power of this system is that routing on the internetwork as a whole occurs between ASes and not individual routers. Information is only shared between one or maybe a couple of routers in each AS, not every router in each AS. The details of routing within an AS are also hidden from the rest of the internetwork. This provides both flexibility for each AS to do routing as it sees fit (thus the name *autonomous*) and efficiency for the overall internetwork. Each AS has its own number, and the numbers are globally managed to make sure they are unique across an internetwork (such as the Internet).

**Key Concept:** Large, modern TCP/IP internetworks can contain thousands of routers. To better manage routing in such an environment, routers are grouped into constructs called *autonomous systems*. Each autonomous system (AS) consists of a group of routers managed independently by a particular organization or entity.

---

### ***Modern Protocol Types: Interior and Exterior Routing Protocols***

The different nature of routing within an AS and between ASes can be seen in the fact that distinct sets of TCP/IP routing protocols are used for each type:

- ☉ **Interior Routing Protocols:** These protocols are used to exchange routing information between routers within an autonomous system. Interior routing protocols are not used between ASes.
- ☉ **Exterior Routing Protocols:** These protocols are used to exchange routing information between autonomous systems. They may in some cases be used between routers within an AS, but primarily deal with exchanging information between autonomous systems.

**Key Concept:** Interior routing protocols are used to share routing information within an autonomous system; each AS may use a different interior routing protocol because the system is, as the name says, autonomous. Exterior routing protocols convey routing data between autonomous systems; each AS must use the same exterior protocol to ensure that they can communicate.

---

Since autonomous systems are just sets of routers, this means that ASes are connected by linking a router in one AS to a router in another AS. Architecturally, an AS consists of a set of routers with two different types of connectivity:

- ☉ **Internal Routers:** Some routers in an AS connect only to other routers in the same AS. These run interior routing protocols.

- **Border Routers:** Some routers in an AS connect both to routers within the AS and to routers in one or more other ASes. These devices are responsible for passing traffic between the AS and the rest of the internetwork. They run both interior and exterior routing protocols.

Due to its advantages, the autonomous system architecture, an example of which can be seen in [Figure 171](#), has become the standard for TCP/IP networks, most notably the Internet. The division of routing protocols into the interior and exterior classifications has thus also become standard, and all modern TCP/IP routing protocols are first subdivided by type in this manner. You can see this reflected in the subsection titles in the rest of this section on routing protocols.

**Figure 171: TCP/IP Autonomous System (AS) Routing Architecture**

This diagram shows a simplified internet organized into three autonomous systems (ASes), each of which is managed independently of the others. Communication within each AS is done using an interior routing protocol chosen by that AS's administrators (blue links); communication between ASes must be done using a common exterior routing protocol (red links). Internal routers are shown in blue and border routers in red.

### ***Routing Protocol Algorithms and Metrics***

Another key differentiation of routing protocols is on the basis of the *algorithms* and *metrics* they use. An algorithm refers to a method that the protocol uses for determining the best route between any pair of networks, and for sharing routing information between routers. A

---

metric is a measure of “cost” that is used to assess the efficiency of a particular route. Since internetworks can be quite complex, the algorithms and metrics of a protocol are very important, and can be the determining factor in deciding that one protocol is superior to another.

There are two routing protocol algorithms that are most commonly encountered: distance-vector and link-state. There are also protocols that use a combination of these methods, or others.

### **Distance-Vector (Bellman-Ford) Routing Protocol Algorithm**

A *distance vector* routing algorithm, also called a *Bellman-Ford* algorithm after two of its inventors, is one where routes are selected based on the distance between networks. The distance metric is something simple—usually the number of “hops”, or routers between them.

Routers using this type of protocol maintain information about the distance to all known networks in a table. They regularly send that table to each router they immediately connect with (their *neighbors* or *peers*). These routers then update their tables and send to their neighbors. This causes distance information to propagate across the internetwork, so that eventually each router obtains distance information about all networks on the internet.

Distance-vector routing protocols are somewhat limited in their ability to choose the best route. They also are subject to certain problems in their operation that must be worked around through the addition of special heuristics and features. Their chief advantages are simplicity and history (they have been used for a long time).

### **Link-State (Shortest Path First) Routing Protocol Algorithm:**

A *link-state* algorithm selects routes based on a dynamic assessment of the shortest path between any two networks, and is for that reason also called a *shortest-path first* method. Each router maintains a map describing the current topology of the internetwork. This map is updated regularly by testing reachability of different parts of the internet, and by exchanging link-state information with other routers. The determination of the best route (“shortest path”) can be made based on a variety of metrics that indicate the true cost of sending a datagram over a particular route.

Link-state algorithms are much more powerful than distance-vector algorithms. They adapt dynamically to changing internetwork conditions, and also allow routes to be selected based on more realistic metrics of cost than simply the number of hops between networks. However, they are more complicated to set up and use more computer processing resources than distance-vector algorithms, and aren't as well-established.

### **Hybrid Routing Protocol Algorithms**

There are also hybrid protocols that combine features from both types of algorithms, and other protocols that use completely different algorithms. For example, the [Border Gateway Protocol \(BGP\)](#) is a *path-vector* algorithm, which is somewhat similar to the distance-vector

---

algorithm, but communicates much more detailed route information. It includes some of the attributes of distance-vector and link-state protocols, but is more than just a combination of the two.

### ***Static and Dynamic Routing Protocols***

You may also occasionally see routing protocols categorized by type as *static* and *dynamic*, so this is the last concept I want to discuss in this overview. This terminology is somewhat misleading. The term “static routing” simply refers to a situation where the routing tables are manually set up, so they remain static. In contrast, “dynamic routing” is the subject of this entire section: the use of routing protocols to dynamically update routing tables. Thus, ***all*** routing protocols are “dynamic”. There is no such thing as a “static routing protocol” unless you consider a network administrator editing a routing table a “protocol”.

---

## **TCP/IP Interior Routing Protocols (RIP, OSPF, GGP, HELLO, IGRP, EIGRP)**

Modern TCP/IP routing architecture groups routers into *autonomous systems (ASes)* that are independently controlled by different organizations and companies. The routing protocols used to facilitate the exchange of routing information between routers within an AS are called *interior routing protocols* (or historically, *interior gateway protocols*). Since most network administrators are responsible for routers within a particular organization, these are the routing protocols you are most likely to deal with unless you become a major Internet big-shot. ☺

One of the benefits of autonomous systems architecture is that the details of what happens within an AS are hidden from the rest of the internetwork. This means that there is no need for universal agreement on a single “language” for an internet as is the case for exterior routing protocols. As a network administrator for an AS, you are free to choose whatever interior routing protocol best suits your networks. The result of this is that there is no agreement on the use of a single TCP/IP interior routing protocol. There are several common ones in use today, though as is usually the case, some are more popular than others.

In this section I provide a description of six different protocols used for routing within autonomous systems in TCP/IP. The first two sections provide comprehensive descriptions of two of the most popular TCP/IP interior routing protocols: the Routing Information Protocol (RIP) and Open Shortest Path First (OSPF). The third section provides a more brief discussion of two historical interior routing protocols and two proprietary ones developed by networking leader Cisco Systems.

---

## **TCP/IP Routing Information Protocol (RIP, RIP-2 and RIPng)**

The most popular of the TCP/IP interior routing protocols is the *Routing Information Protocol (RIP)*. The simplicity of the name matches the simplicity of the protocol—RIP is one of the easiest to configure and least resource-demanding of all the routing protocols. Its popularity is due both to this simplicity and its long history. In fact, support for RIP has been built into operating systems for as long as TCP/IP itself has existed.

In this section I describe the characteristics and operation of the TCP/IP Routing Information Protocol (RIP). There are three versions of RIP: RIP versions 1 and 2 for IP version 4 and RIPng (*next generation*) for IP version 6. The basic operation of the protocol is mostly the same for all three versions, but there are also some notable differences between them, especially in terms of the format of messages sent.

For this reason, I have divided my description of RIP into two subsections. In the first, I describe the fundamental attributes of RIP and its operation in general terms for all three versions. In the second, I take a closer look at each version, showing the message format used for each and discussing version-specific features as well.

---

## **RIP Fundamentals and General Operation**

The *Routing Information Protocol (RIP)* was one of the first interior routing protocols used in TCP/IP. Over 20 years later, it continues to be widely used. Even though RIP has important limitations that have caused some to malign it and in fact led to the development of newer routing protocols that are technically superior to it, RIP continues to have an important place in TCP/IP routing to this day. Evidence that RIP has a future can be seen in the creation of an IPv6 version of the protocol: *RIPng*.

In this section, I provide an overall description of the characteristics of RIP and how it works in general terms. I begin with an overview and history of the protocol, including a brief discussion of its different versions and the standards that define them. I describe the method that RIP uses to determine routes and the metric used to assess route cost. I describe the general operation of the protocol including message types and when they are sent. I then describe the most important limitations and issues with RIP, and the special features that have been added to the protocol to resolve several problems with the basic RIP algorithm.

### **RIP Overview, History, Standards and Versions**

The Routing Information Protocol (RIP) has been the most popular interior routing protocol in the TCP/IP suite for many years. The history of the protocol and how it came to achieve prominence is a rather interesting one. Unlike many of the other important protocols in the TCP/IP suite, RIP was not first developed formally using the [RFC standardization process](#). Rather, it evolved as a [de facto industry standard](#) and only became an Internet standard later on.

#### ***Early History of RIP***

The history of RIP shares some commonality with that of another networking heavyweight: Ethernet. Like the formidable LAN technology, RIP's roots go back to that computing pioneer, Xerox's Palo Alto Research Center (PARC). At the same time that Ethernet was being developed for tying together local area networks, PARC created a higher layer protocol to run on Ethernet called the *Xerox PARC Universal Protocol (PUP)*. PUP required a routing protocol, so Xerox created a protocol called the *Gateway Information Protocol (GWINFO)*. This was later renamed the *Routing Information Protocol* and used as part of the *Xerox Network System (XNS)* protocol suite.

RIP entered the mainstream when developers at the University of California at Berkeley adapted it for use in the Berkeley Standard Distribution (BSD) of the UNIX operating system. RIP first appeared in BSD version 4.2 in 1982, where it was implemented as the UNIX program *routed* (pronounced “route-dee”, not “rout-ed”—the “d” stands for *daemon*, a common UNIX term for a server process.)

---

BSD was (and still is) a very popular operating system, especially for machines connected to the early Internet. As a result, RIP was widely deployed and became the industry standard for internal routing protocols. It was used both for TCP/IP and also other protocol suites. In fact, a number of other routing protocols, such as the RTP protocol in the AppleTalk suite, were based on this early version of RIP.

### ***RIP Standardization***

For a while, the BSD implementation of *routed* was actually considered the standard for the protocol itself. However, this was not a formally defined standard, and this meant there was no formal definition of how exactly it functioned. This led to slight differences in various implementations of the protocol over time. To resolve potential interoperability issues between implementations, the IETF formally specified RIP in the Internet standard RFC 1058, *Routing Information Protocol*, published in June 1988. This RFC was based directly on the BSD *routed* program. This original version of RIP is now also sometimes called *RIP version 1* or *RIP-1* to differentiate it from later versions.

RIP's popularity was due in large part to its inclusion in BSD; this was in turn a result of the relative simplicity of the protocol. RIP uses the [distance-vector algorithm](#) (also called the Bellman-Ford algorithm after two of its inventors) to determine routes. Each router maintains a routing table containing entries for various networks or hosts in the inter-network. Each entry contains two primary pieces of information: the address of the network or host, and the distance to it, measured in *hops*, which is simply the number of routers that a datagram must pass through to get to its destination.

### ***RIP Operational Overview, Advantages and Limitations***

On a regular basis, each router in the internetwork sends out its routing table in a special message on each of the networks to which it is connected, using [UDP](#). Other routers receive these tables and use them to update their own tables. This is done by taking each of the routes they receive and adding an extra hop. For example, if router *A* receives an indication from router *B* that network *N1* is 4 hops away, then since router *A* and router *B* are adjacent, the distance from router *A* to *N1* is 5. After a router updates its tables, it in turn sends out this information to other routers on its local networks. Over time, routing distance information for all networks propagates over the entire internetwork.

RIP is straight-forward in operation, easy to implement, and undemanding of router processing power, which makes it attractive especially in smaller autonomous systems. There are, however, some important limitations that arise due to the simplicity of the protocol. For starters, hops are often not the best metric to use in selecting routes. There are also a number of problems that arise with the algorithm itself. These include slow convergence (delays in having all routers agree on the same routing information) and problems dealing with network link failures.

RIP includes several special features to resolve some of these issues, but others are inherent limitations of the protocol. For example, RIP only supports a maximum of 15 hops between destinations, making it unsuitable for very large autonomous systems, and this cannot be changed.

**Key Concept:** The *Routing Information Protocol (RIP)* is one of the oldest and most popular interior routing protocols. It uses a distance-vector algorithm with each router maintaining a table indicating how to reach various networks in the autonomous system and the distance to it in hops. RIP is popular because it is well-established and simple, but has a number of important limitations.

---

### ***Development of RIP Version 2 (RIP-2) and RIPng for IPv6***

Some other issues with RIP were a result of its having been developed in the early 1980s when TCP/IP was still in its infancy. Over time, as the use of TCP/IP protocols changed, RIP became outdated. In response, *RIP Version 2*, or *RIP-2* was created in the early 1990s. RIP-2 defines a new message format for RIP and includes a number of new features, including support for classless addressing, authentication, and the use of multicasting instead of broadcasting to improve network performance. It was first defined in RFC 1388, *RIP Version 2 Carrying Additional Information*, published in January 1993. This RFC was revised in RFC 1723, and finalized in RFC 2453, *RIP Version 2*, November 1998.

Over two decades after it was first created, RIP continues to be a popular interior routing protocol. Its limitations have led to many internetworking experts hoping that the protocol would eventually “go away”, in favor of newer protocols like [OSPF](#) that are superior on a strictly technical basis. Some have gone so far as to sarcastically suggest that maybe it would be best if RIP would “R. I. P.” (“rest in peace”). ☺ Once a protocol becomes popular, however, it’s hard to resist momentum, and RIP is likely to continue to be used for many years to come.

In order to ensure that RIP can work with TCP/IP in the future, it was necessary to define a version that would work with the new [Internet Protocol version 6 \(IPv6\)](#). In 1997, RFC 2080 was published, titled *RIPng for IPv6*. The *ng* stands for *next generation*—recall that IPv6 is also sometimes called *IPng*. RIPng is not just a new version of RIP, like RIP-2, but is defined as a new standalone protocol. It is, however, based closely on the original RIP and RIP-2 standards. A distinct protocol (as opposed to a revision of the original) was needed due to the changes made between IPv4 and IPv6, though RIP and RIPng work in the same basic way. RIPng is sometimes also called *RIPv6*.

**Key Concept:** The original version of RIP has the fewest features and is now called *RIP-1*. *RIP-2* was created to add support for classless addressing and other capabilities. *RIPng* is the version created for compatibility with IPv6.

---

### **RIP Route Determination Algorithm and Metric**

As I mentioned in [the overview topic on TCP/IP routing protocols](#), one of the defining characteristics of any routing protocol is the *algorithm* it uses for determining routes. RIP falls into the class of protocols that use a *distance-vector* or *Bellman-Ford* routing algorithm.

---

To help you better understand exactly how RIP determines routes, I will now discuss the specific implementation of the algorithm for RIP and provide an example so you can see exactly how RIP determines routes and propagates information across a network.

### ***RIP Routing Information and Route Distance Metric***

The job of RIP, like any routing protocol, is to provide a mechanism for exchanging information about routes so routers can keep their routing tables up to date. Each router in an RIP internetwork keeps track in its routing table of all networks (and possibly individual hosts) in the internetwork. For each network or host, the device includes a variety of information, of which the following are the most important:

- ☉ The address of the network or host.
- ☉ The distance from that router to the network or host.
- ☉ The first hop for the route: the device to which datagrams must first be sent to eventually get to the network or host.

In theory, the distance metric can be any assessment of cost, but in RIP, distance is measured in *hops*. As you probably already know, in TCP/IP vernacular, a datagram makes a *hop* when it passes through a router. Thus, the RIP distance between a router and a network measures the number of routers that the datagram must pass through to get to the network. If a router connects to a network directly, then the distance is 1 hop. If it goes through a single router, the distance is 2 hops, and so on. In RIP, a maximum of 15 hops are allowed for any network or host. The value 16 is defined as *infinity*, so an entry with 16 in it means “this network or host is not reachable”.

### ***RIP Route Determination Algorithm***

On a regular basis, each router running RIP will send out its routing table entries to provide information to other routers about the networks and hosts it knows how to reach. Any routers on the same network as the one sending out this information will be able to update their own tables based on the information they receive. Any router that receives a message from another router on the same network saying it can reach network X at a cost of  $N$ , knows it can reach network X at a cost of  $N+1$  by sending to the router it received the message from.

### ***RIP Route Determination and Information Propagation Example***

Let's take a specific example to help us understand better how routes are determined using RIP. Consider a relatively simple internetwork with four individual networks, connected as follows:

- ☉ Router A (RA) connects Network 1 (N1) to Network 2 (N2).
- ☉ Routers B (RB) and C (RC) connect Network 2 to Network 3 (N3).
- ☉ Router D (RD) connects Network 3 to Network 4 (N4).

This example autonomous system is illustrated in [Figure 172](#).

**Figure 172: Example RIP Autonomous System**

This is an example of a simple autonomous system that contains four physical networks and four routers.

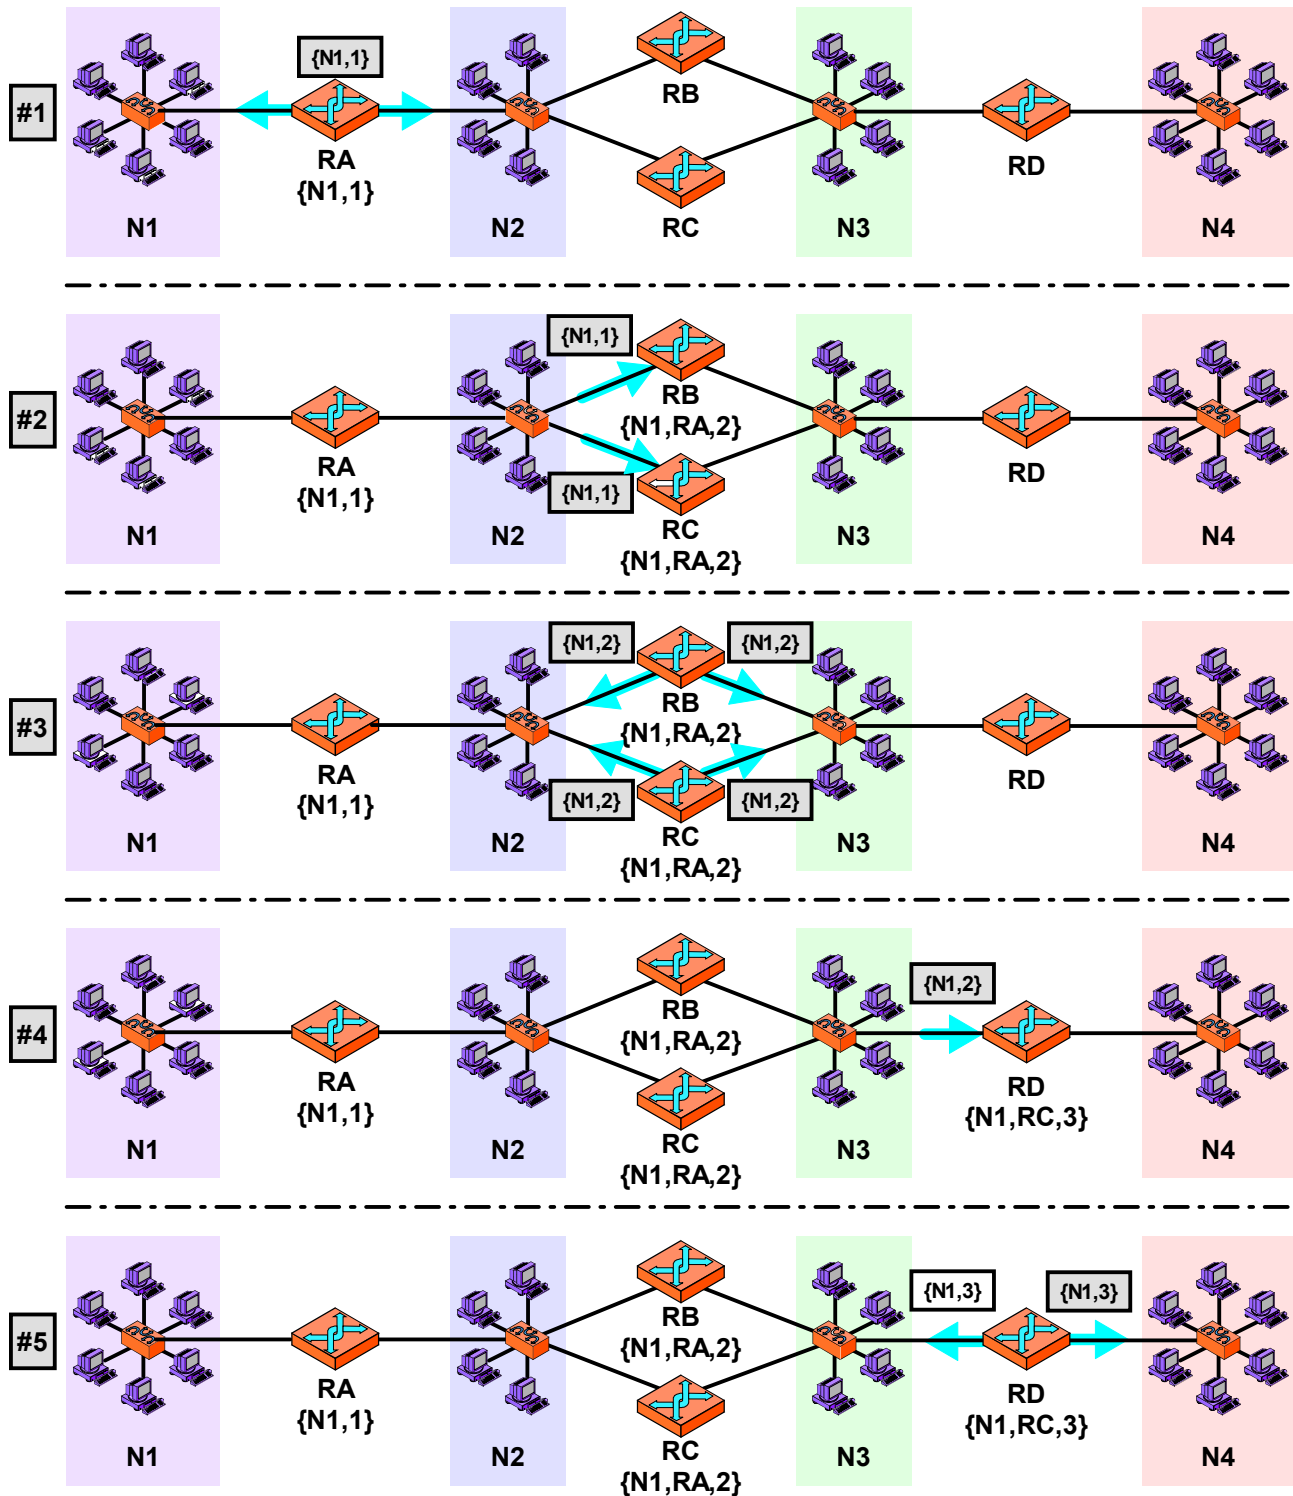

Now, let's suppose that we just turned on router *RA*. It sees that it is directly connected to *N1* and *N2*, so it will have an entry in its routing table indicating that it can reach *N1* at a cost of 1, which we can represent as {*N1*,1}. Information about Network 1 will propagate from Router *RA* across the internetwork in the following sequence of steps (which you can observe graphically in [Figure 173](#)):

1. Router *A* sends out an RIP message containing the entry {*N1*,1} on each of the networks to which it is connected. There are no other routers on *N1*, so nothing happens there. But *RB* and *RC* are on *N2* so they receive the information.
2. *RB* and *RC* will look in their routing tables to see if they already have entries for *N1*. Assuming neither does, they will each create a routing table entry {*N1*,2} for Router *A*. This means "I can reach Network 1 at a cost of 2 hops by sending to Router *A*".
3. *RB* and *RC* will each send their own routing tables out over the networks to which they are connected: *N2* and *N3*. This will contain the entry {*N1*,2}. *RA* will receive that message on *N2* but will ignore it, since it knows it can reach *N1* directly (cost of 1, which is less than 2). But Router *D* will receive the message on *N3*.
4. *RD* will examine its routing table, and seeing no entry for *N1* will add the entry {*N1*,3} for *RB* or *RC*. Of course, either one will work, so which is chosen depends entirely on whether *RD* received information about *N1* first from *RB* or *RC*.
5. *RD* will send the entry {*N1*,3} on Network 4, but of course there are no other routers there to hear it.

RIP is designed so that a routing entry is only replaced if information is received about a **shorter** route; ties go to the incumbent, if you will. This means that once *RD* creates an entry for *N1* with a cost of 3 going through *RB*, if it receives information that it can reach *N1* at the same cost of 3 through *RC*, it will ignore it. Similarly, if it gets *RC*'s info first, it will ignore the information from *RB*.

Naturally, this same propagation scheme will occur for all the other networks as well; I have just shown only how information about *N1* moves from router to router. For example, Router *A* will eventually install an entry for *N4* saying that it is reachable at a cost of 3 going through either *RB* or *RC*: this will be either {*N4*,*RB*,3} or {*N4*,*RC*,3}.

This propagation of network routing information occurs on a regular basis, and also when the structure of the network changes (due to either intentional changes in topography or failure of links or routers). When this happens the change information will move through the

**Figure 173: Propagation of Network Routing Information Using RIP**

This composite diagram illustrates the five steps in propagating route information about network *N1* from *RA* to the rest of the autonomous system. In Step #1 the information is sent from *RA* to both of its connected networks. In Step #2 it reaches routers *RB* and *RC*, which then know they can reach *N1* through *RA* at a cost of one additional hop. In Step #3 these two routers send this information on their networks, and in Step #4 it reaches *RD*. In Step #5 *RD* sends out the information, but no other routers are around to receive it.

---

internetwork so that all routers are eventually updated. For example, suppose a connection were added from Router C to Network 1. If Router D previously had the entry {N1,RB,3}, it would eventually change this to {N1,RC,2}, since it could now reach N1 more quickly by going through Router C.

### **Default Routes**

In some cases it is not convenient for every network or host in a large internetwork to be fully specified with its own routing entry. In this case it may be advantageous to specify a *default route* for the network to use in reaching hosts or networks for which they have no information. The most common example of this is when an autonomous system connects to the public Internet through a single router. Except for that router, the rest of the local network doesn't need to know how to access the Internet.

In RIP, information about a default route is communicated by having routers intended to handle such traffic send information about a “dummy” network with the address 0.0.0.0. This is treated as if it were a regular network when information about routes is propagated on the internetwork using RIP messages, but other devices recognize this special address and understand it means a default route.

**Note:** The algorithm description in this topic is the basic one used by RIP. This is modified in certain ways to address some of the problems that can occur in special circumstances due to how the algorithm works. Topics later in this chapter describe these problems and the special features RIP includes to address them.

---

**Key Concept:** Routing information is propagated between routers in RIP using a simple algorithm. On a regular basis, each router sends out RIP messages that specify what networks it can reach, and how many hops to reach them. Other routers directly connected to that one know that they can then reach those networks through that router at a cost of one additional hop. So if router A sends a message saying it can reach network X for a cost of  $N$  hops, each other router that connects directly to A can reach network X for a cost of  $N+1$  hops. It will put that information into its routing table, unless it knows of an alternate route through another router that has a lower cost.

---

### **RIP General Operation, Messaging and Timers**

RIP is a protocol for exchanging routing information, so its operation can best be described in terms of the messages used to exchange this information, and the rules for when messages are sent. The RIP software in each router sends messages and takes other actions both in reaction to certain events and in response to triggers set off by timers. Timers are also used to determine when routing information should be discarded if not updated.

---

## ***RIP Messages and Basic Message Types***

Communication between RIP software elements in routers on an internetwork is accomplished through the use of *RIP messages*. These messages are sent using the [User Datagram Protocol \(UDP\)](#), with reserved UDP port number 520 for RIP-1 and RIP-2, and 521 for RIPng. Thus, even though RIP is considered part of layer three like other routing protocols, it behaves more like an application in terms of how it sends messages. The exact format of the message is version-dependent, and all three formats (for RIP, RIP-2 and RIPng) are described in detail in [their own section](#). RIP messages can be either sent to a specific device, or can be sent out for multiple devices to receive. If directed to one device they are sent unicast; otherwise, they are either broadcast (in RIP) or multicast (RIP-2 and RIPng).

There are only two basic message types for all three versions of RIP:

- ☉ ***RIP Request***: A message sent by a router to another router asking it to send back all or part of its routing table.
- ☉ ***RIP Response***: A message sent by a router containing all or part of its routing table. Note that despite the name, this message is **not** sent just in response to an *RIP Request* message, as we will see. So it's not really that great a name... oh well.

**Note:** The original RIP also defined a few other message types: *Traceon*, *Traceoff* and a special message type reserved for use by Sun Microsystems. These are obsolete and no longer used, and were removed from the RIP-2 and RIPng standards.

---

## ***RIP Update Messaging and the 30-Second Timer***

*RIP Request* messages are sent under special circumstances, when a router requires that it be provided with immediate routing information. The most common example of this is when a router is first powered on. After initializing, the router will typically send an *RIP Request* on its attached networks to ask for the latest information about routes from any neighboring routers. It is also possible for *RIP Request* messages to be used for diagnostic purposes.

A router receiving an *RIP Request* will process it and send an *RIP Response* containing either all of its routing table, or just the entries the *Request* asked for, as appropriate. Under normal circumstances, however, routers do not usually send *RIP Request* messages asking specifically for routing information. Instead, a special timer is used on each RIP router that goes off every 30 seconds. (This timer is not given a specific name in the RIP standards; it is just “the 30 second timer”).

Each time the timer expires, an unsolicited (unrequested) broadcast/multicast is made of an *RIP Response* message containing the router's entire routing table. The timer is then reset and 30 seconds later goes off again, causing another routine *RIP Response* to be sent. This process ensures that route information is regularly sent around the internet, so routers are always kept up to date about routes.

**Key Concept:** RIP uses two basic message types, the *RIP Request* and *RIP Response*, both of which are sent using the *User Datagram Protocol (UDP)*. *RIP Response* messages, despite their name, are used both for routine periodic routing table updates as well as to reply to *RIP Request* messages. Requests are sent only in special circumstances, such as when a router first joins a network.

---

### ***Preventing Stale Information: The Timeout Timer***

When a router receives routing information and enters it into its routing table, that information cannot be considered valid indefinitely. [In our example in the previous topic](#), suppose that after Router *B* installs a route to Network 1 through Router *A*, the link to between *RA* and *N2* fails. Once this happens, *N1* is no longer reachable from *RB*, but *RB* has a route indicating it **can** reach Network 1.

To prevent this problem, routes are only kept in the routing table for a limited amount of time. A special *Timeout* timer is started whenever a route is installed in the routing table. Whenever the router receives another *RIP Response* with information about that route, the route is considered “refreshed” and its *Timeout* timer is reset. As long as the route continues to be refreshed, the timer will never expire.

If, however, *RIP Responses* containing that route stop arriving, the timer will eventually expire. When this happens, the route is marked for deletion, by setting the distance for the route to 16 (which you may recall is *RIP infinity* and indicates an unreachable network). The default value for the *Timeout* timer is usually 180 seconds. This allows several periodic updates of a route to be missed before a router will conclude that the route is no longer reachable.

### ***Removing Stale Information: The Garbage-Collection Timer***

When a route is marked for deletion, a new *Garbage-Collection* timer is also started. “Garbage collection” is a computer industry phrase for a task that looks for deleted or invalid information and cleans it up. Thus, this is a timer that counts a number of seconds before the newly invalid route will be actually removed from the table. The default value for this timer is 120 seconds.

The reason for using this two-stage removal method is to give the router that declared the route no longer reachable a chance to propagate this information to other routers. Until the *Garbage-Collection* timer expires, the router will include that route, with the “unreachable” metric of 16 hops, in its own *RIP Responses*, so other routers are informed of the problem with that route. When the timer expires the route is deleted. If during the garbage collection period a new *RIP Response* for the route is received, then as you might expect the deletion process is aborted: the *Garbage-Collection* timer is cleared, the route is marked as valid again, and a new *Timeout* timer starts.

---

## ***Triggered Updates***

In addition to the two situations already described where an *RIP Response* is sent—in reply to an *RIP Request* and on expiration of the 30-second timer—an *RIP Response* is also sent out when a route changes. This action, an enhancement to basic RIP operation called a *triggered update*, is intended to ensure that information about route changes is propagated as fast as possible across the internetwork, to help reduce the “slow convergence” problem in RIP. For example, in the case we just saw where a route timed out and the *Garbage-Collection* timer was started, a triggered update would be sent out about the now-invalid route immediately. [This is described in more detail in the topic on RIP special features.](#)

## **RIP Protocol Limitations and Problems**

The simplicity of the Routing Information Protocol is often given as the main reason for its popularity; I certainly have mentioned this enough times in this section. Simplicity is great most of the time, but an unfortunate “price” of simplicity in too many cases is that problems crop up, usually in unusual cases or special situations. And so it is with RIP: the straight-forward distance-vector algorithm and operation mechanism work well most of the time, but they have some important weaknesses. We need to examine these problems to understand both the limitations of RIP and some of the complexities that have been added to the protocol to resolve them.

### ***Problems With RIP’s Basic Algorithm and Implementation***

The most important area where we find serious issues with RIP is with the basic function of the distance-vector algorithm described earlier in this section, and the way that messages are used to implement it. There are four main problems here: slow convergence, routing loops, “counting to infinity” and “small infinity”.

#### **Slow Convergence**

The distance-vector algorithm is designed so that all routers share all their routing information regularly. Over time then, all routers eventually end up with the same information about the location of networks and which are the best routes to use to reach them. This is called *convergence*. Unfortunately, the basic RIP algorithm is rather slow to achieve convergence. It takes a long time for all routers to get the same information, and in particular, it takes a long time for information about topology changes to propagate.

Consider the worst-case situation of two networks separated by 15 routers. Since routers normally send *RIP Response* messages only every 30 seconds, a change to one of this pair of networks might not be seen by the router nearest the other one until many minutes have elapsed—an eternity in networking terms.

The slow convergence problem is even more pronounced when it comes to the propagation of route failures. Failure of a route is only detected through the expiration of the 180-second *Timeout* timer, so that adds up to three minutes more delay before convergence can even begin.

---

## Routing Loops

A routing loop occurs when Router *A* has an entry telling it to send datagrams for Network 1 to Router *B*, and Router *B* has an entry saying that datagrams for Network 1 should be sent to Router *A*. **Larger loops can also exist:** Router *A* says to send to *B*, which says to send to *C*, which says to send to *A*.

While under normal circumstances these loops should not occur, they can happen in special situations. RIP does not include any specific mechanism to detect or prevent routing loops; the best it can do is try to avoid them.

### “Counting To Infinity”

A special case of slow convergence can lead to a routing loop situation where one router passes bad information to another router, which sends more bad information to another router and so on. This causes a situation where the protocol is sometimes described as *unstable*; the problem is called *counting to infinity* for reasons we will soon see.

To understand how this happens, let's modify [the example we looked at in the topic describing the RIP algorithm](#) (you may find it helpful to refer to [Figure 174](#) as you follow this discussion). Suppose that the internetwork is operating properly for a while. Router *B* has an entry indicating it can reach Network 1 through Router *A* at a cost of 2. Now, say the link from Network 1 to Router *A* fails. After the *Timeout* timer for Network 1 expires on Router *A*, *RA* will change the metric for *N1* to 16 to indicate that it is unreachable. In the absence of any mechanism to force *RA* to immediately inform other routers of this failure, they will remain “in the dark”. Router *B* will continue to think it can reach Network 1 through Router *A*.

Now, suppose *RB*'s regular 30 second timer goes off before *RA*'s next broadcast. *RB* will send its normal routing table, **which contains a route to Network 1 at a cost of 2**. Router *A* will see this and say “Hey, look, Router *B* has a route to Network 1 with a cost of 2! That means I can get there with a cost of 3, which sure beats my current cost of 16; let's use that!” So, Router *A* installs this route and cancels its *Timeout* timer. Of course, this is bogus information—Router *A* doesn't realize that Router *B*'s claim of being able to reach Network 1 was based on old information from Router *A* itself!

It only gets worse from there. When it is time for Router *A*'s regular routing table update, it will broadcast a route to Network 1 with a cost of 3. Now, Router *B* will then see this and say “Hmm. Well, my route to Network 1 is through Router *A*. Router *A* was saying before that its cost was 1, but now it says the cost is 3. That means I have to change my cost to 4”.

*RB* will later send back to *RA*, and back and forth they will go, each incrementing the cost two at a time. This won't stop until the value of “infinity” (16) is hit—thus the name *counting to infinity*. At this point both routers will finally agree that Network 1 is unreachable, but as you can see, it takes a long time for it to happen.

**Figure 174: The RIP "Counting To Infinity" Problem**

This composite diagram shows part of the autonomous system illustrated in [Figure 172](#). The top panel (#1) shows the normal state of the network, with *RB* able to reach *N1* through *RA* at a cost of 2. In #2, the link between *RA* and *N1* is broken. *RA* changes its cost to reach *N1* to 16 (RIP infinity). In #3, Before *RA* can send out this update to *RB*, it receives a routine RIP message from *RB* indicating that *N1* can be reached for a cost of 2. *RA* is then fooled into thinking it can use *RB* as an alternate route to *N1*, even though *RB*'s information originally came from *RA* in the first place. In #4, *RA* then sends this bogus information out, which is received by *RB* in #5. *RB* then increases its cost to 4, and on its next cycle will send this to *RA*, which will increase its cost to 5, and so on. This cycle will continue, with both routers "counting to infinity" (16).

---

## “Small Infinity”

The use of a relatively small value of “infinity” limits the slow convergence problem. Even in a situation where we “count to infinity” as we just saw, the total amount of time elapsed is at least manageable; imagine if “infinity” were defined as say, 1000! Unfortunately, the drawback of this is that it limits the size of the internetwork that can be used for RIP.

Many people balk at the limit of a span of 15 routers in RIP, but to be honest I think it is much ado about, well, if not nothing, then at least “nothing much”. The 15 value is not a limit on the total number of routers you can use, just on the number of routers between any two networks. Consider that most internetworks are set up hierarchically; even if you have a rather complex four-level hierarchy you wouldn't be close to the 15-router limit. In fact, you could create a huge autonomous system with thousands of routers without having more than 15 routers between any two devices. So this is only a limitation for the very largest of autonomous systems.

On the other hand, RIP's need to send out its entire routing table many times each hour makes it a potentially poor choice for a large internetwork regardless of the “infinity=16” issue. In an internetwork with many routers, the amount of traffic RIP generates can become excessive.

**Key Concept:** One of the most important problems with the operation of RIP is *slow convergence*, which describes the fact that it can take a long time for information about changes to a network to propagate between routers. One specific instance of this problem is the *counting to infinity* problem, in which out-of-date information causes many bogus RIP messages to be exchanged between routers about an unreachable network.

---

To be fair, these problems are mostly general to distance-vector routing algorithms and not RIP in particular. Some of them are corrected through the implementation of specific changes to the algorithm or the rules under which RIP messages are sent, as described in [the next topic](#). According to RFC 2453, there was actually a proposal to increase RIP's “infinity” to a number larger than 16, but this would have caused compatibility problems with older devices (which would view any route with a metric of 16 or higher as unreachable) so it was rejected.

## Problems With RIP's Metric

In addition to these concerns with the algorithm itself, RIP is also often criticized because of its choice of metric. There are two related issues here:

- 🕒 **Hop Count As A Distance Metric:** Simply put, hop count is a poor metric of the cost of sending a datagram between two networks. I believe the use of hop count as the metric in RIP is partially due to the desire for simplicity (it's easy to make the protocol work when hop count is all the routers need to consider) and partially an artifact of RIP being a 20-plus-year-old protocol. Decades ago computers were slow, so each time a

---

datagram passed through a router there was probably a significant delay. Hop count was not a perfect metric even then, but I think it had more correspondence with how long it took to move a datagram across an internetwork than it does today.

Modern routers are lightning fast, making hop count a flawed way of measuring network distance. The number of hops taken often has no correlation with the actual amount of time it takes to move data across a route. To take an extreme case, consider two networks that are connected by a direct dial-up telephone networking link using 56K modems, and also connected by a sequence of three routers using high-speed DS-3 lines. RIP would consider the 56K link a better route because it has fewer hops, even though clearly it is much slower.

- ☛ **Lack Of Support For Dynamic (Real-Time) Metrics:** Even if RIP were to use a more meaningful metric than hop count, the algorithm requires that the metric be fixed for each link. There is no way to have RIP calculate the best route based on real-time data about various links the way protocols like [OSPF](#) do.

These problems are built into RIP and cannot be resolved easily. Interestingly, some RIP implementations apparently do let administrators “fudge” certain routes to compensate for the limitations of the hop count metric. For example, the routers on either end of the 56K link mentioned above could be configured so they considered the 56K link to have a hop count of 10 instead of 1. This would cause any routes using the link to be more “expensive” than the DS-3 path. This is clever, but hardly an elegant or general solution.

**Note:** In addition to the rather long list of problems above, there were also some specific issues with the first version of RIP. Some of the more important of these include lack of support for CIDR, lack of authentication, and the performance reduction caused by the use of broadcasts for messaging. [These were mostly addressed through extensions in RIP-2.](#)

---

## **RIP Special Features For Resolving RIP Algorithm Problems**

The simplicity of the Routing Information Protocol is its most attractive quality, but also leads to [certain problems with how it operates](#). Most of these limitations are related to the basic algorithm used for determining routes, and the method of message passing used to implement the algorithm. In order for RIP to be a useful protocol, it was necessary that some of these issues be addressed, in the form of changes to the basic RIP algorithm and operational scheme we explored earlier in this section.

The solution to problems that arise due to RIP being too simple is to add complexity, in the form of features that add more intelligence to the way that RIP operates. Let's take a look at four of these: split horizon, split horizon with poisoned reverse, triggered updates and hold-down.

---

## Split Horizon

The “counting to infinity” problem is one of the most serious issues with the basic RIP algorithm. In the example in the previous topic, the cause of the problem is immediately obvious: after Network 1 fails and Router A notices it go down, Router B “tricks” Router A into thinking it has an alternate path to Network 1 by sending Router A a route advertisement to N1.

If you think about it, it doesn't really make sense—under **any** circumstances—to have Router B send an advertisement to Router A about a network that Router B can only access through Router A in the first place. In the case where the route fails it causes this problem, which is obviously a good reason not to do it. But even when the route is operational, what is the point of Router B telling Router A about it? Router A already has a shorter connection to the network and will therefore **never** send traffic intended for Network 1 to Router B anyway.

Clearly, the best solution is simply to have Router B not include any mention of the route to Network 1 in any *RIP Response* messages it sends to Router A. We can generalize this by adding a new rule to RIP operation: when a router sends out an *RIP Response* on any of the networks to which it is connected, it omits any route information that was originally learned from that network. This feature is called *split horizon*, since the router effectively splits its view of the internetwork, sending different information on certain links than on others.

With this new rule, let's consider the behavior of Router B. It has an interface on Network 2, which it shares with Router A. It will therefore not include any information on routes it originally obtained from Router A when sending on N2. This will prevent the “counting to infinity” loop we saw in the previous topic. Similarly, since Router D is on Network 3, Router B will not send any information about routes it got from Router D when sending on Network 3.

Note, however, that split horizon may not **always** solve the “counting to infinity” problem, especially in the case where multiple routers are connected indirectly. The classic example would be three routers configured in a triangle. In this situation, problems may still result due to data that is propagated in two directions between any two routers. In this case, the “hold down” feature may be of assistance (see below).

### Split Horizon With Poisoned Reverse

This is an enhancement of the basic split horizon feature. Instead of omitting routes learned from a particular interface when sending *RIP Response* messages on that interface, we include those routes but set their metric to “RIP infinity”, 16. So in the example above, Router B **would** include the route to Network 1 in its transmissions on Network 2, but it would say the cost to reach N1 was 16, instead of its real cost (which is 2).

The “poisoned reverse” refers to the fact that we are *poisoning* the routes that we want to make sure routers on that interface don't use. Router A will see Router B advertise Network 1 but with a cost of 16, which serves as an explicit message to Router A: “there is absolutely no way for you to get to Network 1 through Router B”. This provides more

insurance than the regular split horizon feature, because if the link from Router A to Network 1 dies as we described in the previous topic, Router A will know for certain that it can't try to get a new route through Router B. Figure 175 shows how split horizon with poisoned reverse works.

This technique also works in normal circumstances (meaning, when there is no issue such as a broken link to a network). In that case, Router A will receive updates from RB with a cost of 16 on a periodic basis, but RA will never try to reach Network 1 through Router B anyway, since it is directly connected to Network 1 (cost of 1).

**Figure 175: RIP Problem Solving Using Split Horizon With Poisoned Reverse**

The top panel in this diagram (#1) shows the same example as in Figure 174. In #2, as before, the link between RA and N1 is broken, just as RB is ready to send out its routine update. However, the split horizon with poisoned reverse feature means it sends different messages on its two links; on the network that connects it to RA, it sends a route advertisement with a cost of 16. In #3, Router A receives this, which it will discard, ensuring no counting to infinity problem occurs. On RA's next cycle it will update RB to tell it that N1 is no longer reachable.

---

## Triggered Updates

The routing loop problem we looked at in the previous topic occurred because Router *B* advertised Router *A*'s route back to Router *A*. There's another aspect of the problem that is also significant: after Router *A* discovered that the link to Network *1* failed, it had to wait up to 30 seconds until its next scheduled transmission time to tell other routers about the failure.

For RIP to work well, when something significant happens we want to tell other routers on the internetwork immediately. For this reason, a new rule should be added to the basic RIP router operation: whenever a router changes the metric for a route it is required to (almost) immediately send out an *RIP Response* to tell its immediate neighbor routers about the change. If these routers, seeing this change, update their routing information, they are in turn required to send out updates. Thus, the change of any network route information causes cascading updates to be sent throughout the internetwork, significantly reducing the slow convergence problem. Note that this includes removal of a route due to expiration of its *Timeout* timer, since the first step in route removal is setting the route's metric to 16, which triggers an update.

You probably noticed that I said that triggered updates were sent “almost” immediately. In fact, before sending a triggered update a route waits a random amount of time, from 1 to 5 seconds. This is done to reduce the load on the internetwork that would result from many routers sending update messages nearly simultaneously.

## Hold-Down

Split horizon tries to solve the “counting to infinity” problem by suppressing the transmission of invalid information about routes that fail. For extra insurance, we can implement a feature that changes how devices receiving route information process it in the case of a failed route. The *hold down* feature works by having each router start a timer when they first receive information about a network that is unreachable. Until the timer expires, the router will discard any subsequent route messages that indicate the route is in fact reachable. A typical hold-down timer runs for 60 or 120 seconds.

The main advantage of this technique is that a router won't be confused by receiving spurious information about a route being accessible when it was just recently told that the route was no longer valid. It provides a period of time for out-of-date information to be flushed from the system, which is valuable especially on complex internetworks. The addition of hold-down to split horizon can also help in situations where split horizon alone is not sufficient to prevent counting to infinity, such as when a trio of routers are linked in a “triangle”, as discussed earlier.

The main disadvantage of hold-down is that it forces a delay in a router responding to a route once it is fixed. Suppose that a network “hiccup” causes a route to go down for five seconds. After the network is up again, routers will want to again know about this. However, the hold-down timer must expire before the router will try to use that network again. This makes internetworks using hold-down relatively slow to respond to corrected routes, and may lead to delays in accessing networks that fail intermittently.

**Key Concept:** Four special features represent changes to RIP operation that ameliorate or eliminate the problems with the operation of the basic protocol. *Split horizon* and *split horizon with poisoned reverse* prevent having a router send invalid route information back to the router from which it originally learned the route. *Triggered updates* reduce the slow convergence problem by causing immediate propagation of changed route information. Finally, *hold-down* may be used to provide robustness when information about a failed route is received.

---

Again, while I called the items above “features”, at least some of them are really necessary to ensure proper RIP functionality. Therefore, they are generally considered standard parts of RIP, and most were described even in the earliest RIP documents. However, sometimes performance or stability issues may arise when these techniques are used, especially in combination. For this reason different RIP implementations may omit some features. For example, hold-down slows down route recovery and may not be needed when other features such as split horizon are used. As always, care must be taken to ensure that all routers are using the same features, or even greater problems may arise.

Also see [the specific section on RIP-2](#) for a description of the *Next Hop* feature that helps reduce convergence and routing problems when RIP is used.

---

## **RIP Version-Specific Message Formats and Features**

The Routing Information Protocol (RIP) has been in widespread use for over two decades. During that time, internetworks and internetworking technologies have changed. To keep up with the times, RIP has also evolved, and today has three different versions. The basic operation of all three is fairly similar, and was therefore described in [the common section on concepts and operation](#). As you might expect, there are also some differences between the versions (or we wouldn't need versions!) One of the more important of these is the format used for RIP messages in each version, and the meaning and use of the fields within that format.

In this section I describe the message format used by each of the three versions of RIP, as well as certain specific features not common to all versions. I begin with the original RIP, also now known as *RIP Version 1*. I then describe the updated version of RIP called *RIP Version 2* or *RIP-2*. Finally, I discuss *RIPng*, also sometimes called *RIPv6*, the version of RIP used for IP version 6 (IPv6). (Note that this is not technically a new version of the original RIP protocol but a new protocol closely based on RIP versions 1 and 2.

### **RIP Version 1 (RIP-1) Message Format**

RIP [evolved as an industry standard](#) and was popularized by its inclusion in the Berkeley Standard Distribution of UNIX (BSD UNIX). This first version of RIP (now sometimes called RIP-1 to differentiate it from later versions), was eventually standardized in RFC 1058. As part of this standard the original RIP-1 message format was defined, which of course serves RIP-1 itself, and is also the basis for the format used in later versions.

#### ***RIP-1 Messaging***

As explained in [the general discussion on RIP operation](#), route information is exchanged in RIP through the sending of two different types of RIP messages: *RIP Request* and the *RIP Response*. These are transmitted as regular TCP/IP messages using the [User Datagram Protocol \(UDP\)](#), using UDP [reserved port number](#) 520. This port number is used as follows:

- ☉ *RIP Request* messages are sent to UDP destination port 520. They may have a source port of 520 or may use an [ephemeral port number](#).
- ☉ *RIP Response* messages sent in reply to an *RIP Request* are sent with a source port of 520, and a destination port equal to whatever source port the *RIP Request* used.
- ☉ Unsolicited *RIP Response* messages (sent on a routine basis and not in response to a request) are sent with both the source and destination ports set to 520.

## RIP-1 Message Format

The basic message format for RIP-1 is described in [Table 121](#) and illustrated in [Figure 176](#).

**Table 121: RIP Version 1 (RIP-1) Message Format**

Field Name	Size (bytes)	Description																					
<b>Command</b>	1	<b>Command Type:</b> Identifies the type of RIP message being sent. A value of 1 indicates an <i>RIP Request</i> , while 2 means an <i>RIP Response</i> . Originally, three other values and commands were also defined: 3 and 4 for the <i>Traceon</i> and <i>Traceoff</i> commands, and 5 reserved for use by Sun Microsystems. These are obsolete and no longer used.																					
<b>Version</b>	1	<b>Version Number:</b> Set to 1 for RIP version 1.																					
<b>Must Be Zero</b>	2	<b>Reserved:</b> Field reserved; value must be set to all zeroes.																					
<b>RIP Entries</b>	20 to 500, in increments of 20	<b>RIP Entries:</b> The “body” of an RIP message consists of 1 to 25 sets of <i>RIP entries</i> . These entries contain the actual route information that the message is conveying. Each entry is 20 bytes long and has the following subfields: <table><tr><th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr><tr><td><b>Address Family Identifier</b></td><td>2</td><td><b>Address Family Identifier:</b> A fancy name for a field that identifies the type of address in the entry. We are using IP addresses, for which this field value is 2.</td></tr><tr><td><b>Must Be Zero</b></td><td>2</td><td><b>Reserved:</b> Field reserved; value must be set to all zeroes.</td></tr><tr><td><b>IP Address</b></td><td>4</td><td><b>IP Address:</b> The address of the route we are sending information about. No distinction is made between addresses of different types of devices in RIP, so the address can be for a network, a subnet or a single host. It is also possible to send an address of all zeroes, which is interpreted as the “default route” for other devices on the network to use for reaching routes with no specified routing entries. This is commonly used to allow a network to access the Internet.</td></tr><tr><td><b>Must Be Zero</b></td><td>4</td><td><b>Reserved:</b> Field reserved; value must be set to all zeroes.</td></tr><tr><td><b>Must Be Zero</b></td><td>4</td><td><b>Reserved:</b> Field reserved; value must be set to all zeroes. Yes, two of them in a row. ☺</td></tr><tr><td><b>Metric</b></td><td>4</td><td><b>Metric:</b> The distance for the network indicated by the IP address in the <i>IP Address</i> field. Values of 1 to 15 indicate the number of hops to reach the network, while a value of 16 represents “infinity” (an unreachable destination). <a href="#">See the general discussion of the RIP algorithm for more information on the use of metrics.</a></td></tr></table>	Subfield Name	Size (bytes)	Description	<b>Address Family Identifier</b>	2	<b>Address Family Identifier:</b> A fancy name for a field that identifies the type of address in the entry. We are using IP addresses, for which this field value is 2.	<b>Must Be Zero</b>	2	<b>Reserved:</b> Field reserved; value must be set to all zeroes.	<b>IP Address</b>	4	<b>IP Address:</b> The address of the route we are sending information about. No distinction is made between addresses of different types of devices in RIP, so the address can be for a network, a subnet or a single host. It is also possible to send an address of all zeroes, which is interpreted as the “default route” for other devices on the network to use for reaching routes with no specified routing entries. This is commonly used to allow a network to access the Internet.	<b>Must Be Zero</b>	4	<b>Reserved:</b> Field reserved; value must be set to all zeroes.	<b>Must Be Zero</b>	4	<b>Reserved:</b> Field reserved; value must be set to all zeroes. Yes, two of them in a row. ☺	<b>Metric</b>	4	<b>Metric:</b> The distance for the network indicated by the IP address in the <i>IP Address</i> field. Values of 1 to 15 indicate the number of hops to reach the network, while a value of 16 represents “infinity” (an unreachable destination). <a href="#">See the general discussion of the RIP algorithm for more information on the use of metrics.</a>
Subfield Name	Size (bytes)	Description																					
<b>Address Family Identifier</b>	2	<b>Address Family Identifier:</b> A fancy name for a field that identifies the type of address in the entry. We are using IP addresses, for which this field value is 2.																					
<b>Must Be Zero</b>	2	<b>Reserved:</b> Field reserved; value must be set to all zeroes.																					
<b>IP Address</b>	4	<b>IP Address:</b> The address of the route we are sending information about. No distinction is made between addresses of different types of devices in RIP, so the address can be for a network, a subnet or a single host. It is also possible to send an address of all zeroes, which is interpreted as the “default route” for other devices on the network to use for reaching routes with no specified routing entries. This is commonly used to allow a network to access the Internet.																					
<b>Must Be Zero</b>	4	<b>Reserved:</b> Field reserved; value must be set to all zeroes.																					
<b>Must Be Zero</b>	4	<b>Reserved:</b> Field reserved; value must be set to all zeroes. Yes, two of them in a row. ☺																					
<b>Metric</b>	4	<b>Metric:</b> The distance for the network indicated by the IP address in the <i>IP Address</i> field. Values of 1 to 15 indicate the number of hops to reach the network, while a value of 16 represents “infinity” (an unreachable destination). <a href="#">See the general discussion of the RIP algorithm for more information on the use of metrics.</a>																					

If you're like me, the first thing that comes to mind looking at this message format is this: what's with all the extra space? I mean, we have four different fields that are reserved (must be zero), and even most of the other fields are larger than they need to be (a metric of 1 to

**Figure 176: RIP Version 1 (RIP-1) Message Format**

The RIP-1 message format can contain up to 25 *RIP Entries*. Here, *RIP Entry #1* is shown here with each of its constituent subfields.

16 needs only 4 bits, not 32.) The command type and version number could easily have been made only 4 bits each as well (if not less.) And why bother having a two-byte field to identify the address type when we are only going to deal with IP addresses anyway?

This seeming wastefulness is actually an artifact of the generality of the original RIP design. The protocol was intended to be able to support routing for a variety of different internet-working protocols, not just IP. (Remember that it wasn't even originally developed with IP in mind.) So, the *Address Family Identifier* was included to specify address type, and RIP entries were made large enough to handle large addresses. IP only requires 4 bytes per address so some of the space is not used.

### ***RIP-1 Version-Specific Features***

Since RIP version 1 was the first version of the protocol, its features formed the basis for future RIP versions; it doesn't really have any version-specific features. What RIP-1 has is a number of limitations, such as a lack of support for specifying classless addresses and no means for authentication. [RIP version 2](#) was created to address some of RIP-1 shortcomings. As we will see in the next topic, RIP-2's features put to good use those “Must Be Zero” bytes in the RIP-1 format.

**Key Concept:** *RIP-1* was the first version of the Routing Information Protocol and is the simplest in terms of operation and features. The bulk of an *RIP-1* message consists of sets of *RIP* entries that specify route addresses and the distance to the route in hops.

---

## **RIP Version 2 (RIP-2) Message Format and Features**

The original Routing Information Protocol (*RIP-1*) has a number of problems and limitations. As the TCP/IP protocol suite evolved and changed, *RIP-1*'s problems were compounded by it becoming somewhat out of date, unable to handle newer IP features. There were some who felt that the existence of newer and better interior routing protocols meant that it would be best to just give up on *RIP* entirely and move over to something like [Open Shortest Path First \(OSPF\)](#).

However, *RIP*'s appeal was never its technical superiority, but its simplicity and ubiquity in industry. By the early 1990s, *RIP* was already in use in many thousands of networks. For those who liked *RIP*, it made more sense to migrate to a newer version that addressed some of *RIP-1*'s shortcomings than to go to an entirely different protocol. To this end, a new version of the protocol, *RIP Version 2 (RIP-2)* was developed, and initially published in RFC 1388 in 1993. It is now defined in RFC 2453, [RIP Version 2](#), published in November 1998.

### ***RIP-2 Version-Specific Features***

*RIP-2* represents a very modest change to the basic Routing Information Protocol. *RIP-2* works in the same basic way as *RIP-1* (part of why I was able to describe the operation of both in the same general section.) In fact, the new features introduced in *RIP-2* are described as **extensions** to the basic protocol, conveying the fact that they are layered upon regular *RIP-1* functionality. The five key *RIP-2* extensions are:

- 🕒 **Classless Addressing Support and Subnet Mask Specification:** When *RIP-1* was developed, the use of subnets in IP (as described in RFC 950) had not yet been formally defined. It was still possible to use *RIP-1* with subnets, through the use of a heuristic to determine if the destination is a network, subnet or host. However, there was no way to clearly specify the subnet mask for an address using *RIP-1* messages.

*RIP-2* adds explicit support for subnets by allowing a subnet mask within the route entry for each network address. It also provides support for [variable-length subnet masking \(VLSM\)](#) and [classless addressing \(CIDR\)](#).

- 🕒 **Next Hop Specification:** In *RIP-2*, each *RIP* entry includes a space where an explicit IP address can be entered as the next hop router for datagrams intended for the network in that entry. This feature can help improve efficiency of routing by eliminating unnecessary extra hops for datagrams sent to certain destinations.

One common use of this field is when the most efficient route to a network is through a

---

router that is not running RIP. Such a router will not exchange RIP messages and would therefore not normally be selected by RIP routers as a next hop for any network. The explicit *Next Hop* field allows the router to be selected as the next hop regardless of this situation.

- ☉ **Authentication:** RIP-1 included no authentication mechanism, which is a problem because it could potentially allow a malicious host to muck up an internetwork by sending bogus RIP messages around. RIP-2 provides a basic authentication scheme, which allows routers to ascertain the identity of a router before it will accept RIP messages from it.
- ☉ **Route Tag:** Each RIP-2 entry includes a *Route Tag* field, where additional information about a route can be stored. This information is propagated along with other data about the route as RIP entries are sent around the internet. A common use of this field is when a route is learned from a different autonomous system, to identify the autonomous system from which the route was obtained.
- ☉ **Use of Multicasting:** To help reduce network load, RIP-2 allows routers to be configured to use [multicasts](#) instead of broadcasts for sending out unsolicited *RIP Response* messages. These datagrams are sent out using the special reserved multicast address 224.0.0.9. All routers on an internetwork must obviously use multicast if this is to work properly.

As you can see, many of these extensions require more information to be included with each advertised route. This is where all that “extra space” in the message format of RIP-1 routing entries comes in handy, as we will see shortly.

**Key Concept:** *RIP-2* is the most recent version of RIP used in IPv4. It includes a number of enhancements over the original RIP-1, including support for subnet masks and classless addressing, explicit next-hop specification, route tagging, authentication and multicast. For compatibility, it uses the same basic message format as RIP-1, putting the extra information required for its new features into some of the unused fields of the RIP-1 message format.

---

## ***RIP-2 Messaging***

RIP-2 messages are exchanged using the same basic mechanism as RIP-1 messages. Two different message types exist, *RIP Request* and *RIP Response*. They are sent using the [User Datagram Protocol \(UDP\)](#) using UDP [reserved port number](#) 520. The semantics for the use of this port is the same as for RIP-1. For convenience, I repeat the description here:

- ☉ *RIP Request* messages are sent to UDP destination port 520. They may have a source port of 520 or may use an [ephemeral port number](#).
- ☉ *RIP Response* messages sent in reply to an *RIP Request* are sent with a source port of 520, and a destination port equal to whatever source port the *RIP Request* used.
- ☉ Unsolicited *RIP Response* messages (sent on a routine basis and not in response to a request) are sent with both the source and destination ports set to 520.

## RIP-2 Message Format

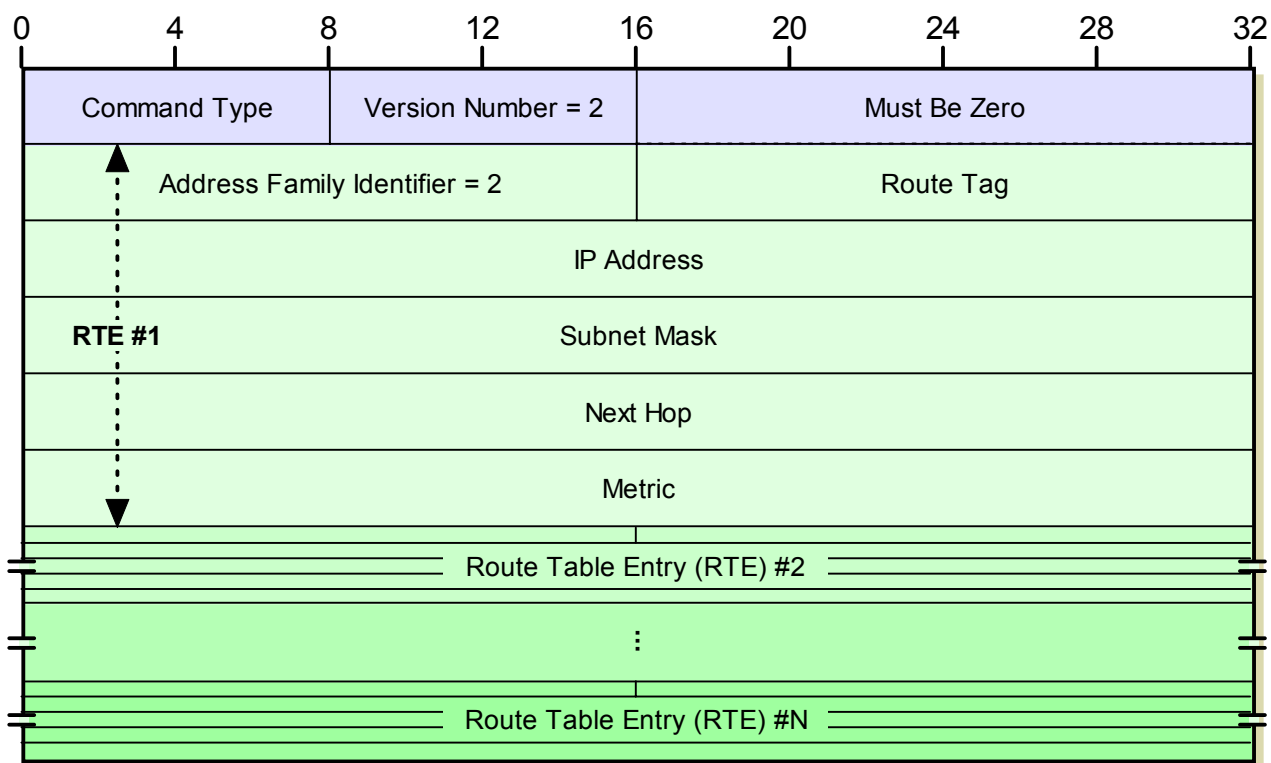

The basic message format for RIP-2 is also pretty much the same as it was for RIP-1, with the *Version* field of course set to 2, to clearly identify the message as being RIP-2. The real differences are in the individual RIP entries, as you can see in [Table 122](#) and [Figure 177](#).

**Table 122: RIP Version 2 (RIP-2) Message Format**

Field Name	Size (bytes)	Description																					
Command	1	<b>Command Type:</b> Identifies the type of RIP message being sent. A value of 1 indicates an <i>RIP Request</i> , while 2 means an <i>RIP Response</i> .																					
Version	1	<b>Version Number:</b> Set to 2 for RIP version 2.																					
Must Be Zero	2	<b>Reserved:</b> Field reserved; value must be set to all zeroes.																					
Route Table Entries (RTEs)	20 to 500, in increments of 20	<b>Route Table Entries (RTEs):</b> As with RIP-1, the “body” of an RIP-2 message consists of 1 to 25 sets of route information. In RIP-2 these are labeled <i>Route Table Entries</i> or <i>RTEs</i> . Each <i>RTE</i> is 20 bytes long and has the following subfields:																					
		<table><tr><th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr><tr><td>Address Family Identifier</td><td>2</td><td><b>Address Family Identifier:</b> Same meaning as for RIP-1; value is 2 to identify IP addresses.</td></tr><tr><td>Route Tag</td><td>2</td><td><b>Route Tag:</b> Additional information to be carried with this route.</td></tr><tr><td>IP Address</td><td>4</td><td><b>IP Address:</b> Same as in RIP-1: the address of the route we are sending information about. No distinction is made between address of different types of devices in RIP, so the address can be for a network, a subnet or a single host. It is also possible to send an address of all zeroes, which is interpreted as the “default route” as in RIP-1.</td></tr><tr><td>Subnet Mask</td><td>4</td><td><b>Subnet Mask:</b> The subnet mask associated with this address.</td></tr><tr><td>Next Hop</td><td>4</td><td><b>Next Hop:</b> Address of the device to use as the next hop for the network advertised in this entry.</td></tr><tr><td>Metric</td><td>4</td><td><b>Metric:</b> The distance for the network indicated by the IP address, as in RIP-1. Values of 1 to 15 indicate the number of hops to reach the network (as described in the general discussion of the RIP algorithm) while a value of 16 represents “infinity” (an unreachable destination).</td></tr></table>	Subfield Name	Size (bytes)	Description	Address Family Identifier	2	<b>Address Family Identifier:</b> Same meaning as for RIP-1; value is 2 to identify IP addresses.	Route Tag	2	<b>Route Tag:</b> Additional information to be carried with this route.	IP Address	4	<b>IP Address:</b> Same as in RIP-1: the address of the route we are sending information about. No distinction is made between address of different types of devices in RIP, so the address can be for a network, a subnet or a single host. It is also possible to send an address of all zeroes, which is interpreted as the “default route” as in RIP-1.	Subnet Mask	4	<b>Subnet Mask:</b> The subnet mask associated with this address.	Next Hop	4	<b>Next Hop:</b> Address of the device to use as the next hop for the network advertised in this entry.	Metric	4	<b>Metric:</b> The distance for the network indicated by the IP address, as in RIP-1. Values of 1 to 15 indicate the number of hops to reach the network (as described in the general discussion of the RIP algorithm) while a value of 16 represents “infinity” (an unreachable destination).
		Subfield Name	Size (bytes)	Description																			
		Address Family Identifier	2	<b>Address Family Identifier:</b> Same meaning as for RIP-1; value is 2 to identify IP addresses.																			
		Route Tag	2	<b>Route Tag:</b> Additional information to be carried with this route.																			
		IP Address	4	<b>IP Address:</b> Same as in RIP-1: the address of the route we are sending information about. No distinction is made between address of different types of devices in RIP, so the address can be for a network, a subnet or a single host. It is also possible to send an address of all zeroes, which is interpreted as the “default route” as in RIP-1.																			
		Subnet Mask	4	<b>Subnet Mask:</b> The subnet mask associated with this address.																			
		Next Hop	4	<b>Next Hop:</b> Address of the device to use as the next hop for the network advertised in this entry.																			
Metric	4	<b>Metric:</b> The distance for the network indicated by the IP address, as in RIP-1. Values of 1 to 15 indicate the number of hops to reach the network (as described in the general discussion of the RIP algorithm) while a value of 16 represents “infinity” (an unreachable destination).																					

As you can see, the unused fields allow the new RIP-2 features to be implemented without changing the basic structure of the RIP entry format. This allows RIP-1 and RIP-2 messages and devices to coexist in the same network. A RIP-2 device can handle both RIP-1 and RIP-2 messages, and will look at the version number to see which version the message is. A RIP-1 device should handle both RIP-2 and RIP-1 messages the same way, simply ignoring the extra RIP-2 fields it doesn't understand.

**Figure 177: RIP Version 2 (RIP-2) Message Format**

The *RIP Entries* of RIP-1 are called *Route Table Entries (RTEs)* in RIP-2; the message format can contain up to 25. The format of *RTE #1* is shown here with each of its subfields (the others are summarized to save space.)

**Note:** Note that if authentication is used, one of the RTEs contains authentication information, limiting the message to 24 “real” RTEs.

## RIPng (“RIPv6”) Message Format and Features

The future of TCP/IP is the new [Internet Protocol version 6 \(IPv6\)](#), which makes some very important changes to IP, especially with regard to addressing. Since IPv6 addresses are different than IPv4 addresses, everything that works with IP addresses must change to function under IPv6. This includes routing protocols, which exchange addressing information.

To ensure a future for the Routing Information Protocol, a new IPv6-compatible version had to be developed. This new version was published in 1997 in RFC 2080, *RIPng for IPv6*, where the *ng* stands for *next generation* (IPv6 is also sometimes called “IP next generation”).

---

RIPng, which is also occasionally seen as *RIPv6* for obvious reasons, was designed to be as similar as possible to the current version of RIP for IPv4, which is RIP Version 2 (RIP-2). In fact, RFC 2080 describes RIPng as “the minimum change” possible to RIP to allow it to work on IPv6. Despite this effort, it was not possible to define RIPng as just a new version of the older RIP protocol, like RIP-2 was. RIPng is a new protocol, which was necessary because of the significance of the changes between IPv4 and IPv6—especially the change from 32-bit to 128-bit addresses in IPv6, which necessitated a new message format.

### ***RIPng Version-Specific Features***

Even though RIPng is a new protocol, a specific effort was made to make RIPng like its predecessors. Its basic operation is almost entirely the same, and it uses the same overall algorithm and operation, as described in [the general section on RIP operation](#). RIPng also does not introduce any specific new features compared to RIP-2, except those needed to implement RIP on IPv6.

RIPng maintains most of the enhancements introduced in RIP-2; some are implemented as they were in RIP-2, while others appear in a modified form. Here's specifically how the five extensions in RIP-2 are implemented in RIPng:

- ☉ **Classless Addressing Support and Subnet Mask Specification:** In IPv6 all addresses are classless, and specified using an address and a prefix length, instead of a subnet mask. Thus, a field for the prefix length is provided for each entry instead of a subnet mask field.
- ☉ **Next Hop Specification:** This feature is maintained in RIPng, but implemented differently. Due to the large size of IPv6 addresses, including a *Next Hop* field in the format of RIPng RTEs would almost double the size of every entry. Since *Next Hop* is an optional feature, this would be wasteful. Instead, when a *Next Hop* is needed, it is specified in a separate routing entry.
- ☉ **Authentication:** RIPng does not include its own authentication mechanism. It is assumed that if authentication and/or encryption are needed, they will be provided using the [standard IPsec features defined for IPv6 at the IP layer](#). This is more efficient than having individual protocols like RIPng perform authentication.
- ☉ **Route Tag:** This field is implemented the same way as it is in RIP-2.
- ☉ **Use of Multicasting:** RIPng uses multicasts for transmissions, using reserved [IPv6 multicast address](#) FF02::9.

### ***RIPng Messaging***

There are two basic RIPng message types, *RIP Request* and *RIP Response*, which are exchanged using the [User Datagram Protocol \(UDP\)](#) as with RIP-1 and RIP-2. Since RIPng is a new protocol, it cannot use the same UDP reserved port number 520 used for RIP-1/ RIP-2. Instead, RIPng uses [well-known port number](#) 521. The semantics for the use of this port is the same as those used for port 520 in RIP-1 and RIP-2. For convenience, here are the rules again:

- ☉ *RIP Request* messages are sent to UDP destination port 521. They may have a source port of 521 or may use an [ephemeral port number](#).

- ☉ *RIP Response* messages sent in reply to an *RIP Request* are sent with a source port of 521, and a destination port equal to whatever source port the *RIP Request* used.
- ☉ Unsolicited *RIP Response* messages (sent on a routine basis and not in response to a request) are sent with both the source and destination ports set to 521.

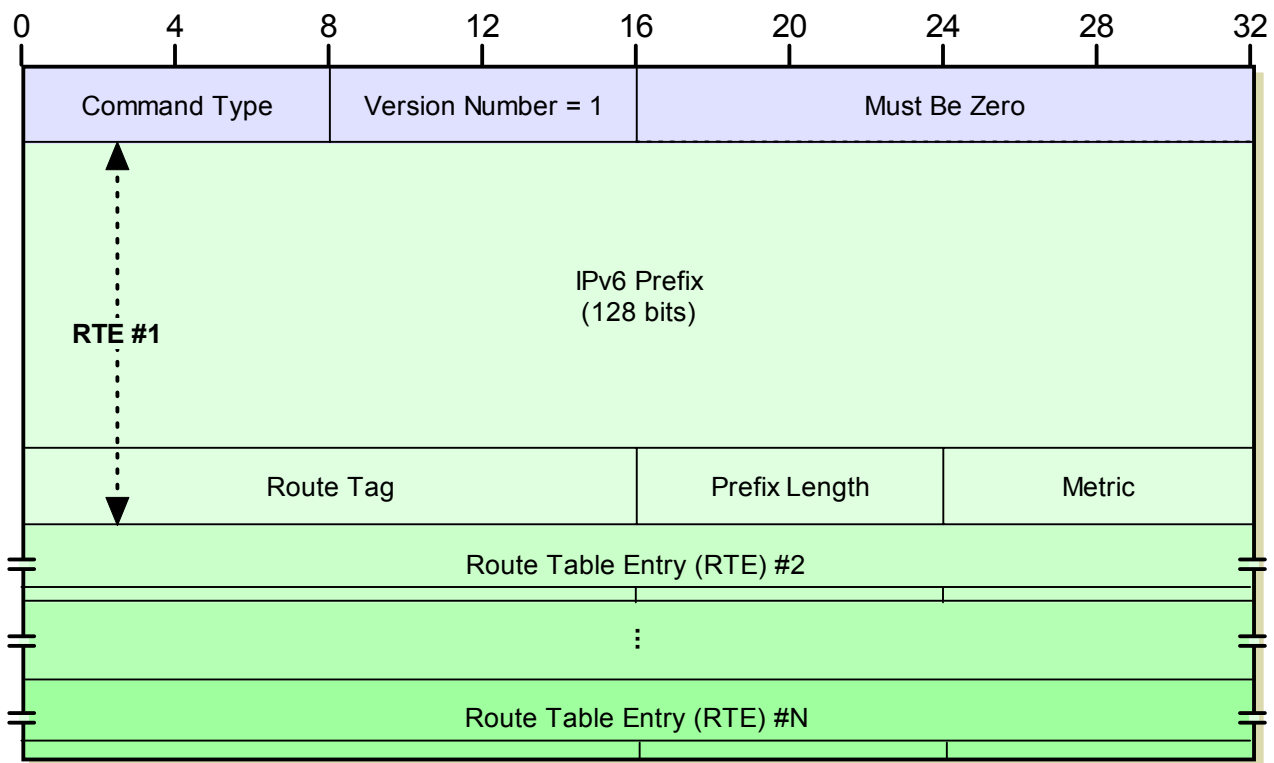

### ***RIPng Message Format***

The message format for RIPng is similar to that of RIP-1 and RIP-2, except for the format of the Route Table Entries; it is shown in [Table 123](#) and [Figure 178](#).

**Table 123: RIPng Message Format**

Field Name	Size (bytes)	Description															
<b>Command</b>	1	<b>Command Type:</b> Identifies the type of RIPng message being sent. A value of 1 indicates an <i>RIPng Request</i> , while 2 means an <i>RIPng Response</i> .															
<b>Version</b>	1	<b>Version Number:</b> Set to 1 (not 6, since this is the first version of the new protocol RIPng.)															
<b>Must Be Zero</b>	2	<b>Reserved:</b> Field reserved; value must be set to all zeroes.															
<b>Route Table Entries (RTEs)</b>	Variable	<p><b>Route Table Entries (RTEs):</b> The body of an RIPng message consists of a variable number of <i>Route Table Entries (RTEs)</i> that contain information about routes. Each entry is 20 bytes long and has the following subfields:</p> <table> <tr> <th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr> <tr> <td><b>IPv6 Prefix</b></td><td>16</td><td><b>IPv6 Prefix:</b> The 128-bit IPv6 address of the network whose information is contained in this <i>RTE</i>.</td></tr> <tr> <td><b>Route Tag</b></td><td>2</td><td><b>Route Tag:</b> Additional information to be carried with this route, as defined in RIP-2.</td></tr> <tr> <td><b>Prefix Len</b></td><td>1</td><td><b>Prefix Length:</b> The number of bits of the IPv6 address that is the network portion (the remainder being the host portion). This is the number that normally would appear after the “slash” when specifying an IPv6 network address, and is analogous to an IPv4 subnet mask. <a href="#">See the description of IPv6 prefix notation for more details.</a></td></tr> <tr> <td><b>Metric</b></td><td>1</td><td><b>Metric:</b> The distance for the network indicated by the IP address, as in RIP-1. Values of 1 to 15 indicate the number of hops to reach the network (as described in <a href="#">the general discussion of the RIP algorithm</a>) while a value of 16 represents “infinity” (an unreachable destination).</td></tr> </table>	Subfield Name	Size (bytes)	Description	<b>IPv6 Prefix</b>	16	<b>IPv6 Prefix:</b> The 128-bit IPv6 address of the network whose information is contained in this <i>RTE</i> .	<b>Route Tag</b>	2	<b>Route Tag:</b> Additional information to be carried with this route, as defined in RIP-2.	<b>Prefix Len</b>	1	<b>Prefix Length:</b> The number of bits of the IPv6 address that is the network portion (the remainder being the host portion). This is the number that normally would appear after the “slash” when specifying an IPv6 network address, and is analogous to an IPv4 subnet mask. <a href="#">See the description of IPv6 prefix notation for more details.</a>	<b>Metric</b>	1	<b>Metric:</b> The distance for the network indicated by the IP address, as in RIP-1. Values of 1 to 15 indicate the number of hops to reach the network (as described in <a href="#">the general discussion of the RIP algorithm</a> ) while a value of 16 represents “infinity” (an unreachable destination).
Subfield Name	Size (bytes)	Description															
<b>IPv6 Prefix</b>	16	<b>IPv6 Prefix:</b> The 128-bit IPv6 address of the network whose information is contained in this <i>RTE</i> .															
<b>Route Tag</b>	2	<b>Route Tag:</b> Additional information to be carried with this route, as defined in RIP-2.															
<b>Prefix Len</b>	1	<b>Prefix Length:</b> The number of bits of the IPv6 address that is the network portion (the remainder being the host portion). This is the number that normally would appear after the “slash” when specifying an IPv6 network address, and is analogous to an IPv4 subnet mask. <a href="#">See the description of IPv6 prefix notation for more details.</a>															
<b>Metric</b>	1	<b>Metric:</b> The distance for the network indicated by the IP address, as in RIP-1. Values of 1 to 15 indicate the number of hops to reach the network (as described in <a href="#">the general discussion of the RIP algorithm</a> ) while a value of 16 represents “infinity” (an unreachable destination).															

The maximum number of RTEs in RIPng is not restricted to 25 as it is in RIP-1 and RIP-2. It is limited only by the [maximum transmission unit \(MTU\)](#) of the network over which the message is being sent.

**Figure 178: RIPng Message Format**

RIPng retains the use of *Route Table Entries (RTEs)* from RIP-2, but their format has been changed to accommodate the much larger IPv6 address size. The limit of 25 entries per message has also been eliminated.

**Key Concept:** *RIPng* is the version of RIP that was developed for use on IPv6 inter-networks. It is technically a distinct protocol from RIP-1 and RIP-2 but is very similar to both. It retains the enhancements to RIP made in RIP-2, making changes to these features and to the RIP message format where needed for compatibility with IPv6.

When a *Next Hop* needs to be specified, a special *RTE* is included as I mentioned before. This *RTE* is included before all the *RTEs* to which it applies. It has the same basic structure as shown for regular *RTEs* in [Table 123](#), with the *IPv6 Prefix* subfield containing the next hop address, the *Route Tag* and *Prefix Len* fields set to 0, and the *Metric* field set to 255 (0xFF).

---

## **Open Shortest Path First (OSPF)**

Interior routing protocols using a [distance-vector routing algorithm](#), such as the [Routing Information Protocol \(RIP\)](#), have a long history and work well in a small group of routers. However, they also have some serious limitations in both scalability and performance that makes them poorly-suited to larger autonomous systems or those with specific performance issues. Many organizations that start out using RIP quickly found that its restrictions and issues made it less than ideal.

To solve this problem, a new routing protocol was developed in the late 1980s that uses the more capable (and more complex) [link-state or shortest path first routing algorithm](#). This protocol is called *Open Shortest Path First (OSPF)*. It fixes many of the issues with RIP and allows routes to be selected dynamically based on the current state of the network, not just a static picture of how routers are connected. It also includes numerous advanced features, including support for a hierarchical topology and automatic load sharing amongst routes. On the downside, it is a complicated protocol, which means it is often not used unless it is really needed. This makes it the complement of RIP and is the reason they both have a place in the spectrum of TCP/IP routing protocols.

In this section I provide a condensed explanation of the concepts and operation behind OSPF. As usual, I begin with an overview of the protocol, discussing how it was developed, its versions and the standards that define them. I describe the concepts behind OSPF, including basic topology and the link state database. I then discuss the more complex optional hierarchical topology of routers, and the roles routers play when this topology is used. I briefly explain the method used for determining routes in OSPF, and the general operation and messaging used in the protocol, including a description of the five OSPF message types. I conclude with an illustration of the formats used for OSPF messages.

**Note:** The difficult thing about networking is that so many protocols and technologies are so involved that each deserves its own book. This is certainly the case with OSPF itself, which is sufficiently complex that the RFC defining OSPF Version 2 is over 240 pages long. Thus, as you have heard me say before, this section, despite including six topics, can only be considered a high-level description of OSPF.

---

### **OSPF Overview, History, Standards and Versions**

In the early days of TCP/IP, the [Routing Information Protocol \(RIP\)](#) became the standard protocol for routing within an [autonomous system \(AS\)](#), almost by default. RIP had two big things going for it: it was simple and easy to use, and it was included in the popular Berkeley Standard Distribution (BSD) of UNIX starting in 1982. Most organizations using TCP/IP started out with relatively small networks, and were able to use RIP with some degree of success.

---

However, as we discussed in our look at RIP, [that protocol has some serious technical issues](#), and these are exacerbated when it is used on a larger AS. Many of its problems are due to it being a distance-vector protocol—the algorithm itself simply limits the ability of RIP to choose the best route and adapt to changing network conditions. Other problems with RIP were based on its implementation, such as the selection of a value of 16 for “infinity” that made it impossible to use RIP in a situation where more than 15 hops might occur between devices. Problems such as the lack of classless addressing support were addressed in Version 2 of RIP, but the basic difficulties with the protocol as a whole persist.

## ***Development and Standardization of OSPF***

The [Internet Engineering Task Force \(IETF\)](#) recognized that RIP by itself simply would not meet the needs of all autonomous systems on the Internet. They formed a working group in 1988 to develop a new routing protocol based on the more capable *link-state* algorithm, also called *shortest path first (SPF)*. Research into this type of protocol had already begun as early as the 1970s, with some of it conducted on the [ARPAnet](#), the predecessor of the Internet upon which much of TCP/IP was developed.

This new protocol was called *Open Shortest Path First*, or *OSPF*, and its name conveys two of its most important characteristics. The first word refers to the fact that the protocol, like all TCP/IP standards, was developed using the open and public [RFC process](#), so it is not proprietary and no license is required to use it. The *SPF* portion of the name refers to the type of algorithm it uses, which is designed to allow routers to dynamically determine the shortest path between any two networks.

The first version of OSPF was described in RFC 1131, published in October 1989. This was quickly replaced by OSPF Version 2 in July 1991, described in RFC 1247. Since then there have been several revisions to the OSPF Version 2 standard, in RFCs 1583, 2178, and 2328, with the last of these the current standard. OSPF Version 2 is the only version in use today, so it is usually what is meant when people (including myself) refer to “OSPF”.

## ***Overview of OSPF Operation***

The fundamental concept behind OSPF is a data structure called the *link-state database (LSDB)*. [Each router in an autonomous system maintains a copy of this database](#), which contains information in the form of a directed graph that describes the current state of the autonomous system. Each link to a network or another router is represented by an entry in the database, and each has an associated cost (or *metric*). The metric can be made to include many different aspects of route performance, not just a simple hop count as is used in RIP.

Information about the autonomous system moves around the autonomous system in the form of *link-state advertisements (LSAs)*, messages that let each router tell the others what it currently knows about the state of the AS. Over time, the information that each router has about the autonomous system converges with that of the others, and they all have the same data. When changes occur to the internetwork, routers send updates to ensure that all the routers are kept up-to-date.

---

To determine actual routes, each router uses its link-state database to construct a *shortest-path tree*. This tree shows the links from the router to each other router and network, and [allows the lowest-cost route to any location to be determined](#). As new information about the state of the internetwork arrives, this tree can be recalculated, so the best route is dynamically adjusted based on network conditions. When more than one route with an equal cost exists, traffic can be shared amongst the routes.

### **OSPF Features and Drawbacks**

In addition to these obvious benefits of the link-state algorithm, OSPF includes several other features of value especially to larger organizations. It supports authentication for security, and all three major types of IP addressing (classful, subnetted classful and classless). For very large autonomous systems, OSPF also allows routers to be grouped, and [arranged into a hierarchical topology](#). This allows for better organization and improved performance through reduced link-state advertisement traffic.

Naturally, the superior functionality and many features of OSPF do not come without a cost. In this case, the primary cost is that of **complexity**. Where RIP is a simple and easy-to-use protocol, OSPF requires more work and more expertise to properly configure and maintain. This means that even though OSPF is widely considered better than RIP technically, it's not for everyone. The obvious role for OSPF is as a routing protocol for larger or higher-performance autonomous systems, leaving RIP to cover the smaller and simpler internetworks.

**Key Concept:** *Open Shortest Path First (OSPF)* was developed in the late 1980s to provide a more capable interior routing protocol for larger or more complex autonomous systems that were not being served well by RIP. It uses the dynamic shortest path first or link state routing algorithm, with each router maintaining a database containing information about the state and topology of the internetwork. As changes to the internetwork occur, routers send out updated state information, which allows each router to dynamically calculate the best route to any network at any point in time. OSPF is a complement to RIP in that RIP is simple but limited, where OSPF is more capable but more complicated.

---

### **OSPF Basic Topology and the Link State Database**

OSPF is designed to facilitate routing in both smaller and larger autonomous systems (ASes). To this end, the protocol supports two topologies. When there is only a small number of routers, the entire AS is managed as a single entity. This doesn't have a specific name, but I call it OSPF *basic topology* to convey the simple nature of the topology, and to contrast it with the hierarchical topology we will explore in [the topic following this one](#).

When OSPF basic topology is used, all the routers in the AS function as peers. Each router communicates routing information with each other one, and each maintains a copy of the key OSPF data structure: the *link-state database (LSDB)*. The LSDB is essentially a computerized representation of the topology of the autonomous system. It is the method by

---

which routers “see” the state of the links in the autonomous system—thus the name link-state database (and for that matter, the name of [the entire class of link-state algorithms](#) of which OSPF is a part.)

The LSDB is a bit hard to visualize, but is best viewed as a set of data that is equivalent to a graphical picture showing the topology of an autonomous system. In such a diagram, we typically show routers and networks as nodes, and connections between routers and networks as lines that connect them. The OSPF LSDB takes that information and puts it into a table, to allow a router to maintain a virtual picture of all the connections between routers and networks in the AS.

The LSDB therefore indicates which routers can directly reach which other routers, and also which networks each can reach. Furthermore, it stores for each of these links a *cost* to reach the network. This cost is an arbitrary metric that can be set up based on any criteria important to the administrator. OSPF is not restricted to the overly-simple hop-count metric used in RIP.

### ***OSPF Basic Topology and LSDB Example***

For example, let's consider the same autonomous system we looked at in our examination of the RIP route determination algorithm. This internetwork has four individual networks, connected as follows:

- ☉ Router *A* (*RA*) connects Network 1 (*N1*) to Network 2 (*N2*).
- ☉ Routers *B* (*RB*) and *C* (*RC*) connect Network 2 to Network 3 (*N3*).
- ☉ Router *D* (*RD*) connects Network 3 to Network 4 (*N4*).

To make this example more interesting, I am also going to add a direct link between *RB* and *RC*; the resulting AS is shown in [Figure 179](#). The LSDB for this autonomous system would look something like [Table 124](#).

**Figure 179: Example OSPF Autonomous System**

This is the same AS that we looked at in RIP (as shown in [Figure 172](#)), but with the addition of a link between the two routers RB and RC.

Table 124: Example OSPF Link State Database (LSDB)

To Router / Network	From Router				From Network			
	RA	RB	RC	RD	N1	N2	N3	N4
RA					0	0		
RB			☯			0	0	
RC		☯				0	0	
RD							0	0
N1	☯							
N2	☯	☯	☯					
N3		☯	☯	☯				
N4				☯				

In practice, each of the bullets (“☯”) in Table 124 would be replaced by a metric value indicating the cost to send a datagram from the particular router to another router or network. Note that the chart is symmetric, since if *RB* can reach *RC*, *RC* can reach *RB*. However, the **costs** do not have to be symmetric. It is possible for *RB* to have a metric that is higher for it to send to *RC* than for *RC* to send to *RB*.

Note also that there is no cost to reach a router **from** a network. This ensures that only one cost is “charged” for a router to send to another router over a network—the cost to reach the network from the router. This makes sense, since each router is a member of the network upon which it is connected.

### LSDB Information Storage and Propagation

An important point to remember about the LSDB is that even though each router maintains it, the database isn't constructed from the perspective of the individual router. A router's LSDB represents the topology of the entire AS, including links between routers that may be rather distant from it. So, for example, *RA* would keep the entire database in its storage area, including information about *RC* and *RD*, to which it does not connect directly.

Since in basic topology all the routers are peers and maintain information for the entire AS, they in theory should have the exact same LSDB contents. When a router is first turned on it may in fact have different LSDB information than its neighbors, but this will be corrected through the exchange of update messages containing link-state advertisements (LSAs). Eventually all routers should converge to the same information. We will see how this works in [the topic on OSPF messaging](#).

OSPF, as an interior routing protocol, is of course used only within the autonomous system. In most cases the AS will be connected to other ASes through one or more of its routers. The routers that connect the AS to other ASes are often called *boundary routers*. These

---

devices will use OSPF to communicate within the AS, and an exterior routing protocol (typically [BGP](#)) to talk to routers outside the AS. The name *boundary* router refers to the fact that these devices are usually located on the periphery of the AS.

**Key Concept:** In basic OSPF topology, each of the routers running OSPF is considered a peer of the others. Each maintains a link-state database (LSDB) that contains information about the topology of the entire autonomous system. Each link between a router and network or between two routers is represented by an entry in the LSDB that indicates the cost to send data over the link. The LSDB is updated regularly through the exchange of OSPF link-state advertisements (LSAs).

---

## **OSPF Hierarchical Topology, Areas and Router Roles**

When the number of routers in an autonomous system (AS) is relatively small, using [the basic topology described in the previous topic](#) works well. Each router maintains a common picture of the network topology in the form of an identical link-state database (LSDB). The routers communicate as peers using link-state advertisements (LSAs). While changes in the AS may cause a router to temporarily have different information than its peers, routine exchanges of data will keep all the LSDBs synchronized and up-to-date, and not that much information needs to be sent around because the AS is small.

This simpler topology does scale reasonably well, and can support many smaller and even moderate-sized autonomous systems. However, as the number of routers increases, the amount of communication required to update LSDBs increases as well. In a very large internetwork with dozens or even hundreds of routers, having all the routers be OSPF peers using basic topology can result in performance degradation. This problem occurs due both to the amount of routing information that needs to be passed around, and also the need for each router to maintain a large LSDB containing every router and network in the entire AS.

### ***OSPF Hierarchical Topology and Areas***

To provide better support for these larger internetworks, OSPF supports the use of a more advanced, *hierarchical topology*. In this technique, the autonomous system is no longer considered a single, flat structure of interconnected routers all of which are peers. Instead, a two-level hierarchical topology is constructed. The autonomous system is divided into constructs called *areas*, each of which contains a number of contiguous routers and networks. These areas are numbered, and managed independently by the routers within them, so each area is almost as if it were an autonomous system unto itself. The areas are interconnected so that routing information can be shared between areas, across the entire AS.

The easiest way to understand this hierarchical topology is to consider each area like a “sub-autonomous system” within the autonomous system as a whole. The routers within any area maintain a link-state database containing information about the routers and

---

networks within that area. Routers within more than one area maintain LSDBs about each area they are a part of, and also link the areas together to share routing information between them.

**Key Concept:** To allow better control and management over larger internetworks, OSPF allows a large autonomous system to be structured into a hierarchical form. Contiguous routers and networks are grouped into *areas* that connect together using a logical *backbone*. These areas act as the equivalent of smaller autonomous systems within the larger AS, yielding the same benefits of localized control and traffic management that autonomous systems provide for a large internetwork between organizations.

---

### ***Router Roles in OSPF Hierarchical Topology***

The topology described above is hierarchical because the routers in the AS are no longer all peers in a single group. The two-level hierarchy consists of the lower level containing individual areas, and the higher level that connects them together, which is called the *backbone* and is designated as “Area 0”. The routers are no longer all peers, but in fact play different roles depending on where they are located and how they are connected. There are three different labels applied to routers in this configuration:

- **Internal Routers:** These are routers that are only connected to other routers or networks within a single area. They maintain an LSDB for only that area, and really have no knowledge of the topology of other areas.
- **Area Border Routers:** These are routers that connect to routers or networks in more than one area. They maintain an LSDB for each area of which they are a part. They also participate in the backbone.
- **Backbone Routers:** These are routers that are part of the OSPF backbone. By definition, this includes all area border routers, since those routers pass routing information between areas. However, a backbone router may also be a router that connects only to other backbone (or area border) routers, and is therefore not part of any area (other than Area 0).

To summarize: an area border router is always also a backbone router, but a backbone router is not necessarily an area border router.

**Note:** The classifications above are independent of the designation of a router as being a **boundary** router or not, as described in [the previous topic](#). A boundary router is one that talks to routers or networks outside the AS. Now a boundary router will also often be an area border router or a backbone router, but this is not necessarily the case—a boundary router could be an internal router in one area.

---

Okay, I bet you are now wondering... what is the point of all this? Well, the point is exactly the same as [the point of using autonomous system architecture in the first place](#). The topology of each area matters only to the devices in that area. This means that changes in

---

that topology only need to be propagated within the area. It also means that internal routers within Area 1 don't need to know about anything that goes on within Area 2, and don't need to maintain information about any area other than their own. Only the backbone routers (which include at least one area border router within each area) need to know the details of the entire autonomous system. These backbone routers condense information about the areas so that only a “summary” of each area's topology needs to be advertised on the backbone.

Routing in a hierarchical topology AS is performed in one of two ways, depending on the location of the devices. If the source and destination are in the same area, then routing occurs only over networks and routers in that area. If they are in a different area, then the datagram is routed from the source to an area border router in the source's area, over the backbone to an area border router in the destination's area, and then finally, delivered to the destination. Again, this is analogous to how routing works between ASes in the big-picture internetwork.

### ***OSPF Hierarchical Topology Example***

I'm sure this all made perfect sense the first time you read it. Uh-huh. ☺ Let's take an example to help make things more concrete. We can use the autonomous system in the preceding topic. This AS is really small enough that it's unlikely one would use hierarchical topology, but it will suffice for sake of illustration. Let's divide this AS into two areas, as follows (see [Figure 180](#)):

- ☛ **Area 1:** This area would contain *N1*, *RA*, *N2*, *RB* and *RC*.
- ☛ **Area 2:** This area would contain *RB*, *RC*, *N3*, *RD* and *N4*.

**Figure 180: Example OSPF Hierarchical Topology Autonomous System**

This is the same AS we saw in [Figure 179](#) but arranged into OSPF hierarchical topology. The AS has been split evenly into Area 1 and Area 2. Area 0 contains RB and RC, which are area border routers for both Area 1 and Area 2 in this very simple example AS.

---

In this example, Router *A* and Router *D* are internal routers. Router *B* and Router *C* are area border routers, and comprise the backbone (Area 0) of the internetwork. Routers *A*, *B* and *C* will maintain an LSDB describing Area 1, while Routers *B*, *C* and *D* will maintain an LSDB describing Area 2. Routers *B* and *C* maintain a separate LSDB for the backbone. There is no backbone router other than the area border routers *B* and *C*. However, suppose we had a router *E* that had only direct connections to *RB* and *RC*. This would be a backbone router only.

You have probably already discovered the chief drawback to hierarchical topology: complexity. For large autonomous systems, however, it has significant advantages over making every router a peer. At the same time, the conceptual complexity is made worse by the need for very careful design, especially of the backbone. If the hierarchy is not set up properly, a single failure of a link between routers could disrupt the backbone and isolate one or more of the areas (including all the devices on all networks within the area!)

## **OSPF Route Determination Using SPF Trees**

The key data structure maintained by each router in an OSPF autonomous system (AS) is the *link-state database (LSDB)*. The LSDB contains a representation of the topology of either the entire AS (in [basic topology](#)) or a single area (in [hierarchical topology](#)). As we have seen earlier in this section, each router in the AS or area has the same LSDB, so it represents a neutral view of the connections between routers and networks.

Of course, each router needs to participate in keeping the LSDB up to date, but it also has its own “selfish” concerns. It needs to be able to determine what routes it should use for datagrams it receives from its connected networks—this is, after all, the entire point of a routing protocol.

### ***The SPF Tree***

To find the best route from any router, it must determine the shortest path between itself and each router or network in the AS or area. For this, it needs not a neutral view of the internetwork but a view of it from its own perspective.

The router creates this perspective by taking the information in the LSDB and transforming it into a *shortest path first tree* or *SPF tree*. The term “tree” refers to a data structure with a root that has branches coming out that go to other nodes, which in turn have branches. The structure as a whole looks like an upside-down tree. In this case, the SPF tree shows the topology information of the AS or area with the router constructing the tree at the top. Each directly-connected router or network is one step down in the tree; each router or network connected to these first-level routers or networks is then connected, and so on, until the entire AS or area has been represented.

Again, the router doesn't really **make** the tree; it is just an algorithmic calculation performed by the computer within the router. Once this is done, however, this logical construct can be used to calculate the cost for that router to reach any router or network in the AS (or area). In some cases, there may be more than one way to reach a router or network, so the tree is constructed to show only the shortest (lowest-cost) path to the network.

---

Of course, each router is only responsible for sending a datagram on the next leg of its journey, and not for what happens to the journey as a whole. After the SPF tree is done, the router will create a routing table with an entry for each network, showing the cost to reach it, and also the next hop router to use to reach it.

The SPF tree is created dynamically based on the current state of the LSDB. If the LSDB ever changes, the SPF tree and the routing information are recalculated.

**Key Concept:** To determine what routes it should use to reach networks in its autonomous system, a router generates a *shortest path first tree (SPF tree)* from its link-state database. This tree contains the same basic information as the LSDB but presents it from the point of view of the router doing the calculation so that router can see the costs of various paths to different networks.

---

### OSPF Route Determination Example

I can almost **see** your eyes glazing over, so let's go back again to the example we have been using in this section. I am going to assume we are looking at the whole AS as a whole in basic topology, for simplicity. In [Table 125](#), I have repeated the LSDB for this AS, and I have taken the liberty of replacing the “☹”s with cost metrics; these are shown in [Figure 181](#) as well. Again, remember there is no cost to reach a router **from** a network, so those links have a non-zero cost only going from the router to the network.

**Table 125: Example OSPF Link State Database (LSDB) With Costs**

To Router / Network	From Router				From Network			
	RA	RB	RC	RD	N1	N2	N3	N4
RA					0	0		
RB			5			0	0	
RC		5				0	0	
RD							0	0
N1	2							
N2	3	4	3					
N3		5	6	1				
N4				4				

Now, let's construct the SPF tree for *RC*. We can do this in iterations, as follows (this is shown graphically in [Figure 182](#) as well for your convenience):

#### First Level

To construct the first level of the tree, we look for all devices that *RC* can reach directly. We find:

**Figure 181: Example OSPF Autonomous System With Costs**

This is the same sample AS that is shown in [Figure 179](#), but with costs assigned to each of the links between routers and networks. Costs between routers and networks are applied only in the direction from the router to the network.

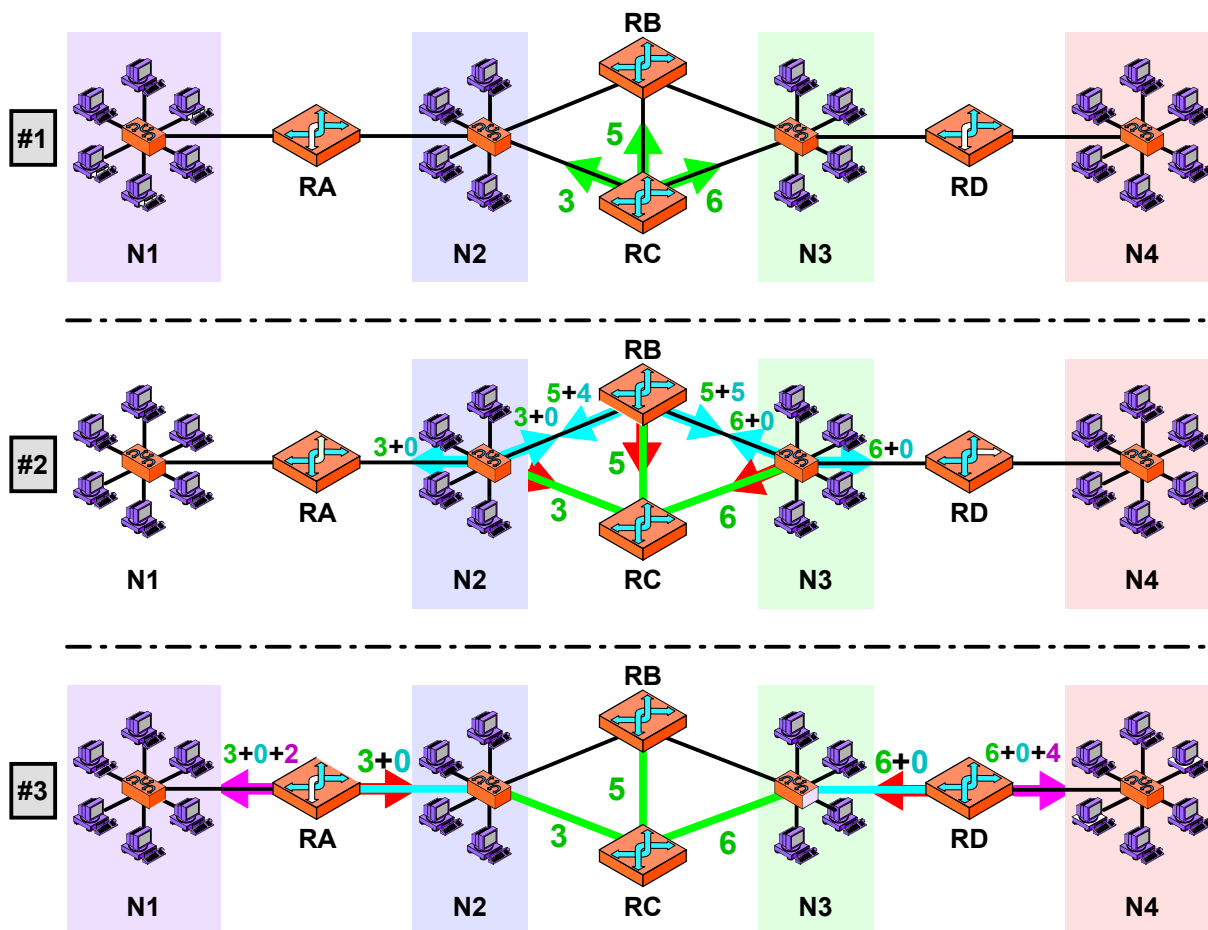

- ☉ **RB**, with a cost of 5.
- ☉ **N2**, with a cost of 3.
- ☉ **N3**, with a cost of 6.

## Second Level

To construct the second level, we look for all devices that the devices on the first level can reach directly. We then add the cost to reach each device on the first level to the cost of each device at the second level:

- ☉ **RB**: **RB** has a cost of 5 and can reach:
  - ☉ **RC**, with a cost of 5, total cost of 10.
  - ☉ **N2**, with a cost of 4, total cost of 9.
  - ☉ **N3**, with a cost of 5, total cost of 10.
- ☉ **N2**: **N2** has a cost of 3 and can reach:
  - ☉ **RA**, with a cost of 0, total cost of 3.
  - ☉ **RB**, with a cost of 0, total cost of 3.
  - ☉ **RC**, with a cost of 0, total cost of 3.
- ☉ **N3**: **N3** has a cost of 6 and can reach:
  - ☉ **RB**, with a cost of 0, total cost of 6.
  - ☉ **RC**, with a cost of 0, total cost of 6.
  - ☉ **RD**, with a cost of 0, total cost of 6.

You probably can see immediately that we ended up with a number of different paths to the same devices or networks, some of which make no sense. For example, we don't really care about any path that goes to RC, since we *are* RC! Similarly, we can weed out certain paths immediately because we already have a shorter path to them; taking a path through RB to N3 with a cost of 10 makes no sense when we can go directly at the first level for a cost of 6. So, after separating out the chaff, we end up with the following “wheat” at the second level:

**Figure 182: OSPF Route Determination Using The Shortest Path First Algorithm**

This diagram shows graphically how a router, in this case *RC*, determines the best path to various networks. The arrows here represent not the transfer of data but rather the examination of various links from a router to other routers or networks. In panel #1, *RC* examines its LSDB and determines the cost for each of its directly-linked devices. In #2, the second level of the SPF tree is constructed by adding to those numbers the costs of all routers/networks that connect to the routers/networks found in panel #1. (The red arrows represent "looking back" in the direction we came from in the prior step, which we don't pursue.) In #3 the process continues, resulting in the determination of a cost of 5 for *RC* to reach *N1* and 10 to reach *N4*.

- ☉ *N2* to *RA*, with a cost of 3.
- ☉ *N3* to *RD*, with a cost of 6.

### Third Level

We continue the process by looking for devices that connect to the "weeded-out" devices we found on the second level (this time I am only showing the meaningful ones):

- ☉ ***RA***: *RA* connects to *N1*, with a cost of 2, total cost of 5.
- ☉ ***RD***: *RD* connects to *N4*, with a cost of 4, total cost of 10.

---

## Shortest Path Tree and Route Calculation Results

In this simple example, we only need three levels to construct the tree for *RC* (we would need more for *RA* or *RD*, however.) The final results would be the tree in [Figure 183](#), and the routing information for *RC* to the four networks that is shown in [Table 126](#).

**Figure 183: OSPF Calculated Shortest Path First Tree**

This is a graphical representation of the SPF tree calculated in [Figure 182](#), showing only the final results of the calculation process.

**Table 126: Example Calculated OSPF Routes**

Destination Network	Cost	Next Hop
N1	5	RA
N2	3	(local)
N3	6	(local)
N4	10	RD

This of course is what you would expect in this very simple example. Note that there are no specific entries for other routers, since they are the “means to the end” of reaching networks. However, if one of the other routers were a boundary router that connected the AS to the outside world, there would be entries for the networks to which the boundary router connected, so *RC* knew to send traffic for those networks to that boundary router.

## OSPF General Operation and Message Types

As a routing protocol, the main job of OSPF is to facilitate the exchange of routing information between routers. Each router in an OSPF autonomous system that runs OSPF software that is responsible for various tasks, such as setting timers to control certain activities that must occur on a regular basis, and the maintenance of important data structures,

---

such as the [link-state database \(LSDB\)](#). Most importantly, each OSPF router must both generate and respond to OSPF messages. It is this messaging system that allows important routing information to be shared within an AS or area, which makes it crucial to understanding how OSPF works. So, it's worth taking a look at the message types and how they are used.

### **OSPF Message Types**

Unlike [RIP](#), OSPF does not send its information using the User Datagram Protocol (UDP). Instead, OSPF forms [IP datagrams](#) directly, packaging them using protocol number 89 for the IP *Protocol* field. OSPF defines five different message types, for various types of communication:

1. **Hello:** As the name suggests, these messages are used as a form of greeting, to allow a router to discover other adjacent routers on its local links and networks. The messages establish relationships between neighboring devices (called *adjacencies*) and communicate key parameters about how OSPF is to be used in the autonomous system or area.
2. **Database Description:** These messages contain descriptions of the topology of the AS or area. That is, they convey the contents of the link-state database for the autonomous system or area from one router to another. Communicating a large LSDB may require several messages to be sent; this is done by having the sending device designated as a *master* device and sending messages in sequence, with the slave (recipient of the LSDB information) responding with acknowledgements.
3. **Link State Request:** These messages are used by one router to request updated information about a portion of the LSDB from another router. The message specifies exactly which link(s) about which the requesting device wants more current information.
4. **Link State Update:** These messages contain updated information about the state of certain links on the LSDB. They are sent in response to a *Link State Request* message, and also broadcast or multicast by routers on a regular basis. Their contents are used to update the information in the LSDBs of routers that receive them.
5. **Link State Acknowledgment:** These messages provide reliability to the link-state exchange process, by explicitly acknowledging receipt of a *Link State Update* message.

### **OSPF Messaging and General Operation**

The use of these messages is approximately as follows. When a router first starts up it will send a *Hello* message out to see if any neighboring routers are around running OSPF, and it will also send them out periodically to discover any new neighbors that may show up. When an adjacency is set up with a new router, *Database Description* messages will then be sent to initialize the router's LSDB.

Routers that have been initialized enter a steady state mode. They will each routinely “flood” their local networks with *Link State Update* messages, advertising the state of their links. They will also send out updates when they detect a change in topology that needs to

---

be communicated. They will of course receive *Link State Update* messages sent by other devices, and respond with *Link State Acknowledgments* accordingly. Routers may also request updates using *Link State Request* messages.

**Key Concept:** The operation of OSPF involves five message types. *Hello* messages are used to establish contact between routers, and *Database Description* messages to initialize a router's link-state database. Routine LSDB updates are sent using *Link State Update* messages, which are acknowledged using *Link State Acknowledgments*. A device may also request a specific update using a *Link State Request*.

---

When hierarchical topology is used, internal routers maintain a single LSDB and perform messaging only within an area. Area border routers have multiple LSDBs and perform messaging in more than one area. They, along with any other OSPF backbone routers, also exchange messaging information on the backbone, including summarized link-state information for the areas they border.

Again, all of this is highly simplified; the OSPF standard contains pages and pages of detailed rules and procedures governing the exact timing for sending and receiving messages.

### ***OSPF Message Authentication***

The OSPF standard specifies that all OSPF messages are authenticated for security. This is a bit misleading, however, since one of the authentication “methods” supported is “null authentication”—meaning no authentication is used. More security is provided by using the optional simple password authentication method, and the most security through the use of cryptographic authentication. These methods are described in Appendix D of RFC 2328.

**Note:** The *Hello* messages used in OSPF are also sometimes called the *Hello Protocol*. This is especially poor terminology because there is an actual routing protocol, described in the next section, called [the HELLO Protocol](#). The two protocols are not related. However, I suspect that the OSPF *Hello* messages may have been so named because they serve a similar purpose to the messages used in the independent HELLO protocol.

---

### **OSPF Message Formats**

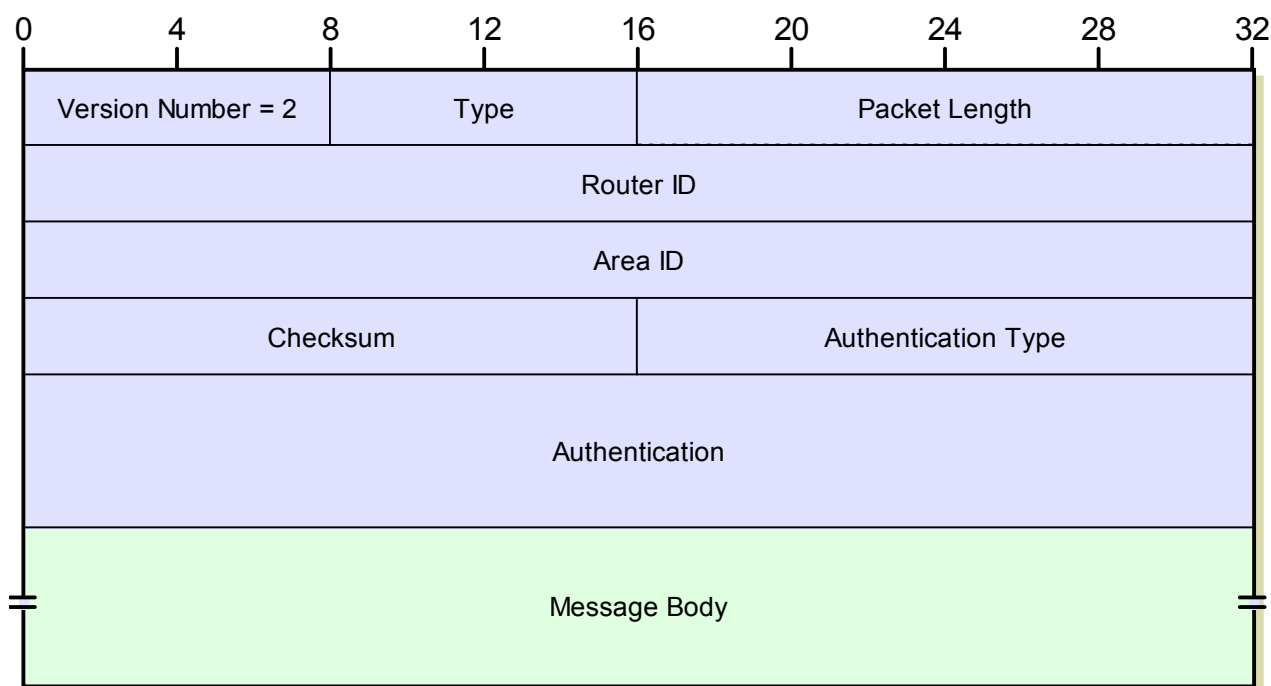

OSPF uses five different types of messages to communicate both link-state and general information between routers within an autonomous system or area. To help illustrate better how the OSPF messages are used, it's worth taking a quick look at the format used for each of these messages. Well, I guess I am being somewhat liberal in my use of the term “quick” here. ☺

## OSPF Common Header Format

Naturally, each type of OSPF message includes a slightly different set of information—otherwise, they wouldn't be different message types! However, they all share a similar message structure, beginning with a shared 24-byte header. This common header allows certain standard information to be conveyed in a consistent manner, such as the number of the version of OSPF that generated the message. It also allows a device receiving an OSPF message to quickly determine which type of message it has received, so it knows whether or not it needs to bother examining the rest of the message. [Table 127](#) and [Figure 184](#) show the common OSPF header format.

**Table 127: OSPF Common Header Format**

Field Name	Size (bytes)	Description												
Version #	1	Version Number: Set to 2 for OSPF version 2.												
Type	1	Type: Indicates the type of OSPF message: <table><tr><th>Type Value</th><th>OSPF Message Type</th></tr><tr><td>1</td><td>Hello</td></tr><tr><td>2</td><td>Database Description</td></tr><tr><td>3</td><td>Link State Request</td></tr><tr><td>4</td><td>Link State Update</td></tr><tr><td>5</td><td>Link State Acknowledgment</td></tr></table>	Type Value	OSPF Message Type	1	Hello	2	Database Description	3	Link State Request	4	Link State Update	5	Link State Acknowledgment
Type Value	OSPF Message Type													
1	Hello													
2	Database Description													
3	Link State Request													
4	Link State Update													
5	Link State Acknowledgment													
Packet Length	2	Packet Length: The length of the message, in bytes, including the 24 bytes of this header.												
Router ID	4	Router ID: The ID of the router that generated this message (generally its IP address on the interface over which the message was sent).												
Area ID	4	Area ID: An identification of the OSPF area to which this message belongs, when areas are used.												
Checksum	2	Checksum: A 16-bit checksum computed in a manner similar to a standard IP checksum. The entire message is included in the calculation except the Authentication field.												
AuType	2	Authentication Type: Indicates the type of authentication used for this message: <table><tr><th>Authentication Type Value</th><th>OSPF Authentication Type</th></tr><tr><td>0</td><td>No Authentication</td></tr><tr><td>1</td><td>Simple Password Authentication</td></tr><tr><td>2</td><td>Cryptographic Authentication</td></tr></table>	Authentication Type Value	OSPF Authentication Type	0	No Authentication	1	Simple Password Authentication	2	Cryptographic Authentication				
Authentication Type Value	OSPF Authentication Type													
0	No Authentication													
1	Simple Password Authentication													
2	Cryptographic Authentication													
Authentication	8	Authentication: A 64-bit field used for authentication of the message, as needed.												

**Figure 184: OSPF Common Header Format**

### ***Specific Message Formats***

Following this header, the body of the message includes a variable number of fields is included that depends on the message type. Each of the message formats is described in detail in RFC 2328; since some are quite long I will describe their fields only briefly here.

### ***Hello Message Format***

These messages have a *Type* value of 1 in the header, and the field structure shown in [Table 128](#) and [Figure 185](#) in the body of the message.

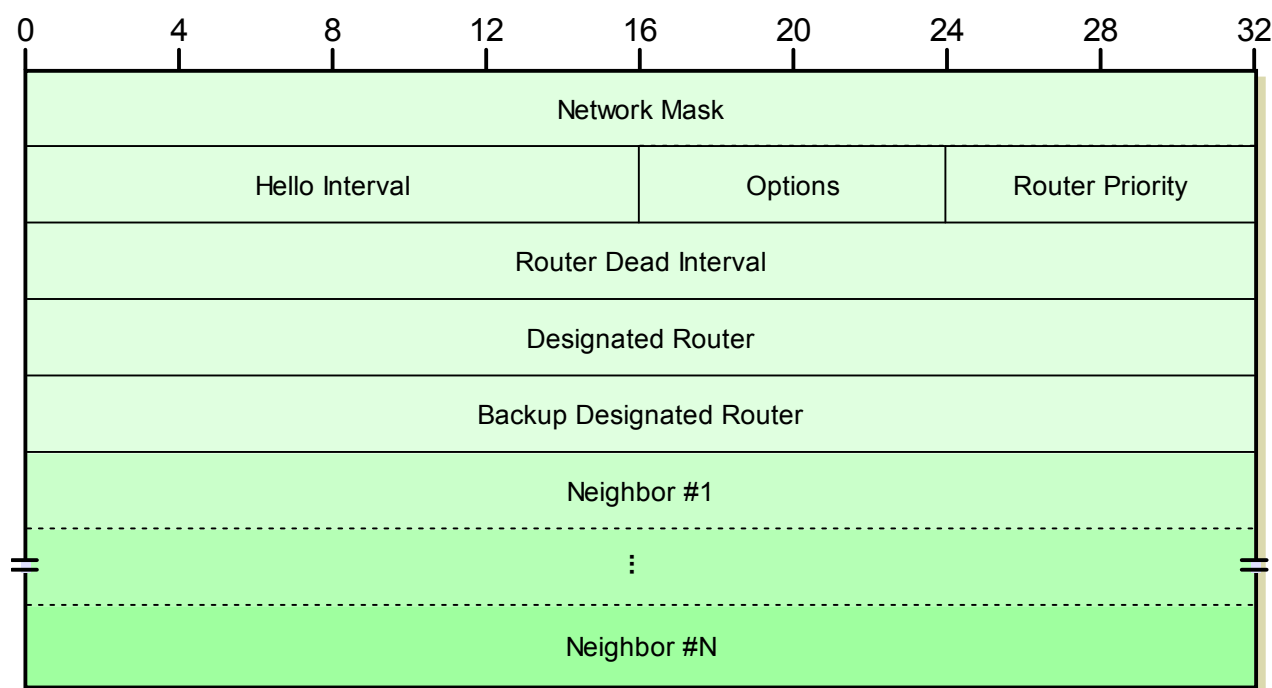

**Table 128: OSPF Hello Message Format (Page 1 of 2)**

Field Name	Size (bytes)	Description
<b>Network Mask</b>	4	<b>Network Mask:</b> The subnet mask of the network the router is sending to.
<b>Hello Interval</b>	2	<b>Hello Interval:</b> The number of seconds this router waits between sending <i>Hello</i> messages.
<b>Options</b>	1	<b>Options:</b> Indicates which optional OSPF capabilities the router supports.
<b>Rtr Pri</b>	1	<b>Router Priority:</b> Indicates the router's priority, when electing a backup designated router.
<b>Router Dead Interval</b>	4	<b>Router Dead Interval:</b> The number of seconds a router can be "silent" before it is considered to have failed.

**Table 128: OSPF Hello Message Format (Page 2 of 2)**

Field Name	Size (bytes)	Description
<b>Designated Router</b>	4	<b>Designated Router:</b> The address of a router designated for certain special functions on some networks. Set to zeroes if there is no designated router.
<b>Backup Designated Router</b>	4	<b>Backup Designated Router:</b> The address of a backup designated router. Set to all zeroes if there is no backup designated router.
<b>Neighbors</b>	Multiple of 4	<b>Neighbors:</b> The addresses of each router from which this router has received Hello messages recently.

**Figure 185: OSPF Hello Message Format**

### Database Description Message Format

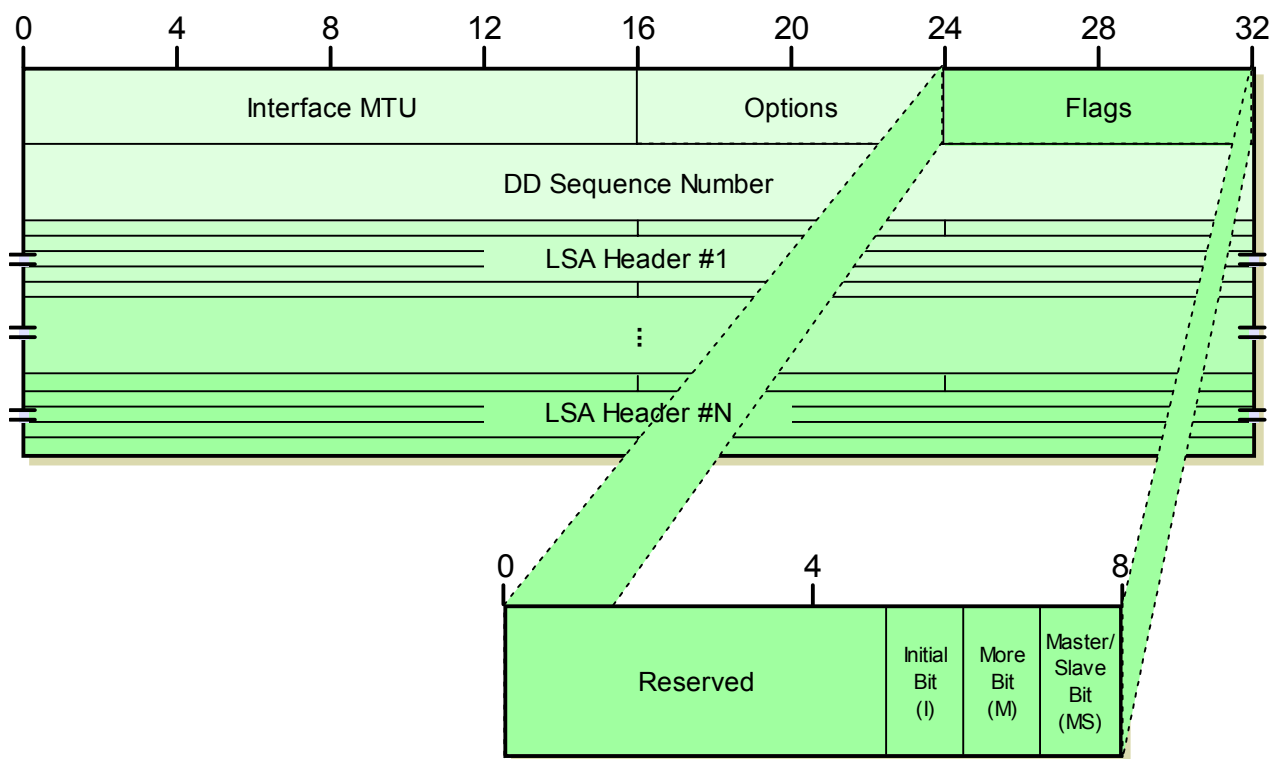

These messages have a *Type* value of 2 in the header, and the body structure depicted in [Table 129](#) and [Figure 186](#).

**Table 129: OSPF Database Description Message Format (Page 1 of 2)**

Field Name	Size (bytes)	Description
<b>Interface MTU</b>	2	<b>Interface MTU:</b> The size of the largest IP message that can be sent on this router's interface without fragmentation.
<b>Options</b>	1	<b>Options:</b> Indicates which of several optional OSPF capabilities the router supports.

**Table 129: OSPF *Database Description* Message Format (Page 2 of 2)**

Field Name	Size (bytes)	Description															
<b>Flags</b>	1	<p><b>Flags:</b> Special flags used to indicate information about the exchange of <i>Database Description</i> messages:</p> <table> <tr> <th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr> <tr> <td><b>Reserved</b></td><td>5/8 (5 bits)</td><td><b>Reserved:</b> Sent and received as zero.</td></tr> <tr> <td><b>I</b></td><td>1/8 (1 bit)</td><td><b>I-Bit:</b> Set to 1 to indicate that this is the first ("initial") in a sequence of <i>Database Description</i> messages.</td></tr> <tr> <td><b>M</b></td><td>1/8 (1 bit)</td><td><b>M-Bit:</b> Set to 1 to indicate that "more" <i>Database Description</i> messages follow this one.</td></tr> <tr> <td><b>MS</b></td><td>1/8 (1 bit)</td><td><b>MS-Bit:</b> Set to 1 if the router sending this message is the master in the communication, or 0 if it is the slave.</td></tr> </table>	Subfield Name	Size (bytes)	Description	<b>Reserved</b>	5/8 (5 bits)	<b>Reserved:</b> Sent and received as zero.	<b>I</b>	1/8 (1 bit)	<b>I-Bit:</b> Set to 1 to indicate that this is the first ("initial") in a sequence of <i>Database Description</i> messages.	<b>M</b>	1/8 (1 bit)	<b>M-Bit:</b> Set to 1 to indicate that "more" <i>Database Description</i> messages follow this one.	<b>MS</b>	1/8 (1 bit)	<b>MS-Bit:</b> Set to 1 if the router sending this message is the master in the communication, or 0 if it is the slave.
Subfield Name	Size (bytes)	Description															
<b>Reserved</b>	5/8 (5 bits)	<b>Reserved:</b> Sent and received as zero.															
<b>I</b>	1/8 (1 bit)	<b>I-Bit:</b> Set to 1 to indicate that this is the first ("initial") in a sequence of <i>Database Description</i> messages.															
<b>M</b>	1/8 (1 bit)	<b>M-Bit:</b> Set to 1 to indicate that "more" <i>Database Description</i> messages follow this one.															
<b>MS</b>	1/8 (1 bit)	<b>MS-Bit:</b> Set to 1 if the router sending this message is the master in the communication, or 0 if it is the slave.															
<b>DD Sequence Number</b>	4	<b>DD Sequence Number:</b> Used to number a sequence of <i>Database Description</i> messages so they are kept in order.															
<b>LSA Headers</b>	Variable	<b>LSA Headers:</b> Contains link-state advertisement headers, which carry information about the LSDB. <a href="#">See near the end of the topic for more information on LSAs.</a>															

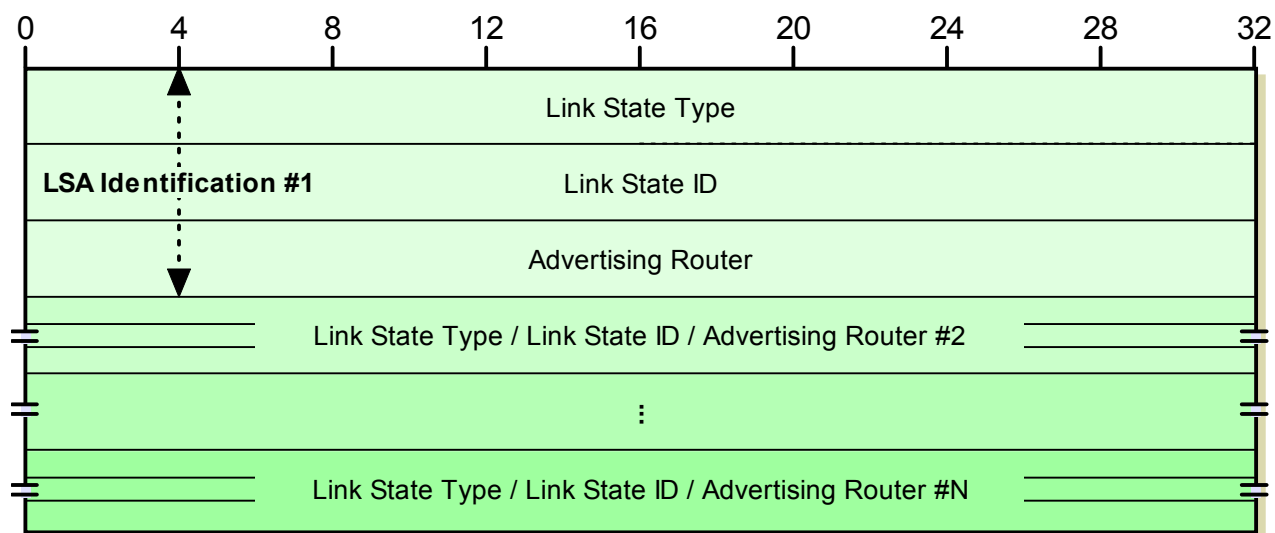

**Figure 186: OSPF Database Description Message Format**

### Link State Request Message Format

These messages have a *Type* value of 3 in the header. Following the header comes one or more sets of three fields that each identify a [link state advertisement \(LSA\)](#) for which the router is requesting an update, as shown in [Figure 187](#). Each LSA identification has the format described in [Table 130](#).

**Table 130: OSPF Link State Request Message Format**

Field Name	Size (bytes)	Description
<b>LS Type</b>	4	<b>Link State Type:</b> The type of link state advertisement (LSA) being sought.
<b>Link State ID</b>	4	<b>Link State ID:</b> The identifier of the LSA, usually the IP address of either the router or network linked.
<b>Advertising Router</b>	4	<b>Advertising Router:</b> The ID of the router that created the LSA whose update is being sought.

**Figure 187: OSPF *Link State Request* Message Format**

#### ***Link State Update* Message Format**

These messages have a *Type* value of 4 in the header, and the fields illustrated in [Table 131](#) and [Figure 188](#).

**Table 131: OSPF *Link State Update* Message Format**

Field Name	Size (bytes)	Description
# LSAs	4	<b>Number of LSAs:</b> The number of link-state advertisements included in this message.
LSAs	Variable	<b>LSAs:</b> One or more <a href="#">link-state advertisements</a> . See below for more details.

**Figure 188: OSPF *Link State Update* Message Format**

#### **Link State Acknowledgment Message Format**

These messages have a *Type* value of 5 in the header. They then contain a list of LSA headers corresponding to the LSAs being acknowledged, as shown in [Table 132](#) and [Figure 189](#).

**Table 132: OSPF *Link State Acknowledgment* Message Format**

Field Name	Size (bytes)	Description
<b>LSA Headers</b>	Variable	<b>LSA Headers:</b> Contains <a href="#">link-state advertisement</a> headers, to identify the LSAs acknowledged.

**Figure 189: OSPF *Link State Acknowledgment* Message Format**

---

## Link State Advertisements (LSAs) and the LSA Header Format

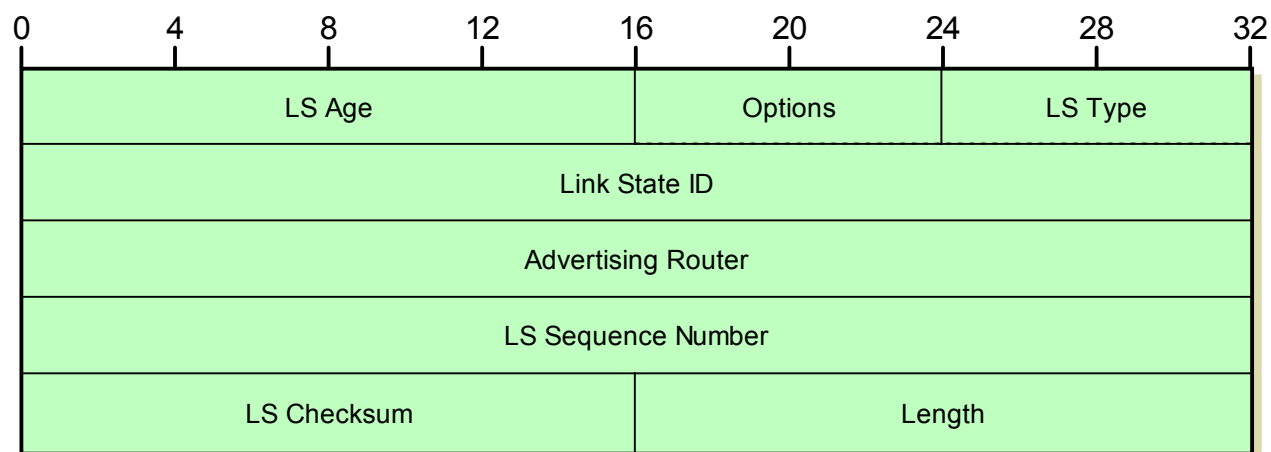

As we saw above, several of the message types include *link state advertisements (LSAs)*, which are the fields that actually carry topological information about the LSDB. There are several types of LSAs, which are used to convey information about different types of links. Like the OSPF messages themselves, each LSA has a common header with 20 bytes, and then a number of additional fields that describe the link.

### LSA Header

The LSA header contains sufficient information to identify the link. It uses the subfield structure in [Table 133](#) and [Figure 190](#).

**Table 133: OSPF Link State Advertisement Header Format**

Subfield Name	Size (bytes)	Description																		
<b>LS Age</b>	2	<b>LS Age:</b> The number of seconds elapsed since the LSA was created.																		
<b>Options</b>	1	<b>Options:</b> Indicates which of several optional OSPF capabilities the router supports.																		
<b>LS Type</b>	1	<b>LS Type:</b> Indicates the type of link this LSA describes: <table><tr><th>Value</th><th>Link Type</th><th>Description</th></tr><tr><td>1</td><td>Router-LSA</td><td>Link to a router</td></tr><tr><td>2</td><td>Network-LSA</td><td>Link to a network</td></tr><tr><td>3</td><td>Summary-LSA (IP Network)</td><td>When areas are used, summary information generated about a network.</td></tr><tr><td>4</td><td>Summary-LSA (ASBR)</td><td>When areas are used, summary information about a link to an AS boundary router.</td></tr><tr><td>5</td><td>AS-External-LSA</td><td>An external link outside the autonomous system.</td></tr></table>	Value	Link Type	Description	1	Router-LSA	Link to a router	2	Network-LSA	Link to a network	3	Summary-LSA (IP Network)	When areas are used, summary information generated about a network.	4	Summary-LSA (ASBR)	When areas are used, summary information about a link to an AS boundary router.	5	AS-External-LSA	An external link outside the autonomous system.
Value	Link Type	Description																		
1	Router-LSA	Link to a router																		
2	Network-LSA	Link to a network																		
3	Summary-LSA (IP Network)	When areas are used, summary information generated about a network.																		
4	Summary-LSA (ASBR)	When areas are used, summary information about a link to an AS boundary router.																		
5	AS-External-LSA	An external link outside the autonomous system.																		
<b>Link State ID</b>	4	<b>Link State ID:</b> Identifies the link. This usually is the IP address of either the router or the network the link represents.																		
<b>Advertising Router</b>	4	<b>Advertising Router:</b> The ID of the router originating the LSA.																		
<b>LS Sequence Number</b>	4	<b>LS Sequence Number:</b> A sequence number used to detect old or duplicate LSAs.																		
<b>LS Checksum</b>	2	<b>LS Checksum:</b> A checksum of the LSA, for data corruption protection.																		
<b>Length</b>	2	<b>Length:</b> The length of the LSA, including the 20 bytes of the header.																		

**Figure 190: OSPF *Link State Advertisement* Header Format**

### LSA Body

Following the LSA header comes the body of the LSA, the specific fields of which depend on the value of the *LS Type* field. It would take several **more** pages to describe all these subfields, and I already probably went overboard in describing each message type, so I will refer you to Appendix A of RFC 2328 if you want all the details. By way of quick summary:

- ☉ For normal links to a router, the LSA includes an identification of the router and the metric to reach it, as well as details about the router such as whether it is a boundary or area border router.
- ☉ LSAs for networks include a subnet mask and information about other routers on the network.
- ☉ Summary LSAs include a metric and a summarized address, as well as a subnet mask.
- ☉ External LSAs include a number of additional fields to allow the external router to be communicated.

---

## Other Interior Routing Protocols

The [Routing Information Protocol \(RIP\)](#) and [Open Shortest Path First \(OSPF\)](#) are the two most well-known interior routing protocols used in the TCP/IP suite, and for this reason I have described each in considerable detail. In addition to these, there are several other TCP/IP interior routing protocols that fall into one of two categories. Some are either protocols that are no longer used today but are interesting from a historical perspective, and others are proprietary alternates to RIP and OSPF that you may encounter today in the networking world but perhaps not as often.

In this section, I provide a brief description of four additional TCP/IP interior routing protocols. I begin with a look at two obsolete protocols that played an important role in the early Internet: the *Gateway-to-Gateway Protocol (GGP)* and the *HELLO Protocol*. I then describe two interior routing protocols developed by Cisco Systems, which are sometimes seen in the industry today as alternatives to RIP and OSPF: the *Interior Gateway Routing Protocol (IGRP)* and the *Enhanced Interior Gateway Routing Protocol (EIGRP)*.

**Background Information:** In some cases in this section, I make comparisons to RIP and OSPF as appropriate, to show where these protocols are similar to or differ from the “big two”. You may wish to have some familiarity with RIP and OSPF before continuing here.

---

### TCP/IP Gateway-to-Gateway Protocol (GGP)

In [the overview topic on key routing protocol concepts](#), I described the evolution of TCP/IP routing architectures. The modern Internet is based on the concept of independent *autonomous systems (ASes)* that run interior routing protocols within them, and exterior routing protocols between them. The early Internet, however, was somewhat simpler; it consisted of a relatively small number of *core* routers that carried detailed information about the Internet as a whole, and *non-core* routers located around the core that knew only partial information.

These core routers used a special routing protocol to communicate called the *Gateway-To-Gateway Protocol (GGP)*. GGP was originally developed in the early 1980s by Bolt, Beranek and Newman (BBN) one of the pioneers of the Internet and TCP/IP. It was documented in RFC 823, *THE DARPA INTERNET GATEWAY*, published September 1982. This protocol is now obsolete, but it played an important role in the early Internet, and also introduced certain concepts that were used in routing protocols developed years later. This makes knowing a little bit about it worthwhile.

#### **Overview of Operation**

GGP is similar in general operation to the [Routing Information Protocol \(RIP\)](#) in that it uses a distance-vector algorithm to determine the best routes between devices. Like RIP, the metric is a simple hop count, so GGP will select a route with the shortest number of hops.

---

While we have seen in our discussion of RIP that hop count is not always the best metric of cost for a router, it was actually a pretty good method of route determination back then. This is because the early Internet used both computers and links that would be considered glacially slow by today's standards, making each hop fairly "expensive" compared to modern routing.

A router using GGP initially starts out in a *null state*, assuming that all links to other routers and local networks are down. It then tests the status of its local networks by seeing if it can send and receive messages on the network. Every 15 seconds, the router sends a GGP *Echo* message to each of its neighbors. If the neighbor receives the message, it responds with a GGP *Echo Reply* message. The router sending the *Echo* messages considers the neighbor up if it receives back replies to a certain percentage of messages, defaulting to 50%.

**Note:** These messages serve a similar function to [ICMPv4 Echo and Echo Reply messages](#), but are not the same.

---

Actual routing information is communicated by sending GGP *Routing Update* messages. These are similar in nature to *RIP Response* messages used in RIP. Each *Routing Update* message contains the information in the sending router's routing table, which specifies which networks the router can reach and at what cost (in hops) for each.

Each router receiving a *Routing Update* message knows that since it can reach the router that sent the update, it can also reach all of those router's reachable networks at the cost of an additional hop. It uses the information to update its own internal tables of destinations and metrics. It then sends out its own *Routing Update* on its own attached networks, to propagate the information learned from other routers on its own networks. This process continues until eventually, routes to all GGP routers spreads across the internetwork, [just as they do in RIP](#).

### ***Propagation of Routing Table Information***

One interesting difference between GGP and RIP is that in GGP, networks and costs aren't sent in pairs. Instead, a GGP router sends its routing table in groups. If it has three networks it can reach at a cost of 1 it sends those in a group with distance value 1, then if it has a few at a cost of 2 it sends those in a group with distance value 2, and so on. Another difference is that GGP *Routing Update* messages are acknowledged. Each *Routing Update* message is sent with a sequence number, which is used to ensure that out-of-date information is not propagated. If the *Routing Update* is received and has a new sequence number (indicating that it is recent information), the router processing it sends back a GGP *Acknowledgment* message back to the originator. If the sequence number indicates the message is stale, a *Negative Acknowledgment* is sent instead and the message discarded.

---

As a distance-vector algorithm using hop count as a metric, GGP shared most of the same pros and cons as RIP. It had simplicity on its side, but had [various problems](#) such as slow convergence and issues such as the “counting to infinity” problem. GGP was a much more rudimentary protocol than RIP, however, and did not include many of the [features included in RIP to handle such issues](#), such as split horizon. GGP was also limited to unsubnetted classful networks, due to its age.

### ***Current Role in TCP/IP***

When Internet architecture moved to the use of autonomous systems, GGP was obsoleted. While it was an important part of TCP/IP history, it is today not formally considered a part of the TCP/IP protocol suite.

**Key Concept:** The *Gateway-to-Gateway Protocol (GGP)* was used to communicate route information between core routers on the early Internet. It is a distance-vector protocol that operates in a manner very similar to RIP. Each router periodically sends out its routing table to neighboring routers, so each router can learn the cost, in hops, to reach every network in the autonomous system. GGP is now considered a historical protocol and is no longer part of TCP/IP.

---

### **The HELLO Protocol (HELLO)**

The TCP/IP Internet as we know it today [evolved over the course of decades](#). It began as an experimental research project started by the United States *Defense Advanced Research Projects Agency (DARPA or ARPA)*, called the *ARPAnet*. The ARPAnet eventually grew through the addition of other networks, such as the important *NSFnet* developed by the *National Science Foundation (NSF)*. The NSFnet backbone grew over the course of many years and was instrumental to the eventual creation of the modern Internet.

The original NSFnet backbone consisted of six *Digital Equipment Corporation (DEC*, absorbed by *Compaq* years ago) LSI-11 computers located across the United States. These computers ran special software colloquially called “fuzzball” that enabled them to function as routers. These “fuzzball routers” connected various networks to the NSFnet and the ARPAnet.

The six NSFnet routers worked as an autonomous system (AS) and like any AS, used an interior routing protocol to exchange routing information. The routing protocol used in these early routers was called the *HELLO* protocol. It was developed in the early 1980s and documented in RFC 891, *DCN Local-Network Protocols*, published December 1983. The name “HELLO” is capitalized, but is not an acronym; it simply refers to the word *hello*, since the protocol uses messages that are sort of analogous to the routers talking to each other.

**Note:** The [Open Shortest Path First \(OSPF\)](#) routing protocol has a message type called *Hello*. The use of these messages is sometimes referred to as “the *Hello Protocol*”. OSPF is not directly related to the HELLO protocol described in this section, other than both protocols being used for routing in an AS. It is possible OSPF borrowed the name *Hello* from the HELLO protocol but I can't find anything definitive on that subject.

---

## Overview of Operation

The HELLO protocol uses a distance-vector algorithm, like the [Routing Information Protocol \(RIP\)](#) and the [Gateway-to-Gateway Protocol \(GGP\)](#). What's interesting about it, however, is that unlike RIP and GGP, HELLO does **not** use hop count as a metric. Instead, it attempts to select the best route by assessing network delays and choosing the path with the shortest delay.

One of the key jobs of routers using HELLO is to compute the time delay to send and receive datagrams to and from its neighbors. On a regular basis, routers exchange HELLO messages that contain clock and timestamp information. By comparing the clock value and timestamp in the message to its own clock using a special algorithm, a receiving device can compute an estimate for the amount of time it takes to send a datagram over the link.

Like RIP and GGP, *HELLO* messages also contain routing information in the form of a set of destinations that the sending router is able to reach and a metric for each. However in this case, the metric is an estimate of the round-trip delay cost for each destination. This information is added to the computed round-trip delay time for the link over which the message was received, and used to update the receiving router's own routing table.

This seems a bit confusing, but is really similar to the way a hop-count distance-vector protocol like RIP works. Router *A* using RIP receiving an *RIP Response* message from Router *B* knows it can reach every destination Router *B* can, but at a cost of one extra hop (the hop to go from Router *A* to Router *B*). Similarly, router *A* receiving a *HELLO* message from Router *B* knows it can reach every destination that Router *B* can, but at an additional approximate cost of the computed delay for the link between Router *A* and Router *B*.

## Issues with Using Delay as a Metric

In theory, using delay calculations should result in more efficient route selection than simply using hop count, but at the cost of more complexity than a hop-count algorithm. This makes HELLO very interesting indeed, especially for a protocol that is over 20 years old. However, since the latency of a link is often unrelated to its bandwidth, using time delay as a link metric may lead to spurious results.

---

Furthermore, it is normal for the delay on any link to vary over time; in the case where there are two routes that are similar in cost, fluctuations in the delay for each route could result in rapid changes between routes (a phenomenon sometimes called *route flapping*). Adjustments are needed to the basic overview of the operation of the HELLO protocol above, to avoid these sorts of problems.

### ***Current Role in TCP/IP***

Like other early routing protocols, HELLO includes nothing fancy like authentication and so on; these features were not really needed in the early days of the Internet, when the inter-networks were small and easily controlled. As the Internet grew, HELLO was eventually replaced by newer routing protocols such as RIP. It is now considered a historical protocol (read: obsolete) and is no longer used.

**Key Concept:** The *HELLO Protocol* was used on very early routers on the precursors of the Internet to exchange routing information. It is a distance-vector protocol like RIP and GGP but differs in that it uses calculated delay as a metric instead of hop count. Like GGP, it is now considered a historical protocol and is no longer part of TCP/IP.

---

## **Interior Gateway Routing Protocol (IGRP)**

If you have read a substantial portion of this Guide already, you have probably noticed that I greatly prefer universal, open standards to proprietary standards. (I explain the reasons why in [the Networking Fundamentals section on standards](#).) I am far from alone in this view, and in fact, it's no exaggeration to say that much of the success of TCP/IP and the Internet is tied to the fact that they were both developed using the open RFC process, and still are to this day.

That said, there are certain situations where a proprietary protocol can be of benefit, and can even achieve considerable success, if a minimum of two factors are true. First, there must be either a lack of a suitable open protocol, or a gap in the feature coverage of existing open protocols that creates an “opportunity” for a proprietary protocol to succeed. Second, the proprietary protocol must be either initiated or strongly supported by a “big player” in the industry, to help ensure that other companies will take notice and give the protocol a chance to become a standard.

This situation arose in the 1980s in the world of routing protocols. At that time, the most popular interior routing protocol was the Routing Information Protocol (RIP). As described in [the RIP section of this Guide](#), RIP does a basically good job, but has a number of [limitations and problems](#) that are inherent to the protocol and not easily resolved. In the mid-1980s, open alternatives like [OSPF](#) did not yet exist; even if it had, OSPF is much more complex than RIP and therefore sometimes not a good alternative.

---

Cisco Systems, definitely one of the “big names” in networking and especially internet-working and routing, decided to develop a new routing protocol that would be similar to RIP but would provide greater functionality and solve some of RIP's inherent problems: the *Interior Gateway Routing Protocol (IGRP)*. IGRP—which conveniently uses both the words “gateway” and “routing” in its name to convey the equivalence of the two words in internet-working standards—was designed specifically to be a replacement for RIP. It is similar in many ways, and keeps RIP's simplicity, one of its key strengths. At the same time, IGRP overcomes two key limitations of RIP: the use of only hop count as a routing metric, and the hop count limit of 15.

## **Overview of Operation**

Like RIP, IGRP is a distance-vector routing protocol designed for use with an autonomous system, and thus uses [the same basic mechanism for route determination](#). Each router routinely sends out on each local network to which it is attached a message containing a copy of its routing table. This message contains pairs of reachable networks and costs (metrics) to reach each network. A router receiving this message knows it can reach all the networks in the message as long as it can reach the router that sent the message. It computes the cost to reach those networks by adding to their costs, the cost to reach the router that sent the message. The routers update their tables accordingly, and send this information out in their next routine update. Eventually, each router in the autonomous system has information about the cost to reach each network in it.

## **Features and Capabilities**

An important difference between RIP and IGRP, however, is that where RIP only allows the cost to reach a network to be expressed in terms of hop count, IGRP provides a much more sophisticated metric. In IGRP, the overall cost to reach a network is computed based on several individual metrics, including internetwork delay, bandwidth, reliability and load. The calculation of cost can be customized by an administrator, who can set relative weightings to the component metrics to reflect the priorities of that autonomous system. So, if a particular administrator feels route cost would be best minimized by emphasizing reliability over bandwidth, he or she can do this. Such a system provides tremendous flexibility over the rigid hop-count system of RIP. Unlike RIP, IGRP also does not have any inherent limit of 15 hops between networks.

To this basic algorithm, IGRP adds a feature called *multipath routing*. This allows multiple paths between routes to be used automatically, with traffic shared between them. The traffic can either be shared evenly, or apportioned unevenly based on the relative cost metric of each path. This provides improved performance and again, flexibility.

Since IGRP is a distance-vector protocol like RIP, it shares many of RIP's algorithmic “issues”. Unsurprisingly, then, IGRP must incorporate many of [the same stability features as RIP](#), including the use of split horizon, split horizon with poisoned reverse (in certain circumstances) and the employment of hold-down timers. Like RIP, IGRP also uses timers to control how often updates are sent, how long routers are “held down”, and how long routes are held in the routing table before being expired.

---

Cisco originally developed IGRP for IP networks, and since IP is predominant in the industry, this is where it is most often seen. IGRP is not specific to IP, however, and can be used with other internetworking protocols if implemented for them. [As we will see in the next topic](#), Cisco also used IGRP as the basis for an improved routing protocol called EIGRP, developed several years after the original.

**Key Concept:** In the 1980s, Cisco Systems created the Interior Gateway Routing Protocol (IGRP) as an improvement over the industry standard protocol RIP. IGRP is a distance-vector protocol like RIP and similar to it in many ways, but includes several enhancements. Amongst the most important of these is an elimination of the 15 hop limit between routers, and the ability to use metrics other than hop count to determine optimal routes.

---

## **Enhanced Interior Gateway Routing Protocol (EIGRP)**

Cisco Systems, a leader in the world of internetworking and routing technology, developed the [Interior Gateway Routing Protocol \(IGRP\)](#) in the mid-1980s as an alternative protocol to [RIP](#) for use in TCP/IP autonomous systems. IGRP represented a substantial improvement over RIP, but like any successful company, Cisco was not content to rest on its laurels. Cisco knew that IGRP had significant room for improvement, so they set to work on creating a better version of IGRP in the early 1990s. The result was the *Enhanced Interior Gateway Routing Protocol (EIGRP)*.

### ***Comparing IGRP and EIGRP***

Compared to the original protocol, EIGRP is more of an evolution than a revolution. EIGRP is still a [distance-vector protocol](#), but is more sophisticated than other distance-vector protocols like IGRP or RIP, and includes certain features that are more often associated with link-state routing protocols like [OSPF](#) than distance-vector algorithms. Also, since Cisco realized many of the organizations deciding to use EIGRP would be migrating to it from IGRP, they took special steps to maximize compatibility between the two.

The chief differences between IGRP and EIGRP are not in what they do, but how they do it. EIGRP changes the way that routes are calculated, in an effort to improve efficiency and the speed of route convergence (agreement on routes between different routers in the inter-network). EIGRP is based on a new route calculation algorithm called the *Diffusing Update Algorithm (DUAL)*, developed at a company called *SRI International* by Dr. J. J. Garcia-Luna-Aceves.

### ***EIGRP's DUAL Route Calculation Algorithm***

DUAL differs from a typical distance-vector algorithm primarily in that it maintains more topology information about the internetwork than that used by protocols like RIP or IGRP. It uses this information to automatically select least-cost, loop-free routes between networks. EIGRP uses a metric that combines an assessment of the bandwidth of a link and the total

---

delay to send over the link. (Other metrics are configurable as well, though not recommended.) When a neighboring router sends changed metric information, routes are recalculated and updates sent as needed. DUAL will query neighboring routers for reachability information if needed (for example, if an existing route fails).

This “as needed” aspect of operation highlights an important way that EIGRP improves performance over IGRP. EIGRP does not send routine route updates, only partial updates as required, reducing the amount of traffic generated between routers. Furthermore, these updates are designed so that only the routers that need the updated information receive them.

### ***Other Features of EIGRP***

In order to build the tables of information it needs to calculate routes, EIGRP requires that each router make and maintain contact with other routers on their local networks. To facilitate this, EIGRP incorporates a *neighbor discovery/recovery* process. This system involves the exchange of small *Hello* messages that let routers discover which other routers on the local network, and to periodically check their reachability. This is very similar to the use of the identically-named *Hello* messages in OSPF, and has a low impact on bandwidth use because the messages are small and infrequently sent.

Some of the features in IGRP carry through to its successor, such as the use of split horizon with poisoned reverse for improved stability. In addition to the basic improvements of efficiency and route convergence that accrue from the algorithm itself, EIGRP includes some other features. These include support for [variable length subnet masks \(VLSM\)](#) and support for multiple network-layer protocols. This means that EIGRP could be configured to function on a network running IP as well as another layer three protocol.

**Key Concept:** Developed in the 1990s, the *Enhanced Interior Gateway Routing Protocol (EIGRP)* is an improved version of Cisco’s IGRP. It is similar to IGRP in many respects, but uses a more sophisticated route calculation method called the *Diffusing Update Algorithm (DUAL)*. EIGRP also includes several features that make it more intelligent in how it computes routes, borrowing concepts from link-state routing protocols, and using more efficient partial updates rather than sending out entire routing tables.

---

---

## TCP/IP Exterior Gateway/Routing Protocols (BGP and EGP)

For ease of administration, [routers on large internetworks are grouped into autonomous systems \(ASes\)](#) that are independently controlled by different organizations and companies. [Interior routing protocols](#) such as RIP and OSPF are used to communicate routing information between routers within an autonomous system. Obviously, if interior routing protocols are used within ASes, we need another set of routing protocols to send that information **between** ASes. These are called *exterior routing protocols*.

The entire point of autonomous system architecture is conveyed in the meaning of the first word in that phrase: *autonomous*. The details of what happens within an AS are hidden from other ASes, which allows the administrator of an AS to have the independence to control how he or she runs it, including the selection of one or more from a variety of different interior routing protocols. In contrast, to reliably connect ASes together, it is essential that each one be running the same exterior routing protocol, or the result would be something akin to the Tower of Babel. The result of this is that in TCP/IP there is generally only one exterior routing protocol in widespread use at a given time.

In this section I describe two different TCP/IP exterior routing protocols. The first is the *Border Gateway Protocol (BGP)*, the one used in modern TCP/IP. BGP is very important since it is used on the current Internet and other larger internetworks, so it is covered in considerable detail. The second is the *Exterior Gateway Protocol (EGP)*. This is an obsolete protocol that was used for communication between non-core routers and the router core in the early Internet, and is described briefly for both completeness and historical interest.

**Background Information:** I am assuming in this section that you are already at least somewhat familiar with interior routing protocols, at least to the extent of understanding what they do in basic terms. If you have not yet read up on RIP, the most common interior routing protocol, [you may wish to skim that section](#). At the very least, make sure you are familiar with [the overview of routing protocol architectures](#).

---

---

## **TCP/IP Border Gateway Protocol (BGP/BGP-4)**

Modern TCP/IP internetworks are comprised of autonomous systems (ASes) that are run independently. Each may use an [interior routing protocol](#) such as RIP, OSPF, IGRP or EIGRP to select routes between networks within the AS. To form larger internetworks, and especially the “mother of all internetworks”, the Internet, these autonomous systems must be connected together. This requires use of a consistent exterior routing protocol that all ASes can agree upon, and in today's TCP/IP that protocol is the *Border Gateway Protocol (BGP)*.

In this section I describe the characteristics, general operation and detailed operation of the Border Gateway Protocol (BGP). The discussion is divided into two subsections. The first provides an overview and general look at the operation of BGP, including a discussion of key concepts such as topology, neighbor relationships, route determination and general messaging. The second gives a more detailed analysis of the different message types and how they are used, and describes the format of each message as well.

BGP is another in the rather large group of protocols and technologies that is so complex it would take dozens of topics to do justice. Therefore, I include here my somewhat standard disclaimer that you will find in this section only a relatively high-level look at BGP. You will need to refer to the BGP standards ([described in the topic on BGP standards and versions](#)) if you need more details.

---

**Note:** The current version of BGP is version 4, also called *BGP-4*. This is the only version widely used today, so unless otherwise indicated, assume BGP-4 wherever you see “BGP”.

---

---

## **BGP Fundamentals and General Operation**

If you were to ask the average Internet user, or even that typical network administrator, to make a list of the ten most important TCP/IP protocols, it's probable that BGP wouldn't often show up. Routing protocols are “worker bees” of the TCP/IP suite and just not very exciting. The reality, however, is that BGP is a critically important protocol to the operation of larger internetworks and the Internet itself. It is the “glue” that binds smaller internetworks (autonomous systems) together, and it ensures that every organization is able to share routing information. It is this function that lets us take disparate networks and internetworks and find efficient routes from any host to any other host, regardless of location.

In this section I begin our look at the very important BGP protocol by covering its basic concepts and general operation. I start, as usual, with an overview of the protocol and discussion of its history, standards and versions, including a discussion of its key features and characteristics. I then cover basic operational concepts, including topology, the notion of BGP *speakers* and neighbor relationships. I discuss BGP traffic types and how policies can be used to control traffic flows on the internetwork. I explain how BGP routers store and advertise routes, and the function of Routing Information Bases (RIBs). I describe the basic algorithm used by BGP and how path attributes describe routes. I then provide a summary of how the BGP route selection process operates. I conclude with a general description of BGP's operation and its high-level use of various messages.

### **BGP Overview, History, Standards and Versions**

As I describe briefly in [the overview of routing protocol concepts](#), the way that routers were connected in the early Internet was quite different than it is today. The early Internet had a set of centralized routers functioning like a “core” autonomous system. These routers used the [Gateway-to-Gateway Protocol](#) for communication between them within the AS, and the aptly-named [Exterior Gateway Protocol \(EGP\)](#) to talk to routers outside the core.

### ***Motivation and Development of BGP***

When the Internet grew and moved to autonomous system (AS) architecture, EGP was still able to function as the exterior routing protocol for the Internet. However, as the number of autonomous systems in an internetwork grows, the importance of communication between them grows as well. EGP was functional but had several weaknesses that became more problematic as the Internet grew in size. It was necessary to define a new exterior routing protocol that would provide enhanced capabilities for use on the growing Internet.

In June 1989, the first version of this new routing protocol was formalized, with the publishing of RFC 1105, [\*A Border Gateway Protocol \(BGP\)\*](#). This initial version of the BGP standard defined most of the concepts behind the protocol, as well as key fundamentals such as messaging, message formats and how devices operate in general terms. It established BGP as the Internet's exterior routing protocol of the future.

---

## BGP Evolution, Versions and Defining Standards

Due to the importance of a protocol that spans the Internet, work continued on BGP for many years after the initial standard was published. The developers of BGP had to correct problems with the initial protocol, refine BGP's operation, improve efficiency, and add features. It was also necessary to make adjustments to allow BGP to keep pace with other changes in the TCP/IP protocol suite, such as the invention of [classless addressing and routing](#).

The result of this ongoing work is that BGP has evolved through several versions and standards. These are sometimes called *BGP-N* where *N* is the version number. [Table 134](#) shows the history of BGP standards, providing the RFC numbers and names and a brief summary of the changes made in each version.

**Table 134: Border Gateway Protocol (BGP) Versions and Defining Standards**

RFC Number	Date	Name	BGP Version	Description
1105	June 1989	<u><i>A Border Gateway Protocol (BGP)</i></u>	BGP-1	Initial definition of the BGP protocol.
1163	June 1990	<u><i>A Border Gateway Protocol (BGP)</i></u>	BGP-2	<p>This version cleaned up several issues with BGP-1, and refined the meaning and use of several of the message types. It also added the important concept of path attributes, which communicate information about routes.</p> <p>BGP-1 was designed around the notion of a directional topology, with certain routers being “up”, “down” or “horizontal” relative to each other; BGP-2 removed this concept, making BGP better suited to an arbitrary AS topology.</p> <p>Note that the RFC title is not a typo; they didn't put “version 2” in the title.</p>
1267	October 1991	<u><i>Border Gateway Protocol 3 (BGP-3)</i></u>	BGP-3	<p>This version optimized and simplified route information exchange, adding an identification capability to the messages used to establish BGP communications, and incorporating several other improvements and corrections.</p> <p>(They left the “A” off the title of this one for some reason. ☺)</p>
1654	July 1994	<u><i>A Border Gateway Protocol 4 (BGP-4)</i></u>	BGP-4	Initial standard for BGP-4, revised in RFC 1771. See just below.
1771	March 1995	<u><i>A Border Gateway Protocol 4 (BGP-4)</i></u>	BGP-4	Current standard for BGP-4. The primary change in BGP-4 is support for <a href="#">Classless Inter-Domain Routing (CIDR)</a> . The protocol was changed to allow prefixes to be specified that represent a set of aggregated networks. Other minor improvements were also made to the protocol.

---

As you might imagine, changing the version of a protocol like BGP is not an easy undertaking. Any modification of the protocol would require the coordination of many different organizations. The larger the Internet grows, the more difficult this would be. As a result, despite frequent version changes in the early 1990s, BGP-4 remains today the current version of the standard, and is the one that is widely used. Unless otherwise specified, any mention of BGP in this Guide refers to BGP-4.

### ***BGP Supplementary Standards***

Supplementing RFC 1771 are three other consecutively-numbered RFCs published simultaneously with it, which provide supporting information about BGP's functions and use, as shown in [Table 135](#).

**Table 135: Additional Defining Standards For BGP-4**

RFC Number	Name	Description
1772	<i><u>Application of the Border Gateway Protocol in the Internet</u></i>	Provides additional conceptual information on the operation of BGP and how it is applied to and used on the Internet.  This document is sometimes considered a companion of RFC 1771 with the pair defining BGP-4.
1773	<i><u>Experience with the BGP-4 Protocol</u></i>	Describes the experiences of those testing and using BGP-4, and provides information that justified its acceptance as a standard.
1774	<i><u>BGP-4 Protocol Analysis</u></i>	Provides more detailed technical information about the operation of the BGP-4 protocol.

### ***Overview of BGP Functions and Features***

If I were to summarize the job of BGP in one phrase, it would be “to exchange network *reachability information* between autonomous systems and from this information determine routes to networks”. In a typical internetwork (and in the Internet) each autonomous system designates one or more routers that run BGP software. BGP routers in each autonomous system are linked to those in one or more other autonomous systems. Each BGP stores information about networks and the routes to them in a set of *Routing Information Bases (RIBs)*. This route information is exchanged between BGP routers, and propagated throughout the entire internetwork, allowing each AS to find paths to each other AS, and thereby enabling routing across the entire internetwork.

**Key Concept:** The exterior routing protocol used in modern TCP/IP internetworks is the Border Gateway Protocol (BGP). Initially developed in the late 1980s as a successor to EGP, BGP has been revised many times; the current version is 4, so BGP is also commonly called *BGP-4*. BGP's primary function is the exchange of network reachability information between autonomous systems to allow each AS on an internetwork to send messages efficiently to every other one.

---

BGP supports an arbitrary topology of ASes, meaning they can be connected in any manner. An AS must have a minimum of one router running BGP, but can have more than one. It is also possible to use BGP to communicate between BGP routers within the same autonomous system.

BGP uses a fairly complex system for route determination. The protocol goes beyond the limited notion of considering only the next hop to a network the way [distance-vector algorithms like RIP](#) function. Instead, the BGP router stores more complete information about the path (sequence of autonomous systems) from itself to a network. Special *path attributes* describe the characteristics of paths, and are used in the process of route selection. Because of its storage of not just next-hop but path information, BGP is sometimes called a *path vector* protocol.

BGP chooses routes using a deterministic algorithm that assess path attributes and chooses an efficient route while avoiding router loops and other problem conditions. The selection of routes by a BGP router can also be controlled through a set of BGP *policies* that specify, for example, whether an AS is willing to carry traffic from other ASes or not. However, BGP cannot guarantee the most efficient route to any destination, because it cannot know what happens within each AS and therefore what the cost is to traverse each AS.

BGP's operation is based on the exchange of messages that perform different functions. BGP routers use *Open* messages to contact neighboring routers and establish BGP sessions. They exchange *Update* messages to communicate information about reachable networks, sending only partial information as needed. They also use *Keepalive* and *Notification* messages to maintain sessions and inform peers of error conditions. The use of these messages is summarized in [the topic on BGP general operation](#), with details (including message formats) in [the section on detailed operation](#).

BGP uses [TCP](#) as a reliable transport protocol, so it can take advantage of the many connection setup and maintenance features of that protocol. This also means that BGP doesn't need to worry about issues such as message sequencing, acknowledgements, or lost transmissions. Since unauthorized BGP messages could wreak havoc with the operation of the Internet, BGP includes an authentication scheme for security.

**Key Concept:** BGP supports an arbitrary topology of autonomous systems. Each autonomous system using BGP assigns one or more routers to implement the protocol. These devices then exchange messages to establish contact with each other and share information about routes through the internetwork using TCP. BGP employs a sophisticated *path vector* route calculation algorithm that determines routes from path attributes that describe how different networks can be reached.

---

**Note:** BGP maintains backwards compatibility with the older exterior routing protocol, [EGP](#).

---

### **BGP Topology, Speakers, Border Routers and Neighbor Relationships (Internal and External Peers)**

In my [overview of BGP](#), I boiled down the function of the Border Gateway Protocol (BGP) into this summary: the exchange of network reachability information between autonomous systems (ASes) of routers and networks, and the determination of routes from this information. The actual method that BGP uses to accomplish this, however, is fairly complex. To help us understand how BGP works, we should start by looking at the structure of BGP internetworks, and also a discussion of key BGP terms.

#### ***BGP Topology and Speakers***

One of the most important characteristics of BGP is its *flexibility*. The protocol can connect together any internetwork of autonomous systems using an arbitrary topology. The only requirement is that each AS have at least one router that is able to run BGP and that this router connect to at least one other AS's BGP router. Beyond that, “the sky's the limit,” as they say. BGP can handle a set of ASes connected in a full mesh topology (each AS to each other AS), a partial mesh, a chain of ASes linked one to the next, or any other configuration. It also handles changes to topology that may occur over time.

Another important assumption that BGP makes is that it doesn't know anything about what happens within the AS. This is of course an important prerequisite to the notion of an AS being *autonomous*—it has its own internal topology and uses its own choice of routing protocols to determine routes. BGP only takes the information conveyed to it from the AS and shares it with other ASes.

Creating a BGP internetwork begins with the designation of certain routers in each AS as ones that will run the protocol. In BGP parlance, these are called BGP *speakers*, since they speak the BGP “language”. A protocol can reasonably be called a language, but I have not encountered this notion of a “speaker” in any other protocol, so it's somewhat interesting terminology.

---

## BGP Router Roles and Neighbors

An autonomous system can contain many routers which are connected in an arbitrary topology. We can draw a distinction between routers in an AS that are connected only to other routers within the AS, versus those that connect to other ASes. Routers in the former group are usually called *internal routers*, while the latter group are called *border routers* in BGP, and similar names in other protocols. For example, in OSPF they are called *boundary routers*.

Of course, the notion of a *border* is the basis for the name of the BGP protocol itself. To actually create the BGP internetwork, the BGP speakers bordering each AS are physically connected to one or more BGP speakers in other ASes, in whatever topology the internetwork designer decrees. When a BGP speaker in one AS is linked to a BGP speaker in another AS, they are deemed *neighbors*. The direct connection between them allows them to exchange information about the ASes of which they are a part.

## BGP Internal and External Peers

Most BGP speakers will be connected to more than one other speaker. This provides both greater efficiency in the form of more direct paths to different networks, and also redundancy to allow the internetwork to cope with either device or connection failures. It is possible (and in many cases, likely) for a BGP speaker to have neighbor relationships with other BGP speakers both within its own AS and outside its AS. A neighbor within the AS is called an *internal peer*, while a neighbor outside the AS is an *external peer*. BGP between internal peers is sometimes called *Internal BGP (IBGP)* while use of the protocol between external peers is *External BGP (EBGP)*. The two are similar, but differ in certain areas, especially [path attributes and route selection](#). You can see an example of BGP topology and the designation of internal and external peers in [Figure 191](#).

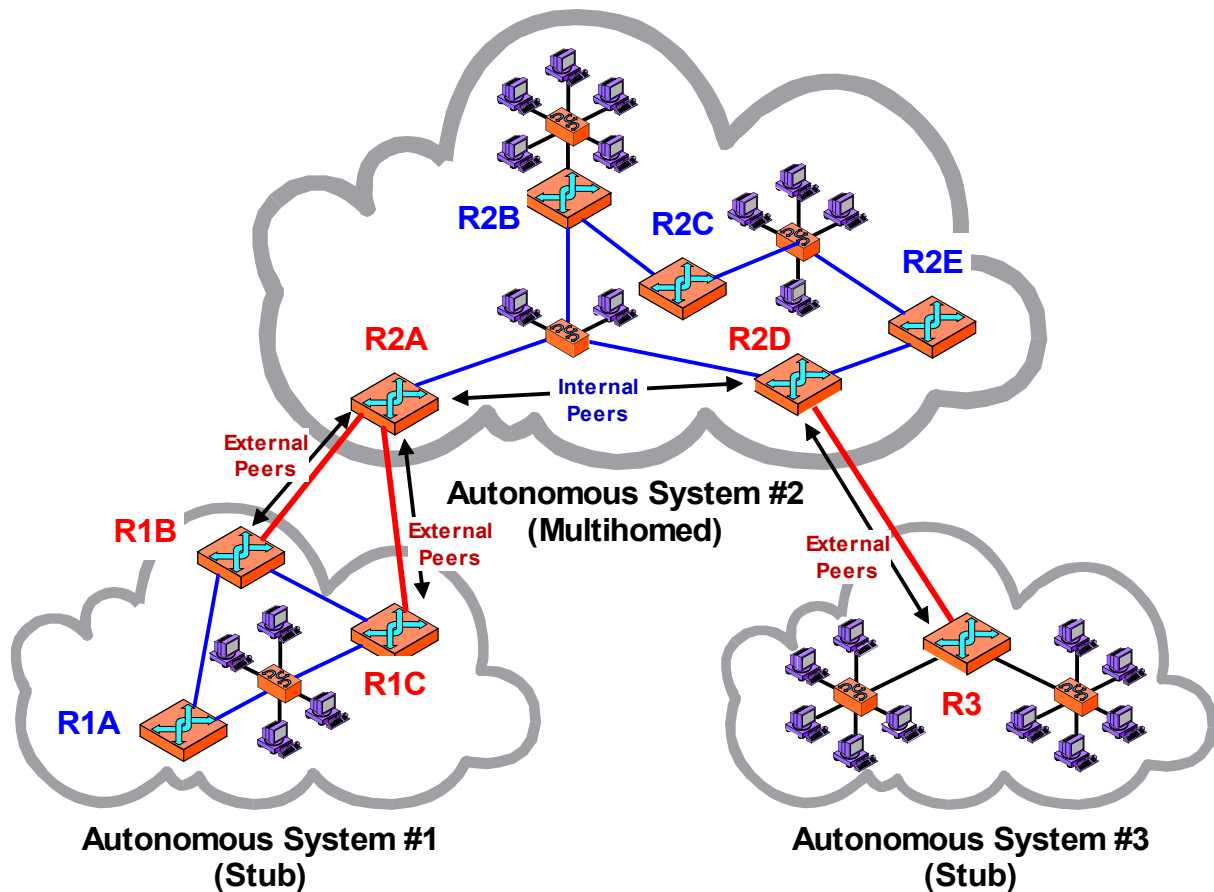

**Key Concept:** Each router configured to use BGP is called a BGP *speaker*; these devices exchange route information using the BGP messaging system. Routers that only connect to other routers in the same autonomous system are called *internal routers*, while those that connect to other ASes are *border routers*. Neighboring BGP speakers in the same AS are called *internal peers*, while those in different ASes are *external peers*.

---

A peer connection between BGP speakers can be either a direct link using some form of layer two technology, or an indirect link using TCP. This allows the BGP speakers to establish BGP sessions and then exchange routing information, using [the messaging system we will see later in this section](#). Of course, it also is the means by which actual “end user” traffic moves between autonomous systems. External peers are normally connected directly, while internal peers are often linked indirectly.

In [the next topic](#) we will see that the method in which ASes are connected has an important impact on the overall function of the internetwork and how traffic is carried on it.

**Figure 191: BGP Example Topology and Designations**

This diagram is a variation on [Figure 171](#) that shows the names used by BGP to refer to different types of routers and autonomous systems. Internal routers are shown in blue while border routers are red. BGP speakers that communicate within an AS are internal peers, while those that communicate between ASes are external peers. This highly simplified internetwork shows two stub ASes, both of which only connect to the multihomed AS #2.

## **BGP Autonomous System Types, Traffic Flows and Routing Policies**

When we connect autonomous systems (ASes) together to form an internetwork, the paths between AS border routers form the conduit by which messages move from one AS to another. It is very important that the flow of messages between ASes be carefully controlled. Depending on circumstances, we may wish to limit or even prohibit certain types of messages from going to or from a certain AS. These decisions in turn have a direct impact on BGP route determination.

### ***BGP Traffic Flow and Traffic Types***

The flow of messages in an internetwork is sometimes collectively called *traffic*. This term presents a good analogy, because we can consider the matter of traffic flow control in a BGP internetwork in much the same way we do on the streets of a city. You have probably in the past seen signs on residential streets that say “No Through Traffic” or “Local Traffic

---

Only”. These are attempt to control the flow of traffic over those streets. A more extreme example of this would be a street in the neighborhood where I used to live, where a barricade was intentionally erected in the middle to turn a busy through street into a pair of dead-ends. Again, the goal was traffic control.

These measures highlight a key distinction between *local traffic* and *through traffic* in a neighborhood. The very same categorization is important in BGP:

- ☉ **Local Traffic:** Traffic carried within an autonomous system that either originated in that same AS, **or** is intended to be delivered within that AS. This is like local traffic on a street.
- ☉ **Transit Traffic:** Traffic that was generated outside that AS **and** is intended to be delivered outside the AS. This is like what we commonly call *through traffic* on the streets.

### ***BGP Autonomous System Types***

In the [previous topic](#) we discussed the distinction between internal routers and border (or boundary) routers in an AS. If we look at the entire BGP internetwork, we can make a similar distinction between different types of ASes, based on how they are interconnected in the overall BGP topology. There are two main types of AS:

- ☉ **Stub AS:** This is an AS that is connected to only one other AS. It is comparable to a cul-de-sac (dead-end street) in our road analogy; usually, only vehicles coming from or going to houses on the street will be found on that street.
- ☉ **Multihomed AS:** This is an AS that is connected to two or more other ASes. It is comparable to a through street in our road analogy, because it is possible that cars may enter the street and pass through it without stopping at any of the street's houses.

In the example BGP internetwork in [Figure 191](#), I have linked border routers in AS #2 to both AS #1 and AS #3. While traffic from AS #2 can flow both to and from AS #1 and AS #3, it is possible that traffic from AS #1 may also flow to AS #3 and vice-versa. AS #2 acts as the “through street” for these datagrams.

### ***BGP Autonomous System Routing Policies***

The reason why BGP makes a distinction between traffic types and AS types is the same as why it is done on the streets: many folks have a dim view of through traffic. In a neighborhood, everyone wants to be able to get from their homes to anywhere they need to go in the city, but they don't want lots of other people using their streets. Similarly, every autonomous system must use at least one other autonomous system to communicate with distance ASes, but many are less than enthusiastic about being a conduit for lots of external traffic.

This reluctance really does make sense in many cases, both in the case of a neighborhood or in the case of BGP. Having lots of cars and trucks on a residential street can be a problem in a number of ways: safety issues, wear and tear on the road, pollution and so forth. Similarly, if a multihomed AS was forced to carry all transit traffic that other ASes want to send to it, it might become overloaded.

---

To provide control over the carrying of transit traffic, BGP allows an AS to set up and use *routing policies*. These are sets of rules that govern how an AS will handle transit traffic. A great deal of flexibility exists in how an AS decides to handle transit traffic. Some of the many options include:

- ☉ **No Transit Policy:** An AS can have a policy that it will not handle transit traffic at all.
- ☉ **Restricted AS Transit Policy:** An AS may allow handling of traffic from certain ASes but not others. In this case it tells the ASes it will handle that they may send it traffic, but does not say this to the others.
- ☉ **Criteria-Based Transit Policy:** An AS may use a number of different criteria to decide whether to allow transit traffic. For example, it might allow transit traffic only during certain times, or only when it has enough spare capacity.

**Note:** An autonomous system that is willing to carry transit traffic is sometimes called a *transit AS*.

---

In a similar manner, policies can be set that control how an AS will have its own traffic handled by other autonomous systems. Obviously a stub AS will always connect to the internetwork as a whole using the single AS to which it connects. A multihomed AS, however, may have policies that influence route selection by specifying the conditions under which one AS should be used over another. These policies may be based on considerations of security (if one connecting AS is deemed more secure than another), performance (one AS is faster than another), reliability or other factors.

### ***Issues With Routing Policies and Internetwork Design***

What would happen to a city if every street only allowed local traffic? It would be pretty hard to get around. Of course this problem never occurs in well-designed cities, because traffic planners understand the dual need for connectivity and through-traffic avoidance in residential areas. Cities are laid out in a somewhat hierarchical fashion, so local traffic “funnels” to thoroughfares intended specifically to carry non-local traffic.

The same basic situation exists in an internetwork. It wouldn't work very well if every AS declared it was not interested in carrying transit traffic! Usually, internetworks are designed so that certain autonomous systems are intended to carry large amounts of transit traffic. This is typically the function of high-speed, high-capacity backbone connections, which serve other ASes as customers. An AS will usually only carry another AS's traffic if arrangements have been made to allow this.

**Key Concept:** One important issue in BGP is how to handle the flow of traffic between autonomous systems. Each autonomous system in a BGP internetwork is either a *stub AS*, if it connects to only one other AS, or a *multihomed AS* if it connects to two or more others. BGP allows the administrators of a multihomed AS to establish routing policies that specify under what conditions the AS is willing to handle *transit traffic* (messages sent over the AS whose source and destination are both external to that AS.)

---

## **BGP Route Storage and Advertisement, and BGP Routing Information Bases (RIBs)**

The job of the Border Gateway Protocol is to facilitate the exchange of route information between BGP devices, so that each router can determine efficient routes to each of the networks on an IP internetwork. This means that descriptions of routes are the key data that BGP devices work with. Every BGP speaker is responsible for managing route descriptions according to specific guidelines established in the BGP standards.

### ***BGP Route Information Management Functions***

Conceptually, the overall activity of route information management can be considered to encompass four main tasks:

- 🕒 **Route Storage:** Each BGP stores information about how to reach networks in a set of special databases. It also uses databases to hold routing information received from other devices.
- 🕒 **Route Update:** When a BGP device receives an *Update* from one of its peers, it must decide how to use this information. Special techniques are applied to determine when and how to use the information received from peers to properly update the device's knowledge of routes.
- 🕒 **Route Selection:** Each BGP uses the information in its route databases to select good routes to each network on the internetwork.
- 🕒 **Route Advertisement:** Each BGP speaker regularly tells its peers what it knows about various networks and methods to reach them. This is called *route advertisement* and is accomplished using BGP *Update* messages. We'll learn more about these messages in the next few topics, and examine them in detail in [the detailed section on BGP message formats](#).

### ***BGP Routing Information Bases (RIBs)***

The heart of BGP's system of routing information management and handling is the database where routes are stored. This database is collectively called the *Routing Information Base (RIB)*, but it is in fact not a monolithic entity. It is comprised of three separate sections that are used by a BGP speaker to handle the input and output of routing information. Two of these sections themselves consist of several individual parts, or copies.

The three RIB sections (using the cryptic names given them by the BGP standards, sorry!) are:

- 
- ☉ **Adj-RIBs-In:** A set of *input* database parts that holds information about routes received from peer BGP speakers.
  - ☉ **Loc-RIB:** The *local RIB*. This is the core database that stores routes that have been selected by this BGP device and are considered valid to it.
  - ☉ **Adj-RIBs-Out:** A set of *output* database parts that holds information about routes that this BGP device has selected to be disseminated to its peers.

Thus, the RIB can be considered either a single database or a set of related databases, depending on how you look at it. (The divisions above are conceptual in nature; the entire RIB can be implemented as a single database with an internal structure representing the different components, or as separate databases.)

The RIB is a fairly complex data structure, not just because of this multi-section structure, but because BGP devices store considerably more information about routes than simpler routing protocols. Routes are also called *paths* in BGP, and the detailed descriptions of them are stored in the form of special BGP [path attributes](#).

The three sections of the RIB are the mechanism by which information flow is managed in a BGP speaker. Data received from *Update* messages transmitted by peer BGP speakers is held in the *Adj-RIBs-In*, with each *Adj-RIB-In* holding input from one peer. This data is then analyzed and appropriate portions of it selected to update the *Loc-RIB*, which is the main database of routes this BGP speaker is using. On a regular basis, information from the *Loc-RIB* is placed into the *Adj-RIBs-Out* to be sent to other peers using *Update* messages. This information flow is accomplished as part of the system of route update, selection and advertisement known as [the BGP Decision Process](#).

**Key Concept:** The routine operation of BGP requires BGP speakers to store, update, select and advertise routing information. The central data structure used for this purpose is the BGP *Routing Information Base (RIB)*. The RIB actually consists of three sections: a set of input databases (*Adj-RIBs-In*) that hold routing information received from peers, a local database (*Loc-RIB*) that contains the router's current routes, and a set of output databases (*Adj-RIBs-Out*) used by the router to send its routing information to other routers.

---

## **BGP Path Attributes and Algorithm Overview**

Routing protocols using a [distance-vector algorithm](#) such as RIP are relatively simple in large part because the information each device stores about each route is itself simple. Each router only knows that it can reach a network at a specific cost through a particular next-hop router. It doesn't have knowledge of the route that datagrams will take to reach any of these networks. This level of knowledge is simply insufficient for the needs of a protocol like BGP.

---

## BGP's Path-Vector Routing Algorithm and Path Attributes

In order to handle the calculation of efficient, non-looping routes in an arbitrary topology of autonomous systems, we need to know not just “to get to network N7 send to router R4”; we need to have some understanding of the characteristics of the entire path between ourselves and network N7. By storing this additional information, it is possible to make decisions about how to compute and change routes, using knowledge of the entire path between a router and a network.

Thus, in BGP, instead of advertising networks in terms of a destination and the distance to that destination, BGP devices advertise networks as destination addresses and *path descriptions* to reach those destinations. This means BGP uses, instead of a *distance-vector* algorithm, a *path-vector* algorithm. Each communication of a reachable network provides considerable information about the entire sequence of routers to a destination. Due to this inclusion of topology information, path-vector protocols are sometimes described as a combination of distance-vector and link-state algorithms. This doesn't really do them justice, however, since they do not function in the same way as either of those algorithm types.

**On The Web:** If you are interested in additional general information about path-vector algorithms, you can find some in [RFC 1322](#), [\*A Unified Approach to Inter-Domain Routing\*](#). Warning: do not read before operating heavy machinery. ☺

---

The information about the path to each route is stored in the [Routing Information Base \(RIB\)](#) of each BGP speaker in the form of BGP *path attributes*. These attributes are used to advertise routes to networks when BGP devices send out *Update* messages. The storing, processing, sending and receiving of path attributes is “the” method by which routers decide how to create routes, so understanding them is obviously quite important.

There are several different path attributes, each of which describes a particular characteristic of a route. Attributes are divided into different categories based on their level of importance and specific rules designed to manage their propagation. The most important path attributes are called *well-known* attributes; every BGP speaker must recognize and process these, but only some are required to be sent with every route. Other attributes are *optional* and may or not be implemented. These are further differentiated based on how they are handled when received by a device that does not recognize them.

### BGP Path Attribute Classes

The four formal classifications of path attributes are:

- 🕒 **Well-Known Mandatory:** These are the most important path attributes; they must be included in every route description in *Update* messages, and must be processed by each BGP device receiving them.

- ☉ **Well-Known Discretionary:** These path attributes must be recognized by a BGP device if received, but they may or may not be included in an *Update* message. Thus, they are optional for a sender of information, but mandatory for a receiver to process.
- ☉ **Optional Transitive:** These path attributes may be recognized by a BGP router and may be included in an *Update* message. They must be passed on to other BGP speakers when the route is advertised, even if received by a device that does not recognize the attribute.
- ☉ **Optional Non-Transitive:** Optional attributes that may be recognized by a BGP device and may be included in an *Update* message. If received by a device that does not recognize the attribute, it is dropped and not passed on to the next router.

**Note:** As you might imagine, all well-known attributes are by definition transitive—they must be passed on from one BGP speaker to the next.

**Key Concept:** Unlike simpler routing protocols that store only limited information about how to reach a network, such as its cost and the next hop to reach it, BGP stores detailed information about complete routes to various networks. This information takes the form of *path attributes* that describe various characteristics of a path (route) through the ASes that connect a router to a destination network.

### **BGP Path Attribute Characteristics**

Table 136 contains a summary of the characteristics of each of the most common BGP path attributes used to describe the route to a destination, as well as the *Attribute Type* code assigned to each in BGP *Update* messages:

**Table 136: Summary of BGP Path Attributes (Page 1 of 2)**

BGP Path Attribute	Classification	Attribute Type Value	Description
<i>Origin</i>	Well-Known Mandatory	1	Specifies the origin of the path information. This attribute indicates whether the path came originally from an interior routing protocol, the older exterior routing protocol EGP, or some other source.
<i>AS_Path</i>	Well-Known Mandatory	2	A list of autonomous system numbers that describes the sequence of ASes through which this route description has passed. This is a critically important attribute, since it contains the actual path of autonomous systems to the network. It is used to calculate routes and to detect routing loops.
<i>Next_Hop</i>	Well-Known Mandatory	3	The next-hop router to be used to reach this destination.

**Table 136: Summary of BGP Path Attributes (Page 2 of 2)**

BGP Path Attribute	Classification	Attribute Type Value	Description
<b>Multi_Exit_Disc (MED)</b>	Optional Non-Transitive	4	When a path includes multiple exit or entry points to an AS, this value may be used as a metric to discriminate between them (that is, choose one exit or entry point over the others.)
<b>Local_Pref</b>	Well-Known Discretionary	5	Used in communication between BGP speakers in the same AS to indicate the level of preference for a particular route.
<b>Atomic_Aggregate</b>	Well-Known Discretionary	6	In certain circumstances, a BGP speaker may receive a set of overlapping routes where one is more specific than the other. For example, consider a route to the network 34.15.67.0/24 and to the network 34.15.67.0/26. The latter network is a subset of the former, which makes it more specific. If the BGP speaker uses the less-specific route (in this case, 34.15.67.0/24) it sets this path attribute to a value of 1 to indicate that this was done.
<b>Aggregator</b>	Optional Transitive	7	Contains the AS number and BGP ID of the router that performed route aggregation; used for troubleshooting.

Some of these path attributes are straight-forward to understand; others are fairly cryptic and probably confusing. Delving into any more detail on the path attributes leads us into a full-blown description of detailed inter-AS route calculations. We'll look at that to some degree in [the next topic](#).

For full details on the message format used to communicate path attributes, see [the format of BGP Update messages](#).

## **BGP Route Determination and the BGP Decision Process**

The last two topics have described the fundamentals of how BGP devices store and manage information about routes to networks. This included an overview of the four route information management activities performed by BGP speakers: route storage, update, selection and advertisement. [Route storage is the function of the Routing Information Base \(RIB\)](#) in each BGP speaker. [Path attributes](#) are the mechanism by which BGP stores details about routes and also describes those details to BGP peers.

### ***BGP Decision Process Phases***

As we have seen, the RIB also contains sections for holding input information received from BGP peers, and for holding output information each BGP device wants to send to those peers. The functions of route update, selection and advertisement are concerned with analyzing this input information, deciding what to include in the local database, updating

---

that database, and then choosing what routes to send from it to peer devices. In BGP, a mechanism called the *Decision Process* is responsible for these tasks. It consists of three overall phases:

1. **Phase 1:** Each route received from a BGP speaker in a neighboring AS is analyzed and assigned a preference level. The routes are then ranked according to preference and the best one for each network advertised to other BGP speakers within the autonomous system.
2. **Phase 2:** The best route for each destination is selected from the incoming data based on preference levels, and used to update the local routing information base (the *Loc-RIB*).
3. **Phase 3:** Routes in the *Loc-RIB* are selected to be sent to neighboring BGP speakers in other ASes.

### ***Criteria for Assigning Preferences to Routes***

Obviously, if a BGP speaker only knows of a single route to a network, it will install and use that route (assuming there are no problems with it). The assigning of preferences amongst routes only becomes important when more than one route has been received by a BGP speaker for a particular network. Preferences can be determined based on a number of different criteria. Just a few typical ones include:

- ☉ The number of autonomous systems between the router and the network (fewer generally being better).
- ☉ The existence of certain policies that may make certain routes unusable; for example, a route may pass through an AS that this AS is not willing to trust with its data.
- ☉ The origin of the path—that is, where it came from.

In the case where a set of routes to the same network are all calculated to have the same preference, a “tie-breaking” scheme is used to select from among them. Additional logic is used to handle special circumstances, such as the case of overlapping networks ([see the description of the Atomic\\_Aggregate path attribute](#) for an example of this).

The selection of routes for dissemination to other routers in Phase 3 is based on a rather complex algorithm that I cannot do justice here. Route advertisement is guided by the [routing policies](#) we discussed earlier in this section. Different rules are used to select routes for advertising to internal peers compared to external peers.

**Key Concept:** The method used by a BGP speaker to determine what new routes to accept from its peers and what routes to advertise back them is called the *BGP Decision Process*. It is a complex algorithm in three phases that involves the computation of the best route based on both pre-existing and incoming path information.

---

---

## Limitations on BGP's Ability to Select Efficient Routes

When considering the route selection process, it's very important to remember that BGP is a routing protocol that operates at the *inter-autonomous-system* level. Thus, routes are chosen between ASes and not at the level of individual routers within an AS. So, for example, when BGP stores information about the path to a network, it stores it as a sequence of autonomous systems, not a sequence of specific routers. BGP cannot deal with individual routers in an AS because by definition, the details of what happens within an AS are supposed to be “hidden” from the outside world. It doesn't know the structure of ASes outside its own.

However, this has an important implication for how BGP selects routes: BGP cannot guarantee that it will pick the fastest, lowest-cost route to every network. It can select a route that minimizes the number of ASes that lie between itself and a particular network, but of course ASes are not all the same. Some ASes are large and consist of many slow links, while others are small and fast. Choosing a route through two of the latter type of AS will be better than choosing a route through one of the former, but BGP can't know that. Policies can be used to influence AS selection to some extent, but in general, since BGP doesn't know what happens in an AS, it cannot guarantee the efficiency of a route overall. (Incidentally, this is the reason why there is no general “cost” or “distance” path attribute in BGP.)

**Key Concept:** As an exterior routing protocol, BGP operates at the autonomous system level. Its routes are calculated based on paths between ASes, not individual routers. Since BGP, by definition, does not know the internal structure of routers within an AS, it cannot know for certain the cost to send a datagram across a given AS. This in turn means that BGP cannot always guarantee that it will select the absolute lowest-cost route between any two networks.

---

## Originating New Routes and Withdrawing Unreachable Routes

Naturally, a facility exists to allow BGP speakers to originate new routes to networks. A BGP speaker may obtain knowledge about a new route from an interior routing protocol on an AS to which it is directly attached and choose to share this information with other ASes. It will create a new entry in its RIB for this network and then send information about it out to other BGP peers.

BGP also includes a mechanism for not only advertising routes it can reach, but those it cannot. The latter are called *unfeasible* or *withdrawn* routes, and are [mentioned in Update messages as needed](#) to indicate that a router can no longer reach the specific network.

## BGP General Operation and Messaging

In the previous topics we have seen how BGP stores information about routes and uses it to determine paths to various networks. Let's now take a high-level look at how BGP operates in general terms. Like many other protocols covered in this Guide, BGP's

---

operation can be described primarily in the form of messaging. The use of messages is the means by which route information is communicated between BGP peers. This eventually allows knowledge of how to reach networks to spread throughout the entire internetwork.

### ***Speaker Designation and Connection Establishment***

Before messaging can begin, [BGP speakers must be designated](#), and then linked together. The BGP standard does not specify how neighboring speakers are determined; this must be done outside the protocol. Once accomplished, ASes are connected into a BGP-enabled internetwork. Topological linking provides the physical connection and the means for datagrams to flow between ASes. At this point the dance floor is prepared, but nobody is dancing; BGP can function but isn't yet in operation.

BGP operation begins with BGP peers forming a transport protocol connection. BGP uses [TCP](#) for its reliable transport layer, so the two BGP speakers establish a TCP session that remains in place during the course of the subsequent message exchange. When this is done, each BGP speaker sends a BGP *Open* message. This message is like an “invitation to dance”, and begins the process of setting up the BGP link between the devices. In this message, each router identifies itself and its autonomous system, and also tells its peer what parameters it would like to use for the link. This includes an exchange of authentication parameters. Assuming that each device finds the contents of its peer's *Open* message acceptable, it acknowledges it with a *Keepalive* message and the BGP session begins.

Under normal circumstances, most BGP speakers will maintain simultaneous sessions with more than one other BGP speaker, both within its own AS and outside the AS. Links between ASes are of course what enable BGP routers to learn how to route through the internetwork. Links within the AS are important to ensure that each BGP speaker in the AS maintains consistent information.

### ***Route Information Exchange***

Assuming the link is initialized, the two peers begin an ongoing process of telling each other what they know about networks and how to reach them. Each BGP speaker encodes information from its [Routing Information Bases \(RIBs\)](#) into BGP *Update* messages. These messages contain lists of known network addresses, as well as information about paths to various networks, described in the form of [path attributes](#). This information is then used for the route determination as described in the preceding topic.

When a link is first set up between two peers, they ensure complete information is held by each router by exchanging their complete routing tables. Subsequently, *Update* messages are sent that contain only incremental updates about routes that have changed. Exchanging only updated information as needed reduces unnecessary bandwidth on the network, making BGP more efficient than it would be if it sent full routing table information on a regular basis.

---

## Connectivity Maintenance

The TCP session between BGP speakers can be kept open for a very long time, but *Updates* need to be sent only when changes occur to routes, which are usually infrequent. This means many seconds may elapse between the transmission of *Update* messages. To ensure that the peers maintain contact with each other, they both send *Keepalive* messages on a regular basis when they don't have other information to send. These are null messages that contain no data and just tell the peer device "I'm still here". These messages are sent infrequently—no more often than one per second—but regularly enough that the peers won't think the session was interrupted.

## Error Reporting

The last type of BGP message is the BGP *Notification* message. This is an error message; it tells a peer that a problem occurred and describes the nature of the error condition. After sending a BGP *Notification* message, the device that sent it will terminate the BGP connection between the peers. A new connection will then need to be negotiated, possibly after the problem that led to the *Notification* has been corrected.

**Key Concept:** BGP is implemented through the exchange of four different message types between BGP speakers. A BGP session begins with a TCP connection being established between two routers and each sending an *Open* message to the other. BGP *Update* messages are the primary mechanism by which routing information is exchanged between devices. Small BGP *Keepalive* messages are used to maintain communication between devices between periods that they need to exchange information. Finally, *Notification* messages are used for problem reporting.

---

For more details on the four BGP message types and a description of the format used by each, refer to [the detailed BGP operation section](#).

---

## **BGP Detailed Messaging, Operation and Message Formats**

The [previous section](#) described the concepts and general operation of the Border Gateway Protocol (BGP). To get a better understanding of exactly how BGP works, it is helpful to take a deeper look at its four different message types and how they are used. As we do this, we can examine the fields in each message type, to help us comprehend not just the way that messaging is accomplished, but the way that routing data is actually communicated.

In this section I provide a comprehensive description of the communication that takes place between BGP speakers by providing details on BGP message types, how they are used, and the data elements they contain. I begin with a description of common attributes of BGP message generation and transport, and the general format used for all BGP messages. I then provide a detailed description of each of the four BGP message types: *Open*, *Update*, *Keepalive* and *Notification* messages.

**Background Information:** If you have not yet already done so, you should read [the high-level description of general BGP operation and messaging](#), which shows how these messages fit together.

---

### **BGP Message Generation and Transport, and General Message Format**

Each router running BGP generates messages to implement the various functions of the protocol. Some of these messages are created on a regular basis by the BGP software during the course of its normal operation. These are generally controlled by timers that are set and count down to cause them to be sent. Other messages are sent in response to messages received from BGP peers, possibly after a processing step.

#### ***BGP Message Transport***

BGP is different from most other routing protocols in that it was designed from the start to operate using a *reliable* method of message delivery. The [Transmission Control Protocol \(TCP\)](#) is present in the software of every IP router, making it the obvious choice for reliable data communication in a TCP/IP internet, and that's what BGP uses. Routing protocols are usually considered part of layer three, but this one runs over a layer four protocol, making BGP a good example of why architectural [models are best used only as a guideline](#).

TCP provides numerous advantages to BGP by taking care of most of the details of session setup and management, allowing BGP to focus on the data it needs to send. TCP takes care of session setup and negotiation, ensuring that messages are received and acknowledged, flow control, congestion-handling and any necessary retransmissions of lost messages. BGP uses well-known TCP port 179 for connections.

---

## BGP General Message Format

The use of TCP also has an interesting impact on the way BGP messages are structured. One thing that stands out when you look at the BGP message format (as we will see shortly) is that a BGP message can have an odd number of bytes. Most routing protocols are sized in units of 4 or 8 bytes, but since TCP sends data as a stream of octets there is no need for BGP messages to break on a 32-bit or 64-bit boundary. The other impact is the need of a special *Marker* field to help ensure that BGP messages can be differentiated from each other in the TCP stream (more about this in a moment).

Like most messaging protocols, BGP uses a common message format for each of its four message types. Each BGP message is conceptually divided into a header and a body (called the *data portion* in the BGP standard). The header has three fields and is fixed in length at 19 bytes. The body is variable in length, and in fact is omitted entirely in *Keepalive* messages, since it is not needed for them.

The general format for all BGP message types is shown in [Table 137](#) and [Figure 192](#).

**Table 137: BGP General Message Format**

Field Name	Size (bytes)	Description										
Marker	16	<b>Marker:</b> This large field at the start of each BGP message is used for synchronization and authentication.										
Length	2	<b>Length:</b> The total length of the message in bytes, including the fields of the header. The minimum value of this field is 19 for a <i>Keepalive</i> message; it may be as high as 4,096.										
Type	1	<b>Type:</b> Indicates the BGP message type: <table><tr><th>Type Value (Decimal)</th><th>Message Type</th></tr><tr><td>1</td><td><i>Open</i></td></tr><tr><td>2</td><td><i>Update</i></td></tr><tr><td>3</td><td><i>Notification</i></td></tr><tr><td>4</td><td><i>Keepalive</i></td></tr></table>	Type Value (Decimal)	Message Type	1	<i>Open</i>	2	<i>Update</i>	3	<i>Notification</i>	4	<i>Keepalive</i>
Type Value (Decimal)	Message Type											
1	<i>Open</i>											
2	<i>Update</i>											
3	<i>Notification</i>											
4	<i>Keepalive</i>											
Message Body / Data Portion	Variable	<b>Message Body / Data Portion:</b> Contains the specific fields used to implement each message type, for <i>Open</i> , <i>Update</i> and <i>Notification</i> messages.										

### The Marker Field, Message Synchronization and Authentication

The *Marker* field is the most interesting one in the BGP message format, and as mentioned in the table is used for both synchronization and authentication. BGP uses a single TCP session to send many messages in a row. TCP is a stream-oriented transport protocol

**Figure 192: BGP General Message Format**

which just sends bytes across the link without any knowledge of what the bytes represent. This means that [the protocol using TCP is responsible for deciding where the line is drawn between data units](#), in this case BGP messages.

Normally, the *Length* field tells each BGP device where to draw the line between the end of one message and the start of the next. However, it is possible that due to various conditions a device might lose track of where the message boundary is. The *Marker* field is filled with a recognizable pattern that clearly marks the start of each message, to keep BGP peers synchronized.

Before a BGP connection is established, the *Marker* field is just filled with all ones. thus, this is the pattern used for *Open* messages. Once a BGP session is negotiated, if agreement is reached on an authentication method between the two devices, the *Marker* field takes on the additional role of authentication. Instead of looking for a *Marker* containing all ones, BGP devices look for a pattern generated using the agreed-upon authentication method. Detection of this pattern simultaneously synchronizes the devices and ensures that messages are authentic.

In extreme cases, BGP peers may be unable to maintain synchronization, and if so, a *Notification* message is generated and the session is closed. This will also happen if the *Marker* field contains the wrong data when authentication is enabled.

**Key Concept:** All four BGP message types use a general message format that contains three fixed header fields—*Marker*, *Length* and *Type*—and room for a message body that differs for each message type. The large *Marker* field is used to denote the start of a new BGP message, and is also used to facilitate the BGP authentication method.

## **BGP Connection Establishment: *Open* Messages**

Before a BGP session can be used to exchange routing information, a connection must first be established between BGP peers. This process begins with the creation of a TCP connection between the devices. Once this is done, the BGP devices will attempt to create a BGP session by exchanging BGP *Open* messages.

The *Open* message has two main purposes. The first is identification and initiation of a link between the two devices; it allows one peer to tell the other “I am a BGP speaker named X on autonomous system Y, and I want to start exchanging BGP information with you”. The second is negotiation of session parameters. These are the terms by which the BGP session will be conducted. One important parameter negotiated using *Open* messages is the method that each device wants to use for authentication. The importance of BGP means that authentication is essential, to avoid bad information or a malicious person from disrupting routes.

Each BGP receiving an *Open* message processes it. If its contents are acceptable, including the parameters the other device wants to use, it responds with a [Keepalive](#) message as an acknowledgment. Each peer must send an *Open* and receive a *Keepalive* acknowledgment for the BGP link to be initialized. If either is not willing to accept the terms of the *Open*, the link is not established. In that case, a [Notification](#) message may be sent to convey the nature of the problem.

### **BGP *Open* Message Format**

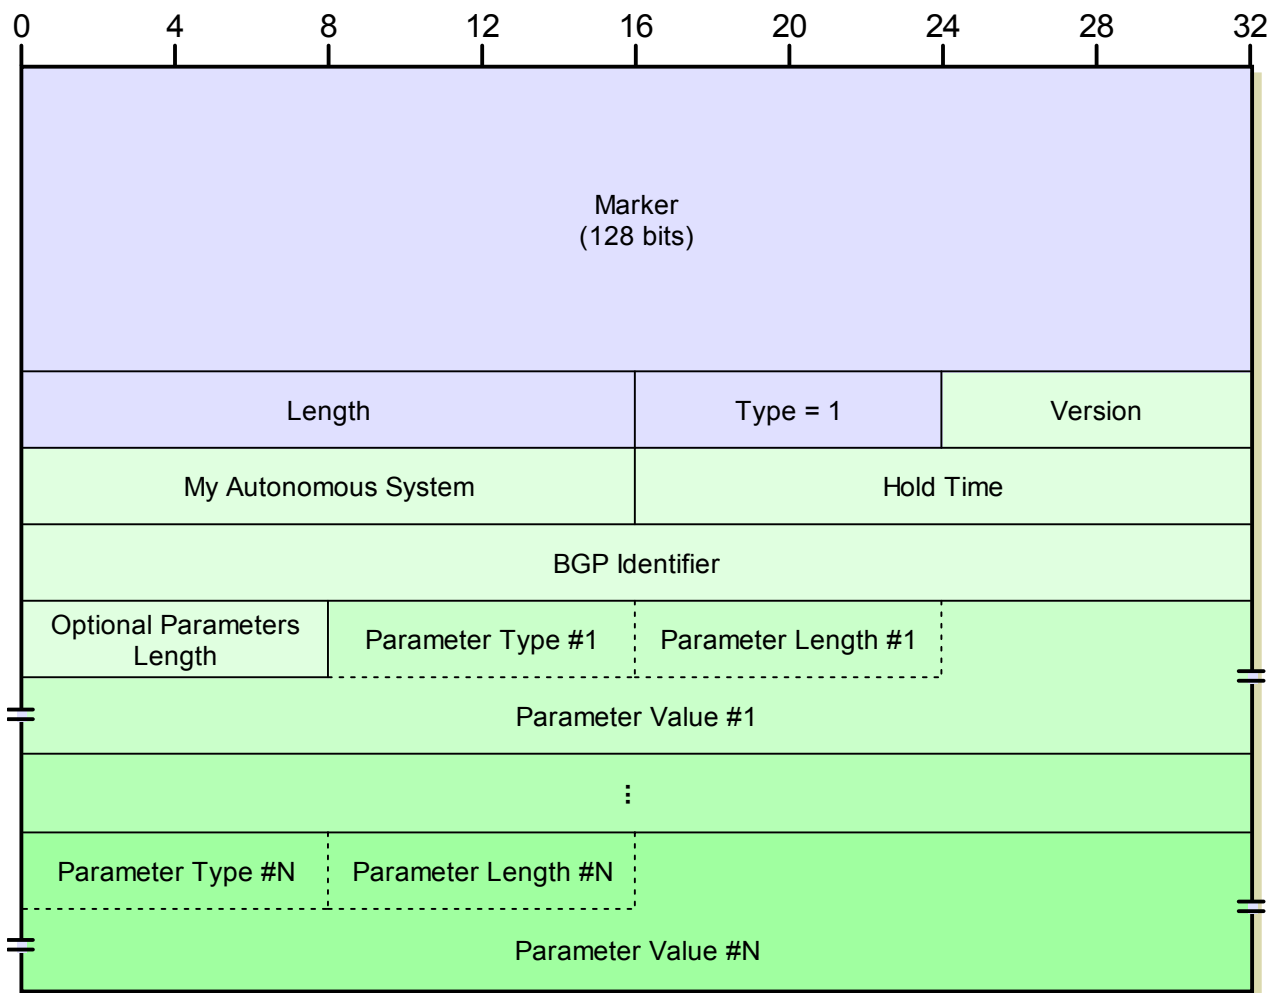

The specific format for BGP *Open* messages can be found in [Table 138](#) and [Figure 193](#).

**Table 138: BGP *Open* Message Format (Page 1 of 2)**

Field Name	Size (bytes)	Description
<b>Marker</b>	16	<b>Marker:</b> This large field at the start of each BGP message is used for synchronization and authentication. <a href="#">See the discussion of the BGP general message format for details.</a>
<b>Length</b>	2	<b>Length:</b> The total length of the message in bytes, including the fields of the header. <i>Open</i> messages are variable in length.
<b>Type</b>	1	<b>Type:</b> BGP message type, value is 1 for <i>Open</i> messages.

Table 138: BGP Open Message Format (Page 2 of 2)

Field Name	Size (bytes)	Description												
<b>Version</b>	1	<b>Version:</b> Indicates the BGP version the sender of the <i>Open</i> message is using. This field allows devices to reject connections with devices using versions they may not be capable of understanding. The current value is 4, for BGP-4, and is used by most, if not all, current BGP implementations.												
<b>My Autonomous System</b>	2	<b>My Autonomous System:</b> Identifies the autonomous system number of the sender of the <i>Open</i> message. AS numbers are <a href="#">centrally managed across the Internet</a> in a manner similar to how IP addresses are administered.												
<b>Hold Time</b>	2	<p><b>Hold Time:</b> The number of seconds that this device proposes to use for the BGP hold timer, which specifies how long a BGP peer will allow the connection to be left silent between receipt of BGP messages. A BGP device may refuse a connection if it doesn't like the value that its peer is suggesting; usually, however, the two devices agree to use the smaller of the values suggested by each device.</p> <p>The value must be at least 3 seconds, or 0. If 0, this specifies that the hold timer is not used. <a href="#">See the Keepalive message discussion for more on how the hold timer is used.</a></p>												
<b>BGP Identifier</b>	4	<b>BGP Identifier:</b> Identifies the specific BGP speaker. Recall that IP addresses are associated with interfaces, not devices, so each router will have at least two IP addresses. Normally the BGP identifier is chosen as one of these addresses. Once chosen, this identifier is used for all BGP communications with BGP peers. This includes BGP peers on the interface from which the identifier was chosen, and also BGP peers on other interfaces as well. So, if a BGP speaker with two interfaces has addresses <i>IP1</i> and <i>IP2</i> , it will choose one as its identifier and use it on both of its interfaces.												
<b>Opt Parm Len</b>	1	<b>Optional Parameters Length:</b> The number of bytes used for <i>Optional Parameters</i> (see below). If 0, no optional parameters are in this message.												
<b>Optional Parameters</b>	Variable	<p><b>Optional Parameters:</b> Allows the <i>Open</i> message to communicate any number of extra parameters during BGP session setup. Each parameter is encoded using a rather standard “type / length / value” triple, as follows:</p> <table> <tr> <th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr> <tr> <td><b>Parm Type</b></td><td>1</td><td><b>Parameter Type:</b> The type of optional parameter. At present, only one value is defined, 1, for authentication Information.</td></tr> <tr> <td><b>Parm Length</b></td><td>1</td><td><b>Parameter Length:</b> Specifies the length of the <i>Parameter Value</i> subfield (thus, this value is the length of the entire parameter less 2).</td></tr> <tr> <td><b>Parm Value</b></td><td>Variable</td><td><b>Parameter Value:</b> The value of the parameter being communicated.</td></tr> </table>	Subfield Name	Size (bytes)	Description	<b>Parm Type</b>	1	<b>Parameter Type:</b> The type of optional parameter. At present, only one value is defined, 1, for authentication Information.	<b>Parm Length</b>	1	<b>Parameter Length:</b> Specifies the length of the <i>Parameter Value</i> subfield (thus, this value is the length of the entire parameter less 2).	<b>Parm Value</b>	Variable	<b>Parameter Value:</b> The value of the parameter being communicated.
Subfield Name	Size (bytes)	Description												
<b>Parm Type</b>	1	<b>Parameter Type:</b> The type of optional parameter. At present, only one value is defined, 1, for authentication Information.												
<b>Parm Length</b>	1	<b>Parameter Length:</b> Specifies the length of the <i>Parameter Value</i> subfield (thus, this value is the length of the entire parameter less 2).												
<b>Parm Value</b>	Variable	<b>Parameter Value:</b> The value of the parameter being communicated.												

**Figure 193: BGP Open Message Format**

BGP *Open* messages currently use only one optional parameter: *Authentication Information*. Its *Parameter Value* subfield contains a one-byte *Authentication Code* sub-subfield, which specifies the type of authentication a device wishes to use. Following this is a variable-length *Authentication Data* sub-subfield. The *Authentication Code* specifies how authentication is to be performed, including the meaning of the *Authentication Data* field, and the manner in which *Marker* fields are to be calculated.

**Key Concept:** BGP sessions begin with each peer in a connection sending the other a BGP Open message. The purpose of this message is to establish contact between devices, identify the sender of the message and its autonomous system, and negotiate important parameters that dictate how the session will be conducted.

---

## **BGP Route Information Exchange: Update Messages**

Once BGP speakers have made contact and a link has been established using *Open* messages, the devices begin the actual process of exchanging routing information. Each BGP router uses the [BGP Decision Process](#) to select certain routes to be advertised to its peer. This information is then placed into BGP *Update* messages, which are sent to every BGP device for which a session has been established. These messages are the way that network reachability knowledge is propagated around the internetwork.

Each *Update* message contains either one or both of the following:

- 🕒 **Route Advertisement:** The characteristics of a single route.
- 🕒 **Route Withdrawal:** A list of networks that are no longer reachable.

Only one route can be advertised in an *Update* message, but several can be withdrawn. This is because withdrawing a route is simple; it requires simply the address of the network for which the route is being removed. In contrast, a route advertisement requires a fairly complex set of [path attributes](#) to be described, which takes up a significant amount of space. (Note that it is possible for an *Update* to only specify withdrawn routes and not advertise a route at all.)

### ***BGP Update Message Format***

Because of the amount of information it contains, and the complexity of that information, BGP Update messages use one of the most complicated structures in all of TCP/IP. The basic structure of the message is described in [Table 139](#), and illustrated in [Figure 194](#). As you can see in that table, several of the fields have their own substructure. The Attribute Type subfield of the Path Attributes field has itself a complex substructure, which I have shown separately in [Table 140](#) to avoid overloading [Table 139](#).

When you examine this format, you may find it confusing that there can be more than one prefix in the *NLRI* field, given that I just said that an *Update* message advertises only one route. There is in fact no inconsistency here. A single route may be associated with more than one network; or, to put it another way, multiple networks may have the same path and path attributes. In that case, specifying multiple network prefixes in the same *Update* is more efficient than generating a new one for each network.

**Table 139: BGP Update Message Format (Page 1 of 3)**

Field Name	Size (bytes)	Description
<b>Marker</b>	16	<b>Marker:</b> This large field at the start of each BGP message is used for synchronization and authentication. <a href="#">See the discussion of the BGP general message format for details.</a>
<b>Length</b>	2	<b>Length:</b> The total length of the message in bytes, including the fields of the header. <i>Update</i> messages are variable in length.
<b>Type</b>	1	<b>Type:</b> BGP message type, value is 2 for <i>Update</i> messages.

**Table 139: BGP Update Message Format (Page 2 of 3)**

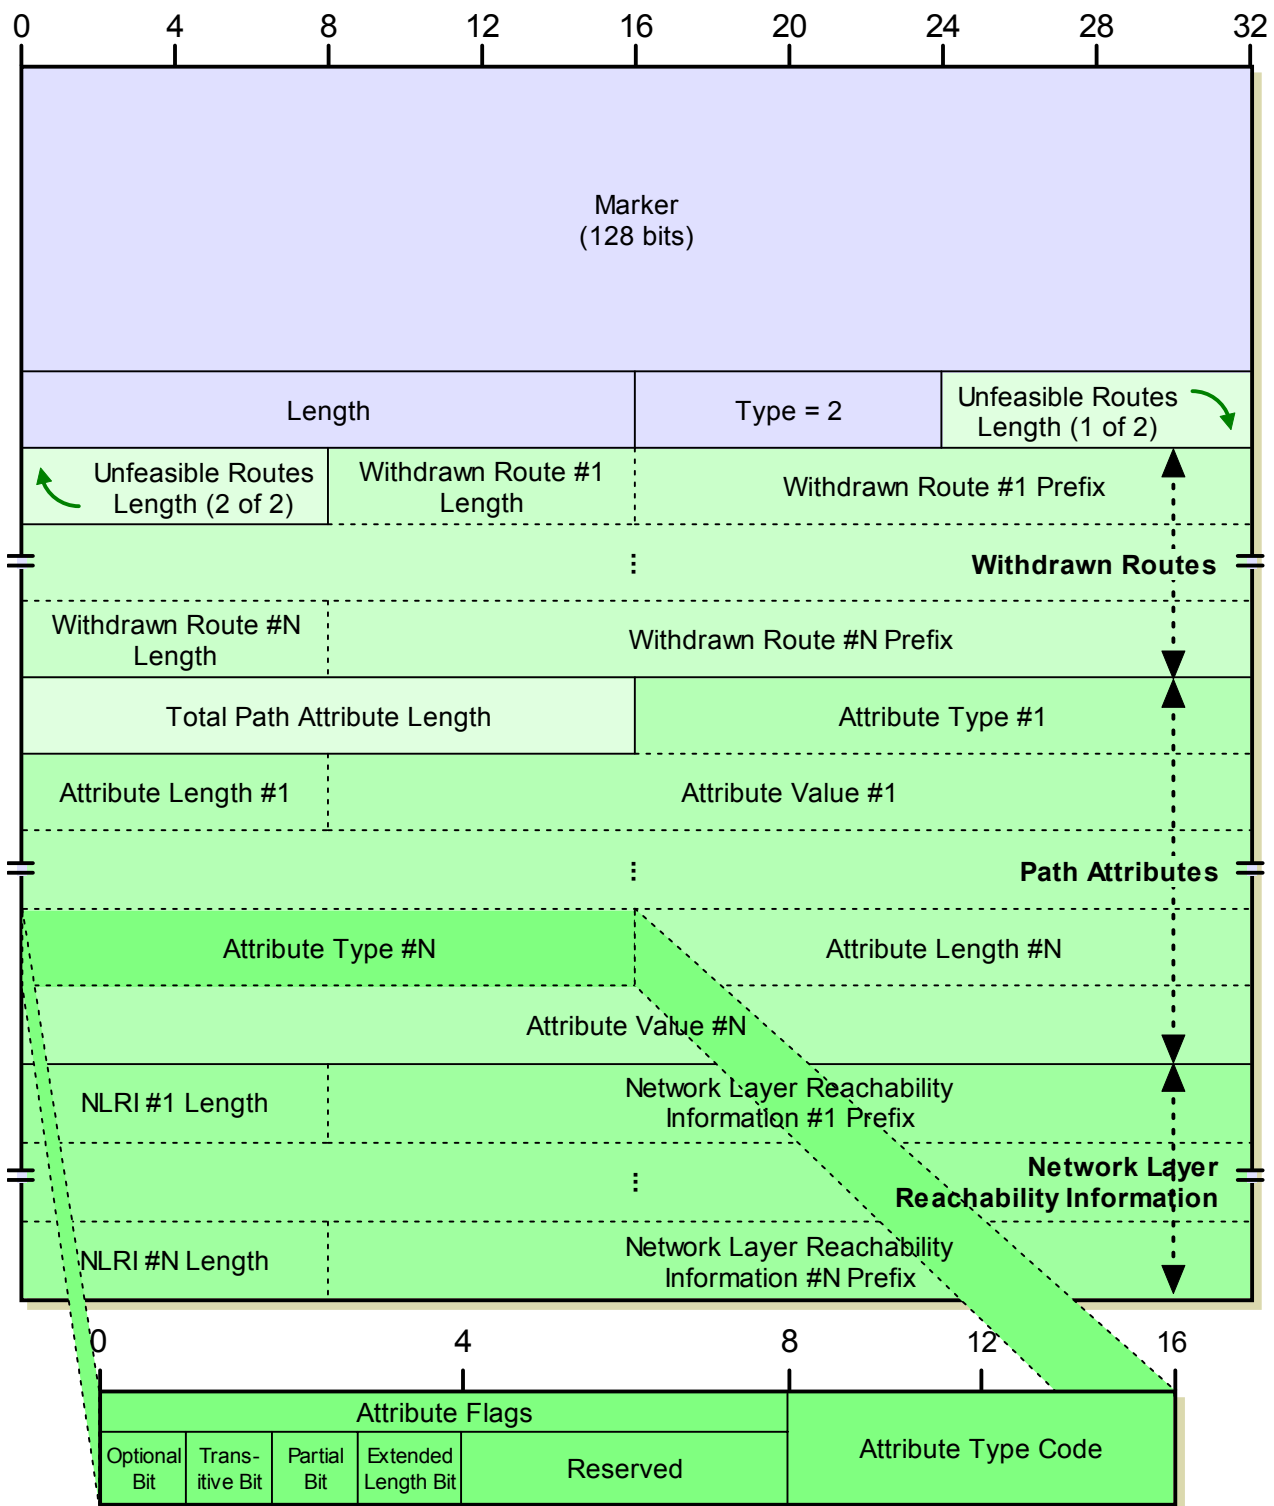

Field Name	Size (bytes)	Description									
<b>Unfeasible Routes Length</b>	2	<b>Unfeasible Routes Length:</b> The length of the <i>Withdrawn Routes</i> field, in bytes. If 0, no routes are being withdrawn and the <i>Withdrawn Routes</i> field is omitted.									
<b>Withdrawn Routes</b>	Variable	<p><b>Withdrawn Routes:</b> Specifies the addresses of networks for which routes are being withdrawn from use. Each address is specified using the following substructure:</p> <table> <tr> <th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr> <tr> <td><b>Length</b></td><td>1</td><td><b>Length:</b> The number of bits in the IP address <i>Prefix</i> subfield below that are significant.</td></tr> <tr> <td><b>Prefix</b></td><td>Variable</td><td> <p><b>Prefix:</b> The IP address prefix of the network whose route is being withdrawn. If the number of bits in the prefix is not a multiple of 8, this field is padded with zeroes so it falls on a byte boundary.</p> <p>The length of this field is 1 byte if the preceding <i>Length</i> field is 8 or less; 2 bytes if it is 9 to 16; 3 bytes if it is 17 to 24; and 4 bytes if 25 or greater.</p> </td></tr> </table>	Subfield Name	Size (bytes)	Description	<b>Length</b>	1	<b>Length:</b> The number of bits in the IP address <i>Prefix</i> subfield below that are significant.	<b>Prefix</b>	Variable	<p><b>Prefix:</b> The IP address prefix of the network whose route is being withdrawn. If the number of bits in the prefix is not a multiple of 8, this field is padded with zeroes so it falls on a byte boundary.</p> <p>The length of this field is 1 byte if the preceding <i>Length</i> field is 8 or less; 2 bytes if it is 9 to 16; 3 bytes if it is 17 to 24; and 4 bytes if 25 or greater.</p>
Subfield Name	Size (bytes)	Description									
<b>Length</b>	1	<b>Length:</b> The number of bits in the IP address <i>Prefix</i> subfield below that are significant.									
<b>Prefix</b>	Variable	<p><b>Prefix:</b> The IP address prefix of the network whose route is being withdrawn. If the number of bits in the prefix is not a multiple of 8, this field is padded with zeroes so it falls on a byte boundary.</p> <p>The length of this field is 1 byte if the preceding <i>Length</i> field is 8 or less; 2 bytes if it is 9 to 16; 3 bytes if it is 17 to 24; and 4 bytes if 25 or greater.</p>									
<b>Total Path Attribute Length</b>	2	<b>Total Path Attribute Length:</b> The length of the <i>Path Attributes</i> field, in bytes. If 0, indicates no route is being advertised in this message, so <i>Path Attributes</i> and <i>Network Layer Reachability Information</i> are omitted.									

Table 139: BGP Update Message Format (Page 3 of 3)

Field Name	Size (bytes)	Description												
<b>Path Attributes</b>	Variable	<p><b>Path Attributes:</b> Describes the <a href="#">path attributes</a> of the route advertised. Since some attributes require more information than others, attributes are described using a flexible structure that minimizes message size compared to using fixed fields that would often be empty. Unfortunately it also makes the field structure confusing. ☺ Each attribute has the following subfields:</p> <table> <tr> <th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr> <tr> <td><b>Attribute Type</b></td><td>2</td><td><b>Attribute Type:</b> A two-byte subfield that defines the type of attribute and describes it. This subfield itself has a two-level substructure, so it won't even fit it here! See <a href="#">Table 140</a>.</td></tr> <tr> <td><b>Attribute Length</b></td><td>1 or 2</td><td><b>Attribute Length:</b> The length of the attribute in bytes. This field is normally one byte, allowing for fields with a length up to 255 bytes. For longer attributes, the <i>Extended Length</i> flag is set (see <a href="#">Table 140</a>), indicating that this <i>Attribute Length</i> field is two bytes, for attributes up to 65,535 bytes.</td></tr> <tr> <td><b>Attribute Value</b></td><td>Variable</td><td><b>Attribute Value:</b> The value of the attribute. The size and meaning of this field depends on the type of path attribute. For example, for an <i>Origin</i> attribute it is a single integer value indicating the origin of the route; for an <i>AS_Path</i> attribute this field contains a variable-length list of the autonomous systems in the path to the network.</td></tr> </table>	Subfield Name	Size (bytes)	Description	<b>Attribute Type</b>	2	<b>Attribute Type:</b> A two-byte subfield that defines the type of attribute and describes it. This subfield itself has a two-level substructure, so it won't even fit it here! See <a href="#">Table 140</a> .	<b>Attribute Length</b>	1 or 2	<b>Attribute Length:</b> The length of the attribute in bytes. This field is normally one byte, allowing for fields with a length up to 255 bytes. For longer attributes, the <i>Extended Length</i> flag is set (see <a href="#">Table 140</a> ), indicating that this <i>Attribute Length</i> field is two bytes, for attributes up to 65,535 bytes.	<b>Attribute Value</b>	Variable	<b>Attribute Value:</b> The value of the attribute. The size and meaning of this field depends on the type of path attribute. For example, for an <i>Origin</i> attribute it is a single integer value indicating the origin of the route; for an <i>AS_Path</i> attribute this field contains a variable-length list of the autonomous systems in the path to the network.
Subfield Name	Size (bytes)	Description												
<b>Attribute Type</b>	2	<b>Attribute Type:</b> A two-byte subfield that defines the type of attribute and describes it. This subfield itself has a two-level substructure, so it won't even fit it here! See <a href="#">Table 140</a> .												
<b>Attribute Length</b>	1 or 2	<b>Attribute Length:</b> The length of the attribute in bytes. This field is normally one byte, allowing for fields with a length up to 255 bytes. For longer attributes, the <i>Extended Length</i> flag is set (see <a href="#">Table 140</a> ), indicating that this <i>Attribute Length</i> field is two bytes, for attributes up to 65,535 bytes.												
<b>Attribute Value</b>	Variable	<b>Attribute Value:</b> The value of the attribute. The size and meaning of this field depends on the type of path attribute. For example, for an <i>Origin</i> attribute it is a single integer value indicating the origin of the route; for an <i>AS_Path</i> attribute this field contains a variable-length list of the autonomous systems in the path to the network.												
<b>Network Layer Reachability Information</b>	Variable	<p><b>Network Layer Reachability Information (NLRI):</b> Contains a list of IP address prefixes for the route being advertised. Each address is specified using the same general structure as that used for <i>Withdrawn Routes</i>:</p> <table> <tr> <th>Subfield Name</th><th>Size (bytes)</th><th>Description</th></tr> <tr> <td><b>Length</b></td><td>1</td><td><b>Length:</b> The number of bits in the <i>Prefix</i> field below that are significant.</td></tr> <tr> <td><b>Prefix</b></td><td>Variable</td><td> <p><b>Prefix:</b> The IP address prefix of the network whose route is being advertised. If the number of bits in the prefix is not a multiple of 8, this field is padded with zeroes so it falls on a byte boundary.</p> <p>The length of this field is 1 byte if the preceding <i>Length</i> field is 8 or less; 2 bytes if it is 9 to 16; 3 bytes if it is 17 to 24; and 4 bytes if 25 or greater.</p> </td></tr> </table> <p>Unlike most of the other fields in the <i>Update</i> message, the length of the <i>NLRI</i> field is not explicitly stated. It is computed from the overall message <i>Length</i> field, less the lengths of the other fields that are explicitly specified.</p>	Subfield Name	Size (bytes)	Description	<b>Length</b>	1	<b>Length:</b> The number of bits in the <i>Prefix</i> field below that are significant.	<b>Prefix</b>	Variable	<p><b>Prefix:</b> The IP address prefix of the network whose route is being advertised. If the number of bits in the prefix is not a multiple of 8, this field is padded with zeroes so it falls on a byte boundary.</p> <p>The length of this field is 1 byte if the preceding <i>Length</i> field is 8 or less; 2 bytes if it is 9 to 16; 3 bytes if it is 17 to 24; and 4 bytes if 25 or greater.</p>			
Subfield Name	Size (bytes)	Description												
<b>Length</b>	1	<b>Length:</b> The number of bits in the <i>Prefix</i> field below that are significant.												
<b>Prefix</b>	Variable	<p><b>Prefix:</b> The IP address prefix of the network whose route is being advertised. If the number of bits in the prefix is not a multiple of 8, this field is padded with zeroes so it falls on a byte boundary.</p> <p>The length of this field is 1 byte if the preceding <i>Length</i> field is 8 or less; 2 bytes if it is 9 to 16; 3 bytes if it is 17 to 24; and 4 bytes if 25 or greater.</p>

**Figure 194: BGP Update Message Format**

This diagram shows the complete BGP *Update* message format, including a set of withdrawn routes, path attributes and *NLRI* entries. The exploded view shows the substructure of the *Attribute Type* subfield of *Path Attributes*, as described in [Table 140](#).

**Key Concept:** The most important message type in BGP is the Update message, which is used to send detailed information about routes between BGP devices. It uses a complex structure that allows a BGP speaker to efficiently specify new routes, update existing ones, and withdraw routes that are no longer valid. Each message may include the full description of one existing route, and may also withdraw from use a list of multiple routes.

---

### **BGP Connectivity Maintenance: Keepalive Messages**

Once a BGP connection is established using *Open* messages, BGP peers will initially use *Update* messages to send each other a large amount of routing information. They will then settle into a routine, where the BGP session is maintained, but *Update* messages are sent only when needed. Since these updates correspond to route changes, and route changes are normally infrequent, this means many seconds may elapse between receipt of consecutive *Update* messages.

#### ***The BGP Hold Timer and Keepalive Message Interval***

While a BGP peer is waiting to hear the next *Update* message, it remains sort of like a person who has been put “on hold” on the telephone. Now, seconds may not seem like much to us, but to a computer they are a very long time. Like you, a BGP speaker that is put on hold for too long might become impatient, and start to wonder if maybe the other guy hung up on them. Computers don't get offended at being put on hold, but they might wonder if perhaps a problem arose that led to the connection being interrupted.

To keep track of how long it has been on hold, each BGP device maintains a special *hold timer*. This hold timer is set to an initial value each time its peer sends a BGP message. It then counts down until the next message is received, when it is reset. If the hold timer ever expires, the connection is assumed to have been interrupted and the BGP session is terminated.

The length of the hold timer is negotiated as part of session setup using *Open* messages. It must be at least three seconds long, or may be negotiated as a value of zero. If zero, the hold timer is not used; this means the devices are “infinitely patient” and don't care how much time elapses between messages.

To ensure that the timer doesn't expire even when no *Updates* need to be sent for a long while, each peer periodically sends a BGP *Keepalive* message. The name says it all: the message just keeps the BGP connection alive. The rate at which *Keepalive* messages is sent is implementation-dependent, but the standard recommends that they be sent with an interval of one-third the value of the hold timer. So if the hold timer has a value of three seconds, each peer sends a *Keepalive* every second (unless it needs to send some other message type in that second). To prevent excess bandwidth use, *Keepalives* must be sent no more often than once per second, so that is the minimum interval even if the hold timer is shorter than three seconds.

---

## BGP Keepalive Message Format

The point of a *Keepalive* message is the message itself; there's no data to be communicated. In fact, we want to keep the message short and sweet. Thus, it is really a “dummy” message containing only a BGP header—a nice change after that incredibly long *Update* message format! The format of the *Keepalive* message can be found in [Table 141](#) and [Figure 195](#).

**Table 141: BGP Keepalive Message Format**

Field Name	Size (bytes)	Description
<b>Marker</b>	16	<b>Marker:</b> This large field at the start of each BGP message is used for synchronization and authentication. <a href="#">See the discussion of the BGP general message format for details.</a>
<b>Length</b>	2	<b>Length:</b> The total length of the message in bytes, including the fields of the header. <i>Keepalive</i> messages are fixed in length at 19 bytes.
<b>Type</b>	1	<b>Type:</b> BGP message type, value is 4 for <i>Keepalive</i> messages.

**Figure 195: BGP Keepalive Message Format**

There is also one other, special use of *Keepalive* messages: as acknowledgment of receipt of a valid *Open* message [during initial BGP session setup](#).

**Key Concept:** BGP *Keepalive* messages are sent periodically during idle periods when no real information needs to be sent between connected BGP speakers. They serve only to keep the session alive, and thus contain only a BGP header and no data.

---

---

## BGP Error Reporting: *Notification* Messages

Once established, a BGP session will remain open for a considerable period of time, allowing routing information to be exchanged between devices on a regular basis. During the course of operation, certain error conditions may crop up that may interfere with normal communication between BGP peers. Some of these are serious enough that the BGP session must be terminated. When this occurs, the device detecting the error will inform its peer of the nature of the problem by sending it a BGP *Notification* message, and then close the connection.

Of course, having someone tell you “I found an error, so I quit” is not of much value. Therefore, the BGP *Notification* message contains a number of fields that provide information about the nature of the error that caused the message to be sent. This includes a set of primary error codes, as well as subcodes within some of these error codes. Depending on the nature of the error, an additional data field may also be included to aid in diagnosing the problem.

In addition to the use of *Notification* messages to convey the occurrence of an error, this message type is also used for other purposes. For example, one may be sent if two devices cannot agree on how to negotiate a session, which isn't, strictly speaking, an error. A *Notification* message is also used to allow a device to tear down a BGP session for reasons having nothing to do with an error.

### **BGP Notification Message Format**

The format for the BGP *Notification* messages is detailed in [Table 142](#) and [Figure 196](#).

**Table 142: BGP Notification Message Format**

Field Name	Size (bytes)	Description
<b>Marker</b>	16	<b>Marker:</b> This large field at the start of each BGP message is used for synchronization and authentication. <a href="#">See the discussion of the BGP general message format for details.</a>
<b>Length</b>	2	<b>Length:</b> The total length of the message in bytes, including the fields of the header. <i>Notification</i> messages are variable in length.
<b>Type</b>	1	<b>Type:</b> BGP message type, value is 3 for <i>Notification</i> messages.
<b>Error Code</b>	1	<b>Error Code:</b> Specifies the general class of the error. <a href="#">Table 143</a> shows the possible error types with a brief description of each.
<b>Error Subcode</b>	1	<b>Error Subcode:</b> This field provides more specific indication of the cause of the error for three of the <i>Error Code</i> values. The possible values of this field for each <i>Error Code</i> value are shown in <a href="#">Table 144</a> .
<b>Data</b>	Variable	<b>Data:</b> This field contains additional information to help diagnose the error; its meaning is dependent on the type of error specified in the <i>Error Code</i> and <i>Error Subcode</i> fields. In most cases, this field is filled in with whatever bad value caused the error to occur. For example, for “Message Header Error / Bad Message Type”, the value of the bad <i>Type</i> field is placed here.

**Figure 196: BGP Notification Message Format**

### ***BGP Notification Message Error Codes and Error Subcodes***

[Table 143](#) and [Table 144](#) show the values permitted for the *Error Code* and *Error Subcode* fields, respectively, and thus provide a good summary of the types of errors that *Notification* messages can report (as well as demonstrating the other non-error uses of the message type).

**Table 143: BGP Notification Message Error Codes (Page 1 of 2)**

Error Code Value	Code Name	Description
1	Message Header Error	A problem was detected either with the contents or length of the BGP header. The <i>Error Subcode</i> provides more details on the nature of the problem.
2	Open Message Error	A problem was found in the body of an <i>Open</i> message. The <i>Error Subtype</i> field describes the problem in more detail. Note that authentication failures or inability to agree on a parameter such as hold time are included here.
3	Update Message Error	A problem was found in the body of an <i>Update</i> message. Again, the <i>Error Subtype</i> provides more information. Many of the problems that fall under this code are related to issues detected in the routing data or path attributes sent in the <i>Update</i> message, so these messages provide feedback about such problems to the device sending the erroneous data.
4	Hold Timer Expired	A message was not received before the hold time expired. <a href="#">See the description of the Keepalive message for details on this timer.</a>

**Table 143: BGP Notification Message Error Codes (Page 2 of 2)**

Error Code Value	Code Name	Description
5	Finite State Machine Error	The BGP <i>finite state machine</i> refers to the mechanism by which the BGP software on a peer moves from one operating state to another based on events ( <a href="#">see the TCP finite state machine description for some background on this concept</a> ). If an event occurs that is unexpected for the state the peer is currently in, it will generate this error.
6	Cease	Used when a BGP device wants to break the connection to a peer for a reason not related to any of the error conditions described by the other codes.

**Table 144: BGP Notification Message Error Subcodes (Page 1 of 2)**

Error Type	Error Subcode Value	Subcode Name	Description
Message Header Error (Error Code 1)	1	Connection Not Synchronized	The expected value in the <i>Marker</i> field was not found, indicating that the connection has become unsynchronized. <a href="#">See the description of the Marker field</a> .
	2	Bad Message Length	The message was less than 19 bytes, greater than 4096 bytes, or not consistent with what was expected for the message type.
	3	Bad Message Type	The <i>Type</i> field of the message contains an invalid value.
Open Message Error (Error Code 2)	1	Unsupported Version Number	The device does not “speak” the version number its peer is trying to use.
	2	Bad Peer AS	The router doesn't recognize the peer's autonomous system number or is not willing to communicate with it.
	3	Bad BGP Identifier	The BGP <i>Identifier</i> field is invalid.
	4	Unsupported Optional Parameter	The <i>Open</i> message contains an optional parameter that the recipient of the message doesn't understand.
	5	Authentication Failure	The data in the <i>Authentication Information</i> optional parameter could not be authenticated.
	6	Unacceptable Hold Time	The router refuses to open a session because the proposed hold time its peer specified in its <i>Open</i> message is unacceptable.

**Table 144: BGP Notification Message Error Subcodes (Page 2 of 2)**

Error Type	Error Subcode Value	Subcode Name	Description
Update Message Error (Error Code 3)	1	Malformed Attribute List	The overall structure of the message's <a href="#">path attributes</a> is incorrect, or an attribute has appeared twice.
	2	Unrecognized Well-Known Attribute	One of the mandatory well-known attributes was not recognized.
	3	Missing Well-Known Attribute	One of the mandatory well-known attributes was not specified.
	4	Attribute Flags Error	An attribute has a flag set to a value that conflicts with the attribute's type code.
	5	Attribute Length Error	The length of an attribute is incorrect.
	6	Invalid Origin Attribute	The <i>Origin</i> attribute has an undefined value.
	7	AS Routing Loop	A routing loop was detected.
	8	Invalid Next_Hop Attribute	The <i>Next_Hop</i> attribute is invalid.
	9	Optional Attribute Error	An error was detected in an optional attribute.
	10	Invalid Network Field	The <i>Network Layer Reachability Information</i> field is incorrect.
	11	Malformed AS_Path	The <i>AS_Path</i> attribute is incorrect.

Note that, perhaps ironically, no mechanism exists to report an error in a *Notification* message itself. This is likely because the connection is normally terminated after such a message is sent.

**Key Concept:** BGP *Notification* messages are used for error reporting between BGP peers. Each message contains an *Error Code* field that indicates what type of problem occurred. For certain *Error Codes*, an *Error Subcode* field provides additional details about the specific nature of the problem. Despite these field names, *Notification* messages are also used for other types of special non-error communication, such as terminating a BGP connection.

---

## **TCP/IP Exterior Gateway Protocol (EGP)**

Routing in the early Internet was done using a small number of centralized *core* routers that maintained complete information about network reachability on the Internet. They exchanged information using the historical interior routing protocol, the [Gateway-to-Gateway Protocol \(GGP\)](#). Around the periphery of this core were located other *non-core* routers, sometimes standalone and sometimes collected into groups. These exchanged network reachability information with the core routers using the first TCP/IP exterior routing protocol: the *Exterior Gateway Protocol (EGP)*.

### ***History and Development***

Like its interior routing counterpart GGP, EGP was developed by Internet pioneers Bolt, Beranek and Newman (BBN) in the early 1980s. It was first formally described in an Internet standard in RFC 827, *Exterior Gateway Protocol (EGP)*, published in October 1982. This draft document was superseded in April 1984 by RFC 904, *Exterior Gateway Protocol Formal Specification*. Like GGP, EGP is now considered obsolete, having been replaced by the [Border Gateway Protocol \(BGP\)](#). However, also like GGP, it is an important part of the history of TCP/IP routing, so it is worth examining briefly.

**Note:** As I explained in [the introduction to this overall section on TCP/IP routing protocols](#), routers were in the past often called *gateways*. As such, exterior routing protocols were “exterior gateway protocols”. The EGP protocol discussed here is a specific instance of an exterior gateway protocol, for which the abbreviation is also *EGP*. Thus, you may occasionally see BGP also called an “exterior gateway protocol” or an “EGP”, which is the generic use of this term.

---

### ***Overview of Operation***

EGP is responsible for communication of network reachability information between neighboring routers, which may or may not be in different autonomous systems. The operation of EGP is somewhat similar to that of BGP. Each EGP router maintains a database of information regarding what networks it can reach and how to reach them. It sends this information out on a regular basis to each router to which it is directly connected. Routers receive these messages and update their routing tables, and then use this new information to update other routers. Information about how to reach each network propagates across the entire internetwork.

### ***Routing Information Exchange Process***

The actual process of exchanging routing information involves several steps to discover neighbors and then set up and maintain communications. Briefly, the steps are:

- 
1. **Neighbor Acquisition:** Each router attempts to establish a connection to each of its neighboring routers by sending *Neighbor Acquisition Request* messages. A neighbor hearing a request can respond with a *Neighbor Acquisition Confirm* to say that it recognized the request and wishes to connect. It may reject the acquisition by replying with a *Neighbor Acquisition Refuse* message. For an EGP connection to be established between a pair of neighbors, each must first successfully acquire the other with a *Confirm* message.
  2. **Neighbor Reachability:** After acquiring a neighbor, a router checks to make sure the neighbor is reachable and functioning properly on a regular basis. This is done by sending an EGP *Hello* message to each neighbor for which a connection has been established. The neighbor replies with an *I Heard You (IHU)* message. These messages are somewhat analogous to the [BGP Keepalive message](#), but are used in matched pairs.
  3. **Network Reachability Update:** A router sends *Poll* messages on a regular basis to each of its neighbors. The neighbor responds with an *Update* message, which contains details about the networks that it is able to reach. This information is used to update the routing tables of the device that sent the *Poll*.

A neighbor can decide to terminate a connection (called *neighbor de-acquisition*) by sending a *Cease* message; the neighbor responds with a *Cease-ack* (acknowledge) message.

As I mentioned earlier, the primary function in the early Internet was to connect peripheral routers or groups of routers to the Internet core. It was therefore designed under the assumption that the internetwork was connected as a hierarchical tree, with the *core* as the root. EGP was not designed to handle an arbitrary topology of autonomous systems like BGP, and cannot guarantee the absence of routing loops if such loops exist in the interconnection of neighboring routers. This is part of why BGP needed to be developed as the Internet moved to a more arbitrary structure of autonomous system connections; it has now entirely replaced EGP.

## **Error Reporting**

An *Error* message is also defined, which is similar to the [BGP Notification message](#) in role and structure. It may be sent by a neighbor in response to receipt of an EGP message either when the message itself has a problem (such as a bad message length or unrecognized data in a field) or to indicate a problem in how the message is being used (such as receipt of *Hello* or *Poll* messages at a rate deemed excessive). Unlike the BGP *Notification* message, an EGP router does not necessarily close the connection when sending an *Error* message.

**Key Concept:** The *Exterior Gateway Protocol (EGP)* was the first TCP/IP exterior routing protocol and was used with GGP on the early Internet. It functions in a manner similar to BGP: an EGP router makes contact with neighboring routers and exchanges routing information with them. A mechanism is also provided to maintain a session and report errors. EGP is more limited than BGP in capability and is now considered a historical protocol.

---

---

## TCP/IP Transport Layer Protocols

The first three layers of the [OSI Reference Model](#)—the physical layer, data link layer and network layer—are very important layers for understanding how networks function. The physical layer moves bits over wires; the data link layer moves frames on a network; the network layer moves datagrams on an internetwork. Taken as a whole, they are the parts of a protocol stack that are responsible for the actual “nuts and bolts” of getting data from one place to another.

Immediately above these we have the fourth layer of the OSI Reference Model: the *transport layer*, called the host-to-host transport layer in the [TCP/IP model](#). This layer is interesting in that it resides in the very architectural center of the model. Accordingly, it represents an important transition point between the hardware-associated layers below it that do the “grunt work”, and the layers above that are more software-oriented and abstract.

Protocols running at the transport layer are charged with providing several important services to enable software applications in higher layers to work over an internetwork. They are typically responsible for allowing connections to be established and maintained between software services on possibly distant machines. Perhaps most importantly, they serve as the bridge between the needs of many higher-layer applications to send data in a reliable way without needing to worry about error correction, lost data or flow management, and network-layer protocols, which are often unreliable and unacknowledged. Transport layer protocols are often very tightly-tied to the network layer protocols directly below them, and designed specifically to take care of functions that they do not deal with.

In this section I describe transport layer protocols and related technologies used in the TCP/IP protocol. There are two main protocols at this layer; the Transmission Control Protocol (TCP) and the User Datagram Protocol (UDP). I also discuss how transport-layer addressing is done in TCP/IP in the form of ports and sockets.

**Note:** It may seem strange that I have only one subsection here, the one that covers TCP and UDP. This is a result of the fact that The TCP/IP Guide is [excerpted from a larger networking reference](#).

---

---

## **Transmission Control Protocol (TCP) and User Datagram Protocol (UDP)**

TCP/IP is the most important internetworking protocol suite in the world; it is the basis for the Internet, and the “language” spoken by the vast majority of the world's networked computers. TCP/IP includes a large set of protocols that operate at the network layer and above. The suite as a whole is anchored at layer three by the [Internet Protocol \(IP\)](#), which many people consider the single most important protocol in the world of networking.

Of course, there's a bit of *architectural distance* between the network layer and the applications that run at the layers well above. While IP is the protocol that performs the bulk of the functions needed to make an internetwork, it does not include many capabilities that are needed by applications. In TCP/IP these tasks are performed by a pair of protocols that operate at the transport layer: the *Transmission Control Protocol (TCP)* and the *User Datagram Protocol (UDP)*.

Of these two, TCP gets by far the most attention. It is the transport layer protocol that is most often associated with TCP/IP, and, well, its name is right there, “up in lights”. It is also the transport protocol used for many of the Internet's most popular applications, while UDP gets second billing. However, TCP and UDP are really peers that play the same role in TCP/IP. They function very differently and provide different benefits and drawbacks to the applications that use them, which makes them both important to the protocol suite as a whole. The two protocols also have certain areas of similarity, which makes it most efficient that I describe them in the same overall section, highlighting where they share characteristics and methods of operation, as well as where they diverge.

In this section I provide a detailed examination of the two TCP/IP transport layer protocols: the Transmission Control Protocol (TCP) and the User Datagram Protocol (UDP). I begin with a quick overview of the role of these two protocols in the TCP/IP protocol suite, and a discussion of why they are both important. I describe the method that both protocols employ for addressing, using transport-layer ports and sockets. I then have two detailed sections for each of UDP and TCP. I conclude with a summary quick-glance comparison of the two.

Incidentally, I describe UDP before TCP for a simple reason: it is simpler. UDP operates more like a classical message-based protocol, and in fact is more similar to IP itself than is TCP. This is the same reason why the section on TCP is much larger than that covering UDP: TCP much more complex and does a great deal more than UDP.

---

## **TCP and UDP Overview and Role In TCP/IP**

The transport layer in a protocol suite is responsible for a specific set of functions. For this reason, one might expect that the TCP/IP suite would have a single main transport protocol to perform those functions, just as it has [IP](#) as its core protocol at the network layer. It is a curiosity, then, that there are **two** different widely-used TCP/IP transport layer protocols. This arrangement is probably one of the best examples of [the power of protocol layering](#)—and hence, an illustration that it was worth all the time you spent learning to understand that pesky [OSI Reference Model](#). ☺

### ***Differing Transport Layer Requirements in TCP/IP***

Let's start with a look back at layer three. In my [overview of the key operating characteristics of the Internet Protocol](#), I described several important limitations of how IP works. The most important of these are that IP is *connectionless*, *unreliable* and *unacknowledged*. Data is sent over an IP internetwork without first establishing a connection, using a “best effort” paradigm. Messages **usually** get where they need to go, but there are no guarantees, and the sender usually doesn't even know if the data got to its destination.

These characteristics present serious problems to software. Many, if not most, applications need to be able to count on the fact that the data they send will get to its destination without loss or error. They also want the connection between two devices to be automatically managed, with problems such as congestion and flow control taken care of as needed. Unless some mechanism is provided for this at lower layers, every application would need to perform these jobs, which would be a massive duplication of effort.

In fact, one might argue that establishing connections, providing reliability, and handling retransmissions, buffering and data flow is sufficiently important that it would have been best to simply build these abilities directly into the Internet Protocol. Interestingly, that was exactly the case in the early days of TCP/IP. “In the beginning” [there was just a single protocol](#) called “TCP” that combined the tasks of the Internet Protocol with the reliability and session management features just mentioned.

There's a big problem with this, however. Establishing connections, providing a mechanism for reliability, managing flow control and acknowledgments and retransmissions: these all come at a cost: time and bandwidth. Building all of these capabilities into a single protocol that spans layers three and four would mean all applications got the benefits of reliability, but also the costs. While this would be fine for many applications, there are others that both don't need the reliability, and “can't afford” the overhead required to provide it.

### ***The Solution: Two Very Different Transport Protocols***

Fixing this problem was simple: let the network layer (IP) take care of basic data movement on the internetwork, and define two protocols at the transport layer. One would provide a rich set of services for those applications that need that functionality, with the understanding that some overhead was required to accomplish it. The other would be simple, providing little in the way of classic layer-four functions, but it would be fast and easy to use. Thus, the result of two TCP/IP transport-layer protocols:

- 
- 🔊 **Transmission Control Protocol (TCP):** A full-featured, connection-oriented, reliable transport protocol for TCP/IP applications. TCP provides transport-layer addressing to allow multiple software applications to simultaneously use a single IP address. It allows a pair of devices to establish a virtual connection and then pass data bidirectionally. Transmissions are managed using a special *sliding window* system, with unacknowledged transmissions detected and automatically retransmitted. Additional functionality allows the flow of data between devices to be managed, and special circumstances to be addressed.
  - 🔊 **User Datagram Protocol (UDP):** A very simple transport protocol that provides transport-layer addressing like TCP, but little else. UDP is barely more than a “wrapper” protocol that provides a way for applications to access the Internet Protocol. No connection is established, transmissions are unreliable, and data can be lost.

By means of analogy, TCP is a fully-loaded luxury performance sedan with a chauffeur and a satellite tracking/navigation system. It provides lots of frills and comfort, and good performance. It virtually guarantees you will get where you need to go without any problems, and any concerns that do arise can be corrected. In contrast, UDP is a stripped-down race car. Its goal is simplicity and speed, speed, speed; everything else is secondary. You will probably get where you need to go, but hey, race cars can be finicky to keep operating.

**Key Concept:** To suit the differing transport requirements of the many TCP/IP applications, two TCP/IP transport layer protocols exist. The *Transmission Control Protocol (TCP)* is a full-featured, connection-oriented protocol that provides acknowledged delivery of data while managing traffic flow and handling issues such as congestion and transmission loss. The *User Datagram Protocol (UDP)*, in contrast, is a much simpler protocol that concentrates only on delivering data, to maximize the speed of communication when the features of TCP are not required.

---

## Applications of TCP and UDP

Having two transport layer protocols with such complementary strengths and weaknesses provides considerable flexibility to the creators of networking software:

- 🔊 **TCP Applications:** Most “typical” applications need the reliability and other services provided by TCP, and don’t care about loss of a small amount of performance to overhead. For example, most applications that transfer files or important data between machines use TCP, because loss of any portion of the file renders the entire thing useless. Examples include such well-known applications as the [Hypertext Transfer Protocol \(HTTP\)](#) used by the [World Wide Web \(WWW\)](#), the [File Transfer Protocol \(FTP\)](#) and the [Simple Mail Transfer Protocol \(SMTP\)](#). I describe TCP applications in more detail in the TCP section.
- 🔊 **UDP Applications:** I’m sure you’re thinking: “what sort of application doesn’t care if its data gets there, and why would I want to use it?” You might be surprised: UDP is used by lots of TCP/IP protocols. UDP is a good match for applications in two circumstances. The first is when the application doesn’t really care if some of the data gets lost; streaming video or multimedia is a good example, since one lost byte of data won’t even be noticed. The other is when the application itself chooses to provide

---

some other mechanism to make up for the lack of functionality in UDP. Applications that send very small amounts of data, for example, often use UDP under the assumption that if a request is sent and a reply is not received, the client will just send a new request later on. This provides enough reliability without the overhead of a TCP connection. [I discuss some common UDP applications in the UDP section.](#)

---

**Key Concept:** Most classical applications, especially ones that send files or messages, require that data be delivered reliably, and therefore use TCP for transport. Applications using UDP are usually those where loss of a small amount of data is not a concern, or that use their own application-specific procedures for dealing with potential delivery problems that TCP handles more generally.

---

In the next few sections we'll first examine the common transport layer addressing scheme used by TCP and UDP, and then look at each of the two protocols in detail. Following these sections is a [summary comparison](#) to help you see at a glance where the differences lie between TCP and UDP. Incidentally, if you want a good “real-world” illustration of why having both UDP and TCP is valuable, consider [message transport under the Domain Name System \(DNS\)](#), which actually uses UDP for certain types of communication and TCP for others.

Before leaving the subject of comparing UDP and TCP, I want to explicitly point out that even though TCP is often described as being *slower* than UDP, this is a **relative** measurement. TCP is a very well-written protocol that is capable of highly efficient data transfers. It is only slow compared to UDP because of the overhead of establishing and managing connections. The difference can be significant, but is not enormous, so keep that in mind.

---

## **TCP/IP Transport Layer Protocol (TCP and UDP) Addressing: Ports and Sockets**

Internet Protocol (IP) addresses are the universally-used main form of addressing on a TCP/IP network. These [network-layer addresses](#) uniquely identify each network interface, and as such, serve as the mechanism by which data is routed to the correct network on the internetwork, and then the correct device on that network. What some people don't realize, however, is that there is an additional level of addressing that occurs at the transport layer in TCP/IP, above that of the IP address. Both of the TCP/IP transport protocols, TCP and UDP, use the concepts of *ports* and *sockets* for virtual software addressing, to enable the function of many applications simultaneously on an IP device.

In this section I describe the special mechanism used for addressing in both TCP and UDP. I begin with a discussion of TCP/IP application processes, including the client/server nature of communication, which provides a background for explaining how ports and sockets are used. I then give an overview of the concept of ports, and how they enable the multiplexing of data over an IP address. I describe the way that port numbers are categorized in ranges, and assigned to server processes for common applications. I explain the concept of ephemeral port numbers used for clients. I then discuss sockets and their use for connection identification, including the means by which multiple devices can talk to a single port on another device. I then provide a summary table of the most common well-known and registered port numbers.

### **TCP/IP Processes, Multiplexing and Client/Server Application Roles**

I believe the most sensible place to start learning about how the TCP/IP protocol suite works is by examining the [Internet Protocol \(IP\)](#) itself, and the support protocols that function in tandem with it at the network layer. IP is the foundation upon which most of the rest of TCP/IP is built. It is the mechanism by which data is packaged and routed throughout a TCP/IP internetwork.

It makes sense, then, that when we examine the operation of TCP/IP from the perspective of the Internet Protocol, we talk very generically about sending and receiving datagrams. To the IP layer software that sends and received IP datagrams, the higher-level application they come from and go to is really unimportant: to IP, "a datagram is a datagram", pretty much. All datagrams are packaged and routed in the same way, and IP is mainly concerned with lower-level aspects of moving them between devices in an efficient manner.

It's important to remember, however, that this is really an ***abstraction***, for the convenience of describing layer three operation. It doesn't consider how datagrams are really generated and used above layer three. [Layer four represents a transition point](#) between the OSI model hardware-related layers (one, two and three) and the software-related layers (five to seven). This means the TCP/IP transport layer protocols, TCP and UDP, ***do*** need to pay attention to the way that software uses TCP/IP, even if IP really does not.

---

Ultimately, the entire point of having networks, internetworks and protocols suites like TCP/IP is to enable networking *applications*. Most Internet users employ these applications on a daily basis. In fact, most of us will be running many different applications simultaneously. For example, you might be using a [World Wide Web](#) browser to check the news, an [FTP](#) client to upload some pictures to share with family, and an [Internet Relay Chat](#) program to discuss something with a friend or colleague. In fact, it is common to have multiple **instances** of a single application. The most common example is having multiple Web browser windows open (I sometimes find myself with as many as 30 going at one time!)

### ***Multiplexing and Demultiplexing***

Most communication in TCP/IP takes the form of exchanges of information between a program running on one device, and a matching program on another device. Each instance of an application represents a copy of that application software that needs to send and receive information. These application instances are commonly called *processes*. A TCP/IP application process is any piece of networking software that sends and receives information using the TCP/IP protocol suite. This includes both “classic” end-user applications such as the ones described above, as well as support protocols that behave as applications when they send messages. Examples of the latter would include a network management protocol like [SNMP](#), or even the routing protocol [BGP](#) (which sends messages using TCP like an application does).

So, a typical TCP/IP host has multiple processes each needing to send and receive datagrams. All of them, however, must be sent using the same interface to the internetwork, using the IP layer. This means that the data from all applications (with some possible exceptions) is “funneled down”, initially to the transport layer, where it is handled by either TCP or UDP. From there, messages pass to the device's IP layer, where they are packaged in IP datagrams and sent out over the internetwork to different destinations. The technical term for this is *multiplexing*. This term simply means combining, and its use here is a software analog to the way it is done with signals.

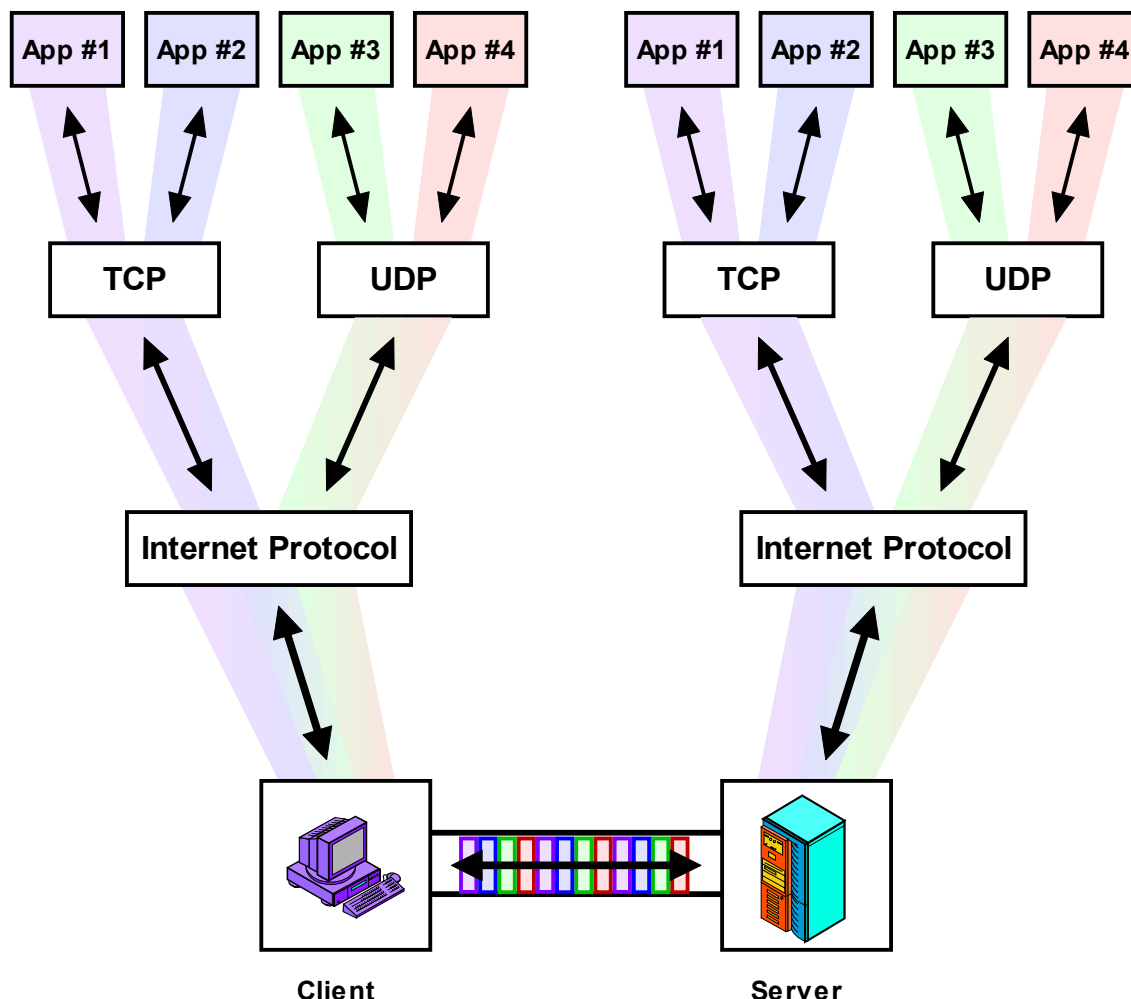

A complementary mechanism is responsible for receipt of datagrams. At the same time that the IP layer multiplexes datagrams from many application processes to be sent out, it receives many datagrams that are intended for different processes. The IP layer must take this stream of unrelated datagrams, and eventually pass them to the correct process (through the transport layer protocol above it). This is the reverse of multiplexing: *demultiplexing*. You can see an illustration of the basic concept behind TCP/IP process multiplexing and demultiplexing in [Figure 197](#).

**Key Concept:** TCP/IP is designed to allow many different applications to send and receive data simultaneously using the same Internet Protocol software on a given device. To accomplish this it is necessary to *multiplex* transmitted data from many sources as it is passed down to the IP layer. As a stream of IP datagrams is received, it is *demultiplexed* and the appropriate data passed to each application software instance on the receiving host.

---

**Figure 197: Process Multiplexing and Demultiplexing In TCP/IP**

In a typical machine running TCP/IP there are many different protocols and applications running simultaneously. This example shows four different applications communicating between a client and server machine. All four are multiplexed for transmission using the same IP software and physical connection; received data is demultiplexed and passed to the appropriate application. IP, TCP and UDP provide the means of keeping distinct the data from each application.

### ***TCP/IP Client Processes and Server Processes***

There's another characteristic of TCP/IP software that is very important to understanding how the transport layer and higher layers of the suite operate: it is generally *asymmetric*. This means that when a TCP/IP application process on one computer tries to talk to an application process on another computer, the two processes are usually not exactly the same. They are instead *complements* of each other, designed to function together as a team.

As I explained in the [overview description of TCP/IP](#), most networking applications use a *client/server* model of operation. This term can be used to refer to the roles of computers, where a server is a relatively powerful machine that provides services to a large number of

---

user-operated clients. It also applies to software. In this context, a *client process* is usually one that runs on a client machine and initiates contact to perform some sort of function. A *server process* usually runs on a hardware server, and listens for requests from clients and responds to them.

The classic example of this is, of course, the World Wide Web. [The WWW uses the Hypertext Transfer Protocol \(HTTP\)](#), a good example of an application protocol. A Web browser is an HTTP client, normally running on an end-user client machine such as you are probably using at this moment. It initiates an exchange of HTTP (Web) data by sending a request to a Web (HTTP) server. A server process on that Web server hears the request and replies either with the requested item(s)—a Web page or other data—or an error message. The server is usually specifically designed to handle many incoming client requests, and in many cases for little else.

Okay, I can practically see the impatient look on your face as you wonder to yourself: “why is he telling me all of this in a section that is supposed to explain TCP and UDP ports”? The answers will become clear shortly, I promise. I started here because the fact that many application processes run simultaneously and have their data multiplexed for transmission is the impetus for why higher-level addressing is a necessity in TCP/IP. The client/server arrangement used by TCP/IP has an important impact on the way that ports are used and the mechanisms for how they are assigned. The next two topics explore these concepts more completely.

## **TCP/IP Ports: Transport Layer (TCP/UDP) Addressing**

A typical host on a TCP/IP internetwork has many different software application processes running concurrently. Each generates data that it sends to either TCP or UDP, which in turn passes it to IP for transmission. This [multiplexed stream of datagrams](#) is sent out by the IP layer to various destinations. Simultaneously, each device's IP layer is receiving datagrams that originated in numerous application processes on other hosts. These need to be demultiplexed, so they end up at the correct process on the device that receives them.

### ***Multiplexing and Demultiplexing Using Ports***

The question is: how do we demultiplex a sequence of IP datagrams that need to go to many different application processes? Let's consider a particular host with a single network interface bearing the IP address 24.156.79.20. Normally, every datagram received by the IP layer will have this value in the IP *Destination Address* field. Consecutive datagrams received by IP may contain a piece of a file you are downloading with your Web browser, an e-mail sent to you by your brother, and a line of text a buddy wrote in an IRC chat channel. How does the IP layer know which datagrams go where, if they all have the same IP address?

---

The first part of the answer lies in the *Protocol* field included in the header of each IP datagram. This field carries a code that identifies the protocol that sent the data in the datagram to IP. Since most end-user applications use TCP or UDP at the transport layer, the *Protocol* field in a received datagram tells IP to pass data to either TCP or UDP as appropriate.

Of course, this just defers the problem to the transport layer: both TCP and UDP are used by many applications at once. This means TCP or UDP must figure out which process to send the data to. To make this possible, an additional addressing element is necessary. This address allows a more specific location—a software process—to be identified within a particular IP address. In TCP/IP, this transport layer address is called a *port*.

**Key Concept:** TCP/IP transport layer addressing is accomplished using TCP and UDP *ports*. Each port number within a particular IP device identifies a particular software process.

---

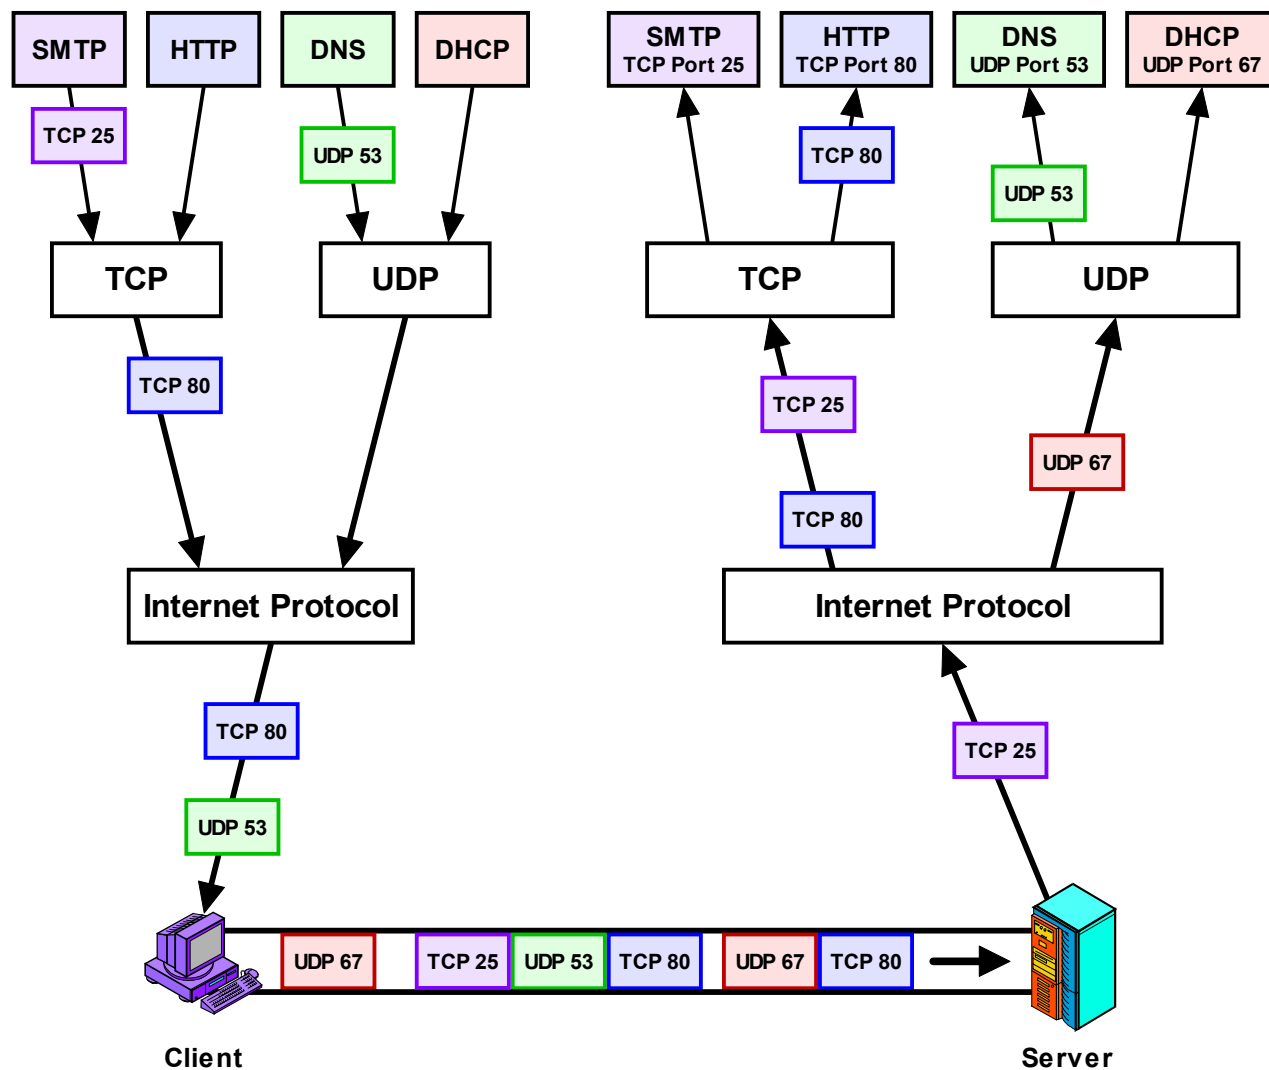

### **Source Port and Destination Port Numbers**

In both UDP and TCP messages two addressing fields appear, for a *Source Port* and a *Destination Port*. These are analogous to [the fields for source address and destination address at the IP level](#), but at a higher level of detail. They identify the originating process on the source machine, and the destination process on the destination machine. They are filled in by the TCP or UDP software before transmission, and used to direct the data to the correct process on the destination device.

TCP and UDP port numbers are 16 bits in length, so valid port numbers can theoretically take on values from 0 to 65,535. [As we will see in the next topic](#), these values are divided into ranges for different purposes, with certain ports reserved for particular uses.

One fact that is sometimes a bit confusing is that both UDP and TCP use the same range of port numbers, and they are independent. So, in theory, it is possible for UDP port number 77 to refer to one application process and TCP port number 77 to refer to an entirely different one. There is no ambiguity, at least to the computers, because as mentioned above, each IP datagram contains a *Protocol* field that specifies whether it is carrying a TCP message or a UDP message. IP passes the datagram to either TCP or UDP, which then sends the message on to the right process using the port number in the TCP or UDP header. This mechanism is illustrated in [Figure 198](#).

In practice, having TCP and UDP use different port numbers is confusing, especially for the reserved port numbers used by common applications. For this reason, by convention, most reserved port numbers are reserved for both TCP and UDP. For example, port #80 is reserved for the Hypertext Transfer Protocol (HTTP) for both TCP and UDP, even though HTTP only uses TCP. [We'll examine this in greater detail in the next topic](#).

**Figure 198: TCP/IP Process Multiplexing/Demultiplexing Using TCP/UDP Ports**

This is a more “concrete” version of [Figure 197](#), showing how TCP and UDP ports are used to accomplish software multiplexing and demultiplexing. Again here there are four different TCP/IP applications communicating, but this time I am showing only the traffic going from the client to the server. Two of the applications are using TCP and two UDP. Each application on the client sends messages using a specific TCP or UDP port number. These port numbers are used by the server’s UDP and TCP software to pass the datagrams to the appropriate application process.

### ***Summary of Port Use for Datagram Transmission and Reception***

So, to summarize, here’s the basics of how transport-layer addressing (port addressing) works in TCP and UDP:

- 
- ☉ **Sending Datagrams:** An application specifies the source and destination port it wishes to use for the communication. These are encoded into the TCP or UDP header, depending on which transport layer protocol the application is using. When TCP or UDP passes data to IP, IP indicates the protocol type appropriate for TCP or UDP in the *Protocol* field of the IP datagram. The source and destination port numbers are encapsulated as part of the TCP or UDP message, within the IP datagram's data area.
  - ☉ **Receiving Datagrams:** The IP software receives the datagram, inspects the *Protocol* field and decides to which protocol the datagram belongs (in this case, TCP or UDP, but of course there are other protocols that use IP directly, such as ICMP). TCP or UDP receives the datagram and passes its contents to the appropriate process based on the destination port number.

**Key Concept:** Application process multiplexing and demultiplexing in TCP/IP is implemented using the IP *Protocol* field and the UDP/TCP *Source Port* and *Destination Port* fields. Upon transmission, the *Protocol* field is given a number to indicate whether TCP or UDP was used, and the port numbers are filled in to indicate the sending and receiving software process. The device receiving the datagram uses the *Protocol* field to determine whether TCP or UDP was used, and then passes the data to the software process indicated by the *Destination Port* number.

---

**Note:** As an aside, I should point out that the term *port* has many meanings aside from this one in TCP/IP. For example, a physical outlet in a network device is often called a *port*. Usually one can discern whether the “port” in question refers to a hardware port or a software port from context, but you may wish to watch out for this.

---

## **TCP/IP Application Assignments and Server Port Number Ranges: Well-Known, Registered and Dynamic/Private Ports**

The port numbers we discussed in the previous topic provide a method of transport-layer addressing that allows many applications to use TCP and UDP simultaneously. By specifying the appropriate destination port number, an application sending data can be sure that the right process on the destination device will receive the message. Unfortunately, there's still a problem we have to work on before this addressing system will work.

### ***The Problem: Identifying Particular Processes on A Server***

To explain it, I need to go back to a familiar example: using the World Wide Web. We fire up our Web browser, which is client software that sends requests using the [Hypertext Transfer Protocol \(HTTP\)](#). We need to either know the IP address of the Web site we want to access, or we may have the IP address supplied to us automatically using [DNS](#). Once we have the address, the Web browser can generate an HTTP message and send it to the Web site's IP address.

---

This HTTP message is being sent not “just anywhere” on that IP address: it is intended for the Web server process on the site we are trying to reach. The problem is: how does the Web browser (client process) know which port number has been assigned to the server process on the Web site? Port numbers can range from 0 to 65,535, which means a lot of choices. And in theory, every Web site could assign a different port number to its Web server process.

### ***The Solution: Reserved Port Numbers***

There are a couple of different ways to resolve this problem. TCP/IP takes what is probably the simplest possible approach: it *reserves* certain port numbers for particular applications. Each common application has a specific port number that is assigned to it for use by server processes that listen for requests for that application and then respond to them. To avoid chaos, the software that implements a particular server process normally uses the same reserved port number on every IP device, so clients can find it easily.

In our example, the reserved port number for HTTP is 80. Every Web browser just “knows” that Web sites are designed to listen for requests sent to port 80. They will thus use this value in requests, to ensure the IP and TCP software on the Web browser direct these HTTP messages to the Web server software. [It is possible for a particular Web server to use a different port number](#), but in this case, the user of the Web browser must be informed of this number somehow, and must explicitly tell the Web browser to use it instead of the default port number (80).

**Key Concept:** To allow client devices to more easily establish connections to TCP/IP servers, server processes for common applications use universal server port numbers that clients are pre-programmed to know to use by default.

---

### ***TCP/UDP Port Number Ranges***

For this system to work well, universal agreement on port assignments is essential. Thus, this becomes another situation where a central authority is needed to manage a list of port assignments that everyone uses. For TCP/IP, it is the same authority responsible for the assignment and coordination of other centrally-managed numbers, including IP addresses, IP *Protocol* numbers and so forth: the [Internet Assigned Numbers Authority \(IANA\)](#).

As we have seen, there are 65,536 port numbers that can be used for processes. But there are also a fairly large number of TCP/IP applications, and the list grows every year. IANA needs to carefully manage the port number “address space” to ensure that port numbers are not wasted on protocols that won’t be widely used, while also providing flexibility for organizations that need to make use of obscure applications. To this end, the full spectrum of TCP and UDP port numbers is divided into three ranges, as shown in [Table 145](#):

The existence of these ranges ensures that there will be universal agreement on how to access a server process for the most common TCP/IP protocols, while also allowing flexibility for special applications. Most of the TCP/IP applications and application protocols use

---

numbers in the well-known port number range for their servers. These port numbers are not generally used for client processes, but there are some exceptions. For example, port 68 is reserved for a client using the [Bootstrap Protocol \(BOOTP\)](#) or [Dynamic Host Configuration Protocol \(DHCP\)](#).

**Table 145: TCP and UDP Port Number Ranges**

Port Range Name	Port Number Range	Description
<b>Well-Known (Privileged) Port Numbers</b>	0 to 1,023	<p>These port numbers are managed by IANA and reserved for only the most universal TCP/IP applications. The IANA assigns these port numbers only to protocols that have been standardized using the <a href="#">TCP/IP RFC process</a>, that are in the process of being standardized, or that are likely to be standardized in the future.</p> <p>On most computers, these port numbers are used only by server processes run by system administrators or privileged users. These generally correspond to processes that implement key IP applications, such as Web servers, FTP servers and the like. For this reason, these are sometimes called <i>system port numbers</i>.</p>
<b>Registered (User) Port Numbers</b>	1,024 to 49,151	<p>There are many applications that need to use TCP/IP but are not specified in RFCs, or are not so universally used that they warrant a worldwide well-known port number. To ensure that these various applications do not conflict with each other, IANA uses the bulk of the overall port number range for registered port numbers. Anyone who creates a viable TCP/IP server application can request to reserve one of these port numbers, and if approved, the IANA will register that port number and assign it to the application.</p> <p>These port numbers are generally accessible by any user on a system and are therefore sometimes called <i>user port numbers</i>.</p>
<b>Private/Dynamic Port Numbers</b>	49,152 to 65,535	<p>These ports are neither reserved nor maintained by IANA. They can be used for any purpose without registration, so they are appropriate for a private protocol used only by a particular organization</p>

**Key Concept:** Port numbers assignments are managed by IANA to ensure universal compatibility around the global Internet. The numbers are divided into three ranges: *well-known* port numbers used for the most common applications, *registered* port numbers for other applications, and *private/dynamic* port numbers that can be used without IANA registration.

---

## **TCP/IP Client (Ephemeral) Ports and Client/Server Application Port Use**

The significance of the asymmetry between clients and servers in TCP/IP becomes evident when we examine in detail how port numbers are used. Since clients initiate application data transfers using TCP and UDP, it is they that need to know the port number of the

---

server process. Consequently, it is servers that are required to use universally-known port numbers. Thus, [well-known and registered port numbers](#) identify server processes. They are used as the destination port number in requests sent by clients.

In contrast, servers respond to clients; they do not initiate contact with them. Thus, the client doesn't need to use a reserved port number. In fact, this is really an understatement: a server **shouldn't** use a well-known or registered port number to send responses back to clients. The reason is that it is possible for a particular device to have both client and server software of the same protocol running on the same machine. If a server received an HTTP request on port 80 of its machine and sent the reply back to port 80 on the client machine, it would be sending the reply to the client machine's HTTP **server** process (if present) and not the client process that sent the initial request.

To know where to send the reply, the server must know the port number the client is using. This is supplied by the client as the *Source Port* in the request, and then used by the server as the destination port to send the reply. Client processes don't use well-known or registered ports. Instead, each client process is assigned a temporary port number for its use. This is commonly called an *ephemeral port number*.

**Note:** Your \$10 word for the day: *ephemeral*: “short-lived; existing or continuing for a short time only.” — Webster's Revised Unabridged Dictionary.

---

### ***Ephemeral Port Number Assignment***

Ephemeral port numbers are assigned as needed to processes by the TCP/IP software. Obviously, each client process running concurrently needs to use a unique ephemeral port number, so the TCP and UDP layers must keep track of which are in use. These port numbers are generally assigned in a *pseudo-random* manner from a reserved pool of numbers. I say “pseudo-random” because there is no specific meaning to an ephemeral port number assigned to a process, so a random one could be selected for each client process. However, since it is necessary to reuse the port numbers in this pool over time, many implementations use a set of rules to minimize the chance of confusion due to reuse.

Consider a client process that just used ephemeral port number 4,121 to send a request, received a reply, and then terminated. Suppose we immediately reallocate 4,121 to some other process. However, the server accessed by the prior user of port 4,121 for some reason sent an extra reply. It would go to the new process, creating confusion. To avoid this, it is wise to wait as long as possible before reusing port number 4,121 for another client process. Some implementations will therefore cycle through the port numbers in to ensure the maximum amount of time elapses between consecutive uses of the same ephemeral port number.

**Key Concept:** Well-known and registered port numbers are needed for server processes since a client must know the server's port number to initiate contact. In contrast, client processes can use any port number. Each time a client process initiates a UDP or TCP communication it is assigned a temporary, or *ephemeral*, port number to use for that conversation. These port numbers are assigned in a pseudo-random way, since the exact number used is not important, as long as each process has a different number.

---

### ***Ephemeral Port Number Ranges***

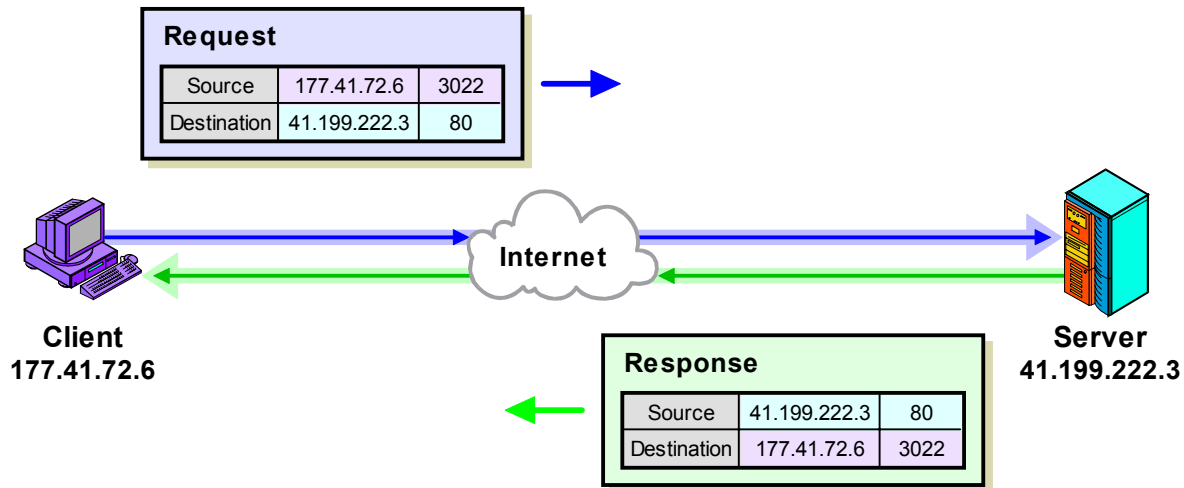

The range of port numbers that is used for ephemeral ports on a device also depends on the implementation. The “classic” ephemeral port range was established by the TCP/IP implementation in BSD (Berkeley Standard Distribution) UNIX, where it was defined as 1,024 to 4,999, providing 3,976 ephemeral ports. This seems like a very large number, and it is indeed usually more than enough for a typical client. However, the size of this number can be deceiving. Many applications use more than one process, and it is theoretically possible to run out of ephemeral port numbers on a very busy IP device. For this reason, most of the time the ephemeral port number range can be changed. The default range may be different for other operating systems.

Just as well-known and registered port numbers are used for server processes, ephemeral port numbers are for client processes only. This means that the use of a range of addresses from 1,024 to 4,999 does not conflict with the use of that same range for registered port numbers as seen in the previous topic.

### ***Port Number Use During a Client/Server Exchange***

So, let's return to the matter of client/server application message exchange. Once assigned an ephemeral port number, it is used as the source port in the client's request TCP/UDP message. The server receives the request, and then generates a reply. In forming this response message, it *swaps* the source and destination port numbers, just as it does the source and destination IP addresses. So, the server's reply is sent **from** the well-known or registered port number on the server process, back **to** the ephemeral port number on the client machine.

Phew, confusing... quick, back to our example! ☺ Our Web browser, with IP address 177.41.72.6 wants to send an HTTP request to a particular Web site at IP address 41.199.222.3. The HTTP request is sent using TCP, with a *Destination Port* number of 80 (the one reserved for HTTP servers). The *Source Port* number is allocated from a pool of ephemeral ports; let's say it's port 3,022. When the HTTP request arrives at the Web server it is conveyed to port 80 where the HTTP server receives it. That process generates a reply, and sends it back to 177.41.72.6, using *Destination Port* 3,022 and *Source Port* 80. The two processes can exchange information back and forth; each time the source port number and destination port number are swapped along with the source and destination IP addresses. This example is illustrated in [Figure 199](#).

**Figure 199: TCP/IP Client/Server Application Port Mechanics**

This highly simplified example shows how clients and servers use port numbers for a request-reply exchange.

The client is making an HTTP request and sends it to the server at HTTP's well-known port number, 80. Its port number for this exchange is the pseudo-randomly-selected 3,022. The server sends its reply back to that port number, which it reads from the request.

**Key Concept:** In most TCP/IP client/server communications, the client uses a random ephemeral port number and sends a request to the appropriate reserved port number at the server's IP address. The server sends its reply back to whatever port number it finds in the *Source Port* field of the request.

## **TCP/IP Sockets and Socket Pairs: Process and Connection Identification**

The preceding topics have illustrated the key difference between addressing at the level of the Internet Protocol, and addressing as it is seen by application processes. To summarize, at layer three, an IP address is all that is really important for properly transmitting data between IP devices. In contrast, application protocols must be concerned with **the port assigned to each instance of the application**, so they can properly use TCP or UDP.

### ***Sockets: Process Identification***

What this all means is that the overall identification of an application process actually uses the **combination** of the IP address of the host it runs on—or the network interface over which it is talking, to be more precise—and the port number which has been assigned to it. This combined address is called a *socket*. Sockets are specified using the following notation:

<IP Address>:<Port Number>

So, for example, if we have a Web site running on IP address 41.199.222.3, the socket corresponding to the HTTP server for that site would be *41.199.222.3:80*.

**Key Concept:** The overall identifier of a TCP/IP application process on a device is the combination of its IP address and port number, which is called a *socket*.

---

You will also sometimes see a socket specified using a host name instead of an IP address, like this:

<Host Name>:<Port Number>

To use this descriptor, the name must first be resolved to an IP address using DNS. For example, you might find a Web site URL like this: “http://www.thisisagreatsite.com:8080”. This tells the Web browser to first *resolve* the name “www.thisisagreatsite.com” to an IP address using [DNS](#), and then send a request to that address using the non-standard server port 8080, which is occasionally used instead of port 80 since it resembles it. ([See the discussion of application layer addressing using URLs for much more.](#))

The *socket* is a very fundamental concept to the operation of TCP/IP application software. In fact, it is the basis for an important TCP/IP application program interface (API) with the same name: *sockets*. A version of this API for Windows is called *Windows Sockets* or *WinSock*, which you may have heard of before. These APIs allow application programs to easily use TCP/IP to communicate.

### **Socket Pairs: Connection Identification**

So, the exchange of data between a pair of devices consists of a series of messages sent from a socket on one device to a socket on the other. Each device will normally have multiple such simultaneous conversations going on. In the case of [TCP](#), a connection is established for each pair of devices for the duration of the communication session. These connections must be managed, and this requires that they be uniquely identified. This is done using the pair of socket identifiers for each of the two devices that are connected.

**Key Concept:** Each device may have multiple TCP connections active at any given time. Each connection is uniquely identified using the combination of the client socket and server socket, which in turn contains four elements: the client IP address and port, and the server IP address and port.

---

Let's return to the example we used in the previous topic ([Figure 199](#)). We are sending an HTTP request from our client at 177.41.72.6 to the Web site at 41.199.222.3. The server for that Web site will use well-known port number 80, so its socket is 41.199.222.3:80, as we saw before. We have been ephemeral port number 3,022 for our Web browser, so the client socket is 177.41.72.6:3022. The overall connection between these devices can be described using this socket pair:

(41.199.222.3:80, 177.41.72.6:3022)

---

For much more on how TCP identifies connections, see [the topic on TCP ports and connection identification](#) in the section on TCP fundamentals.

Unlike TCP, [UDP](#) is a connectionless protocol, so it obviously doesn't use connections. The pair of sockets on the sending and receiving devices can still be used to identify the two processes exchanging data, but since there are no connections the socket pair doesn't have the significance that it does in TCP.

## **Common TCP/IP Applications and Assigned Well-Known and Registered Port Numbers**

The great popularity of the TCP/IP protocol suite has led to the development of literally thousands of different applications and protocols. Most of these use the client/server model of operation that we discussed earlier in this section. Server processes for a particular application are designed to use a particular [reserved port number](#), with clients using an [ephemeral \(temporary\) port number](#) to initiate a connection to the server.

### ***Management of Reserved Port Numbers***

To ensure that everyone agrees on which port numbers server applications for each application should use, they are centrally managed by the [Internet Assigned Numbers Authority \(IANA\)](#). Originally, IANA kept the list of well-known and registered port numbers in a lengthy text document, along with all the many other parameters for which IANA was centrally responsible (such as IP *Protocol* field numbers, [Type and Code field values for ICMP](#), and so on). These were published on a periodic basis in Internet (RFC) standards documents titled [\*Assigned Numbers\*](#).

This system worked fine in the early days of the Internet, but by the mid-1990s, these values were changing so rapidly that using the RFC process was not feasible. It was too much work to keep publishing them, and the RFC was practically out of date the day after it was put out.

The last [\*Assigned Numbers\*](#) standard was RFC 1700, published in October 1994. After that time, IANA moved to a set of World Wide Web documents containing the parameters they manage. This allowed IANA to keep the lists constantly up to date, and for TCP/IP users to be able to get more current information. RFC 1700 was officially obsoleted in 2002.

**On The Web:** Complete information on all the parameters maintained by IANA can be found at <http://www.iana.org/numbers.html>. The URL of the file containing TCP/UDP port assignments is <http://www.iana.org/assignments/port-numbers>.

---

The document mentioned above is the definitive list of all well-known and registered TCP and UDP port assignments. Each port number is assigned a short *keyword*, with a brief description of the protocol that uses it. There are two problems with this document. The first is that it is incredibly **long**: over 10,000 lines of text. Most of the protocols mentioned in

---

those thousands of lines are for obscure applications that you have probably never heard of before (I certainly have never heard of most of them!) This makes it hard to easily see the port assignments for the protocols that are most commonly used.

The other problem with this document is that it shows the same port number as reserved for both TCP and UDP for an application. [As I mentioned earlier](#), TCP and UDP port numbers are actually independent, so one could in theory assign TCP port 80 to one server application type and UDP port 80 to another. It was believed that this would lead to confusion, so with very few exceptions, the same port number is shown in the list for the same application for both TCP and UDP. This makes sense, but showing this in the list has a drawback: you can't tell which protocol the application actually uses, and which has just been reserved for consistency.

Given all that, I've decided to include a couple of summary tables here that show the well-known and registered port numbers for the most common TCP/IP applications, and indicated whether the protocol uses TCP, UDP or both.

### ***Common Well-Known Port Numbers and Applications***

[Table 146](#) lists the well-known port numbers for the most common TCP/IP application protocols.

**Table 146: Common TCP/IP Well-Known Port Numbers and Applications (*Page 1 of 2*)**

Port #	TCP / UDP	Keyword	Protocol Abbreviation	Application or Protocol Name / Comments
7	TCP + UDP	echo	—	Echo Protocol
9	TCP + UDP	discard	—	Discard Protocol
11	TCP + UDP	systat	—	Active Users Protocol
13	TCP + UDP	daytime	—	Daytime Protocol
17	TCP + UDP	qotd	QOTD	Quote Of The Day Protocol
19	TCP + UDP	chargen	—	Character Generator Protocol
20	TCP	ftp-data	FTP (data)	File Transfer Protocol (default data port)
21	TCP	ftp	FTP (control)	File Transfer Protocol (control / commands)
23	TCP	telnet	—	Telnet Protocol
25	TCP	smtp	SMTP	Simple Mail Transfer Protocol
37	TCP + UDP	time	—	Time Protocol
43	TCP	nickname	—	Whois Protocol (also called “Nickname”)
53	TCP + UDP	domain	DNS	Domain Name Server (Domain Name System)
67	UDP	bootps	BOOTP / DHCP	Bootstrap Protocol / Dynamic Host Configuration Protocol (Server)

**Table 146: Common TCP/IP Well-Known Port Numbers and Applications (Page 2 of 2)**

Port #	TCP / UDP	Keyword	Protocol Abbreviation	Application or Protocol Name / Comments
68	UDP	bootpc	BOOTP / DHCP	Bootstrap Protocol / Dynamic Host Configuration Protocol (Client)
69	UDP	tftp	TFTP	Trivial File Transfer Protocol
70	TCP	gopher	—	Gopher Protocol
79	TCP	finger	—	Finger User Information Protocol
80	TCP	http	HTTP	Hypertext Transfer Protocol (World Wide Web)
110	TCP	pop3	POP	Post Office Protocol (version 3)
119	TCP	nntp	NNTP	Network News Transfer Protocol
123	UDP	ntp	NTP	Network Time Protocol
137	TCP + UDP	netbios-ns	—	NetBIOS (Name Service)
138	UDP	netbios-dgm	—	NetBIOS (Datagram Service)
139	TCP	netbios-ssn	—	NetBIOS (Session Service)
143	TCP	imap	IMAP	Internet Message Access Protocol
161	UDP	snmp	SNMP	Simple Network Management Protocol
162	UDP	snmptrap	SNMP	Simple Network Management Protocol (Trap)
179	TCP	bgp	BGP	Border Gateway Protocol
194	TCP	irc	IRC	Internet Relay Chat
443	TCP	https	HTTP over SSL	Hypertext Transfer Protocol over Secure Sockets Layer
500	UDP	isakmp	IKE	IPSec Internet Key Exchange
520	UDP	router	RIP	Routing Information Protocol (RIP-1 and RIP-2)
521	UDP	ripng	RIPng	Routing Information Protocol - "Next Generation"

### ***Common Registered Port Numbers and Applications***

The registered port numbers are by definition for protocols that are not standardized using the RFC process, so they are mostly esoteric applications that I don't feel there is much point in listing at length. [Table 147](#) shows a few that I feel are of particular interest:

**Table 147: Common TCP/IP Registered Port Numbers and Applications**

Port #	TCP / UDP	Keyword	Protocol Abbreviation	Application or Protocol Name / Comments
1512	TCP + UDP	wins	WINS	Microsoft Windows Internet Naming Service
1701	UDP	l2tp	L2TP	Layer Two Tunneling Protocol

---

**Table 147: Common TCP/IP Registered Port Numbers and Applications**

Port #	TCP / UDP	Keyword	Protocol Abbreviation	Application or Protocol Name / Comments
1723	TCP	pptp	PPTP	Point-To-Point Tunneling Protocol
2049	TCP + UDP	nfs	NFS	Network File System
6000 - 6063	TCP	x11	X11	X Window System

---

## TCP/IP User Datagram Protocol (UDP)

The very fact that the TCP/IP protocol suite bears the name of the [Internet Protocol](#) and the [Transmission Control Protocol](#) suggests that these are the two key protocols in the suite: IP at the network layer and TCP at the transport layer. It's no wonder, therefore, that many people don't even realize that there *is* a second transport layer protocol in TCP/IP. Like a shy younger brother, the *User Datagram Protocol (UDP)* sits in the shadows while TCP gets the glory. Its fancier sibling deserves much of this limelight, since TCP is arguably the more important of the two transport layer protocol. However, UDP itself fills a critical niche in the TCP/IP protocol suite, allowing many applications to work at their best when using TCP would be less than ideal.

In this section I describe the simpler and lesser-known TCP/IP transport protocol: the User Datagram Protocol (UDP). I begin with an overview of the protocol and a discussion of its history and standards. I outline how UDP operates, and describe the format used for UDP messages. I conclude with a discussion of what sorts of applications use UDP, and the well-known or registered ports that are assigned to them.

**Note:** There is also a protocol that is part of the NetBIOS/NetBEUI protocol suite called the User Datagram Protocol, also abbreviated UDP. The two are of course not the same.

---

### UDP Overview, History and Standards

I suppose the “sibling rivalry” analogy I drew in the introduction to this section may be a little bit silly. I highly doubt that protocols lie awake at night worrying about how much we use them. ☺ However, it's interesting to discover just how important the User Datagram Protocol (UDP) really is, given how little attention it gets compared to the Transmission Control Protocol (TCP). In fact, in true older-sibling, spotlight-stealing fashion, we can't even really understand the history of UDP without first discussing TCP.

In [the topic that describes the history of TCP/IP](#), I explained that very early on in the development of the protocol suite, there was only one protocol that handled the functions now performed by both IP and TCP. This protocol, itself called TCP, provided network-layer connectivity like IP, and also established connections, provided reliability and took care of the typical transport-layer “quality” requirements as flow control and retransmission handling that we associate with modern TCP.

It didn't take long before the developers of the fledgling combined protocol quickly realized that mixing these functions together was a mistake. While *most* conventional applications needed the classic transport-layer reliability functions, some did not. These features introduced overhead, which would have to be endured even by the applications where reliability features were not needed at all. Worse, there were some applications where the features were not only of no value, but actually a detriment, since even the small amount of lost performance due to the overhead would be a problem.

---

The solution was to separate the original protocol into IP and TCP. Basic internetworking was to be done by IP, and the reliability features by TCP. This paved the way for the creation of an alternative transport-layer protocol for applications that didn't want or need the features provided by TCP. This, of course, is the *User Datagram Protocol (UDP)*.

There are two main attributes that come up again and again when describing UDP: *simple* and *fast*. It is a **simple** protocol that uses a very straight-forward messaging structure that is similar to the message format used by many other TCP/IP protocols (in contrast to the more complex data structures—[streams and segments](#)—used by TCP). In fact, when you boil it down, the only real goal of the protocol is to serve as an interface between networking application processes running at the higher layers, and the internetworking capabilities of IP. Like TCP, UDP layers on top of IP a method of [transport-layer addressing \(and hence, process identification\) through the use of UDP port numbers](#). It does include an optional checksum capability for error-detection, but adds virtually no other functionality.

In fact, the best way to see for yourself the simplicity of UDP is to look at the standards that define it. Or rather, I should say **standard** in the singular, because there is only one. UDP was defined in RFC 768, *User Datagram Protocol*, in 1980. This document is all of three pages in length, and has never needed to be revised.

UDP is a **fast** protocol specifically because it doesn't have all the bells and whistles of TCP. This makes it unsuitable for use by many, if not most, typical networking applications. But for some applications, this is exactly what they want from a transport layer protocol: something that takes their data and quickly shuffles it down to the IP layer with a minimum of fuss. In choosing to use UDP, the application writer takes it upon himself or herself to take care of issues such as reliability and retransmissions, if they are needed. This can be a recipe for success or failure, depending on the application and how carefully UDP is used.

**Key Concept:** The User Datagram Protocol (UDP) was developed for use by application protocols that do not require reliability, acknowledgment or flow control features at the transport layer. It is designed to be simple and fast, providing only transport layer addressing in the form of UDP ports and an optional checksum capability, and little else.

---

## UDP Operation

Uh... Uh... After all these pages, I almost find myself at a loss for words. (Hey, don't skip to the next topic, I said *almost*!) The simplicity of the User Datagram Protocol means that there is not a great deal to say in describing its operation. It is designed to do as little as possible, and little is exactly what it does.

---

## What UDP Does

UDP's only real task is to take data from higher-layer protocols and place it in UDP messages, which are then passed down to the Internet Protocol for transmission. The basic steps for transmission using UDP are:

1. **Higher-Layer Data Transfer:** An application sends a message to the UDP software.
2. **UDP Message Encapsulation:** The higher-layer message is encapsulated into the *Data* field of a UDP message. The headers of the UDP message are filled in, including the *Source Port* of the application that sent the data to UDP, and the *Destination Port* of the intended recipient. The checksum value may also be calculated.
3. **Transfer Message To IP:** The UDP message is passed to IP for transmission.

And that's about it. Of course, on reception at the destination device this short procedure is reversed.

## What UDP Does Not

In fact, UDP is **so** simple, that its operation is very often described in terms of what it does **not** do, instead of what it does. As a transport protocol, some of the most important things UDP does not do include the following:

- ☹ UDP does not establish connections before sending data. It just packages it and... off it goes.
- ☹ UDP does not provide acknowledgments to show that data was received.
- ☹ UDP does not provide any guarantees that its messages will arrive.
- ☹ UDP does not detect lost messages and retransmit them.
- ☹ UDP does not ensure that data is received in the same order that they were sent.
- ☹ UDP does not provide any mechanism to manage the flow of data between devices, or handle congestion.

**Key Concept:** The User Datagram Protocol (UDP) is probably the simplest in all of TCP/IP. All it does is take application layer data passed to it, package it in a simplified message format, and send it to IP for transmission.

---

If these characteristics sound similar to how I described [the limitations of IP](#), you're paying attention. UDP is basically just IP with transport-layer port addressing. (It is for this reason that UDP is sometimes called a “wrapper” protocol, since all it does is wrap application data in its simple message format and send it to IP.)

I should point out that despite the list above, there are a couple of limited feedback and error checking mechanisms that do exist within UDP. One is the optional checksum capability, which can allow detection of an error in transmission or the situation where a UDP message is delivered to the wrong place; [see the next topic for details](#). The other is [ICMP error reporting](#). For example, if a UDP message is sent that contains a destination

---

port number not recognized by the destination device, this will lead to the destination host sending an ICMP *Destination Unreachable* message back to the original source. Of course, ICMP exists for all IP errors of this sort, so I'm stretching a bit here; this isn't really part of UDP.

## **UDP Message Format**

What's the magic word when it comes to UDP? Right, *simple*. This is true of the operation of the protocol, and it is also true of the format used for UDP messages. Interestingly, however, it is here that we will actually encounter probably the only aspect of UDP that is **not** simple. I bet that got you interested, huh? Okay, well, it was a worth a try. ☺

In keeping with the goal of efficiency, the UDP header is only eight bytes in length; this contrasts with the [TCP header size of 20 bytes or more](#). [Table 148](#) and [Figure 200](#) show the format of UDP messages.

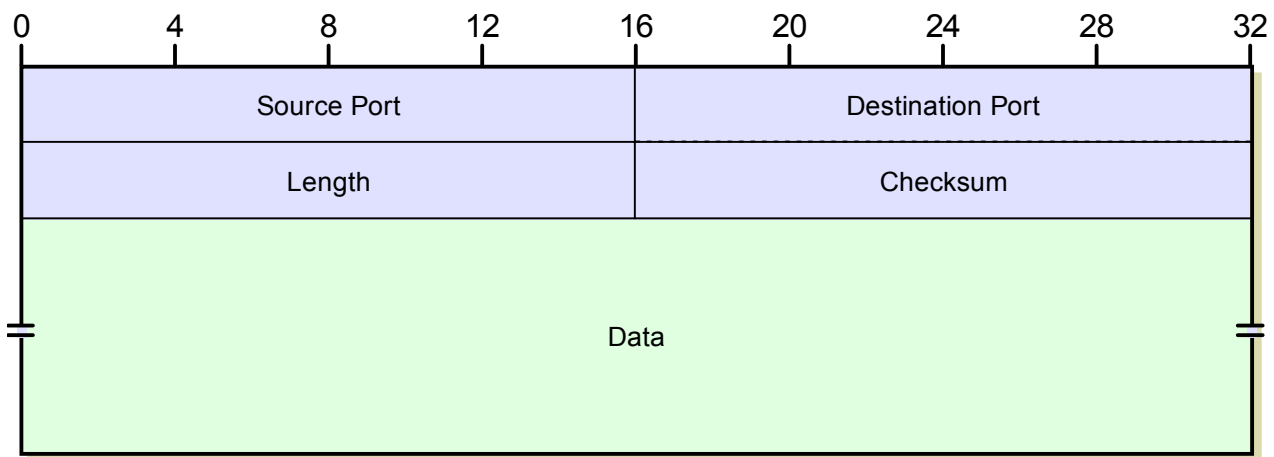

**Table 148: UDP Message Format**

Field Name	Size (bytes)	Description
<b>Source Port</b>	2	<b>Source Port:</b> The 16-bit port number of the process that originated the UDP message on the source device. This will normally be an ephemeral (client) port number for a request sent by a client to a server, or a well-known/registered (server) port number for a reply sent by a server to a client. <a href="#">See the section describing port numbers for details</a> .
<b>Destination Port</b>	2	<b>Destination Port:</b> The 16-bit port number of the process that is the ultimate intended recipient of the message on the destination device. This will usually be a well-known/registered (server) port number for a client request, or an ephemeral (client) port number for a server reply. Again, <a href="#">see the section describing port numbers for details</a> .
<b>Length</b>	2	<b>Length:</b> The length of the entire UDP datagram, including both header and <i>Data</i> fields.
<b>Checksum</b>	2	<b>Checksum:</b> An optional 16-bit checksum computed over the entire UDP datagram plus a special “pseudo header” of fields. See below for more information.
<b>Data</b>	Variable	<b>Data:</b> The encapsulated higher-layer message to be sent.

### ***The Checksum Field and the UDP Pseudo Header***

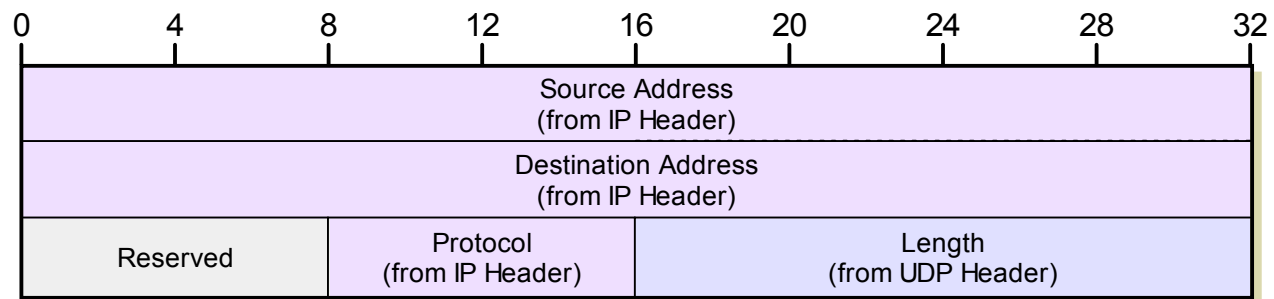

The UDP *Checksum* field is the one area where the protocol actually is a bit confusing. The concept of a checksum itself is nothing new; they are used widely in networking protocols to provide protection against errors. What's a bit odd is this notion of computing the checksum over the regular datagram and also a *pseudo header*. What this means is that instead of calculating the checksum over just the fields in the UDP datagram itself, the UDP software first constructs a “fake” additional header that contains the following fields ([Figure 201](#)):

- ☛ The IP *Source Address* field.
- ☛ The IP *Destination Address* field.

**Figure 200: UDP Message Format**

- ☛ The IP *Protocol* field.
- ☛ The UDP *Length* field.

**Figure 201: UDP Pseudo Header Format**

The total length of this “pseudo header” is 11 bytes. It is padded to 12 bytes with a byte of zeroes and then prepended to the real UDP message. The checksum is then computed over the combination of the pseudo header and the real UDP message, and the value is placed into the *Checksum* field. The pseudo header is used only for this calculation and is then discarded; it is not actually transmitted. The UDP software in the destination device creates the same pseudo header when calculating its checksum to compare to the one transmitted in the UDP header.

Computing the checksum over the regular UDP fields protects against bit errors in the UDP message itself. Adding the pseudo header allows the checksum to also protect against other types of problems as well, most notably the accidental delivery of a message to the wrong destination. The checksum calculation in UDP, including the use of the pseudo header is exactly the same as the method used in TCP (except the *Length* field is different

---

in TCP). [See the topic describing TCP checksum calculation](#) for a full description of why the pseudo header is important, and some of the interesting implications of using IP fields in transport layer datagram calculations.
